Permethrin 1% cream (Nix) rinse applied to affected area and washed off after 10 minutes Pyrethrins with piperonyl butoxide (RID) applied to area and then washed off after 10 minutes	Malathion 0.5% (Ovide) lotion applied for 8–12 hours and washed off (has a strong odor but is useful for resistant cases) Ivermectin (Stromectol) 250 µg/kg orally with food, repeated in 2 weeks	Permethrin 1% cream (Nix) rinse applied to affected area and washed off after 10 minutes Pyrethrins with piperonyl butoxide (RID) applied to area and then washed off after 10 minutes Second-line treatment: Ivermectin (Stromectol) 250 µg/kg orally with food, repeated in 2 weeks; data suggest low risk to fetus during pregnancy Malathion (Ovide) is contraindicated during pregnancy	Permethrin 1% cream (Nix) rinse applied to affected area and washed off after 10 minutes Pyrethrins with piperonyl butoxide (RID) applied to area and then washed off after 10 minutes Second-line treatment: Ivermectin (Stromectol) 250 µg/kg orally with food, repeated in 2 weeks; avoid direct application to the breast Malathion (Ovide) is contraindicated during lactation

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017[7]; U.S. National Library of Medicine. Drugs and lactation database (LactMed). 2016. Available at: https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm. Accessed June 6, 2017.[20]

The CDC advises treatment for all sexual partners from the last month. Household contacts should be examined and treated as needed.[7] Women with pubic lice should be counseled that screening for all common STIs is recommended. Retreatment is necessary if no improvement occurs in 1 week. Resistance to treatment is common, and malathion (Ovide) is recommended for retreatment of women who are not pregnant in cases where resistance is suspected.[7] Pregnant women infected with pubic lice should receive third-trimester rescreening for all STIs.

Other Infectious Agents Spread by Sexual Contact

In addition to the STIs reviewed in this chapter, a wide variety of other infections may spread through sexual contact. For example, viruses such as cytomegalovirus (CMV) and Epstein-Barr virus can be transmitted through sharing of bodily fluids. *Molluscum contagiosum* is a pox virus spread through skin-to-skin contact and, in adults, is most often seen on the genitals, upper thighs, and abdomen with sexual transmission.[48]

Parasites commonly seen in primary care can also be transmitted sexually. Scabies mites can be easily transmitted through close genital contact; such infections should be treated using CDC guidelines. Permethrin or ivermectin are first-line treatments for all adults, although permethrin is preferred for pregnant and lactating women.[7] Scabies-related itching and rash typically persist for as long as 2 weeks, but treatment failures are common due to inadequate treatment or resistant.[7] Alternative treatment regimens may be needed for resistant cases.

Intestinal infections and parasites, such as shigellosis and *Giardia*, can be transmitted sexually, especially when there is contact with the anus or mouth. The CDC provides excellent resources for treatment of women with infectious conditions and provides guidance on the need for sexual-partner and household-contact treatment for conditions spread through sexual or close physical contact. Selected conditions that can be transmitted through sexual contact are described in **Table 14-22**.

Table 14-22 Selected Parasitic Infections Spread by Sexual Contact

Parasitic Infection	Symptoms	Physical Examination	Treatment	Follow-up
Scabies (*Sarcoptes scabiei*)	Severe itching of the groin, between fingers, and in body folds. Itching is bilateral and often occurs more at night.	Excoriations surrounding papules, consisting of small linear or curved burrows, may be present. Definitive diagnosis is based on microscopic visualization of the mite obtained from skin scrapings. Secondary infections are common.	Permethrin 5% applied to the body from the neck down and washed off after 8–14 hours (safe during pregnancy and lactation) OR Ivermectin (Stromectol) 200 mcg/kg orally, repeated in 14 days (This treatment is preferred for outbreaks at residential facilities.) Household linens need to be dried using the hot setting or isolated for 72 hours.	Itching may persist for 2–4 weeks. If treatment fails, lindane is recommended as a second treatment in otherwise well, nonpregnant and nonlactating women.
Molluscum contagiosum	Lesions can be found on any part of the body. With sexual transmission, they are more common on the legs, abdomen, and genital area.	Multiple 2- to 5-mm, shiny white or flesh-colored papules with an indented (umbilicated) center. A thick white discharge can be expressed from the center of the lesion. Large and extensive lesions are more common in HIV-positive adults.	Symptoms are usually self-limiting and resolve without scarring in more than 90% of otherwise healthy adults. Treatments are not usually recommended but can decrease the spread of the infection. Treatments include cryotherapy, excision, oral cimetidine, and topical creams. Transmission can be decreased by covering lesions and not sharing towels or clothing.	None needed; lesions usually heal within 6–12 months.

Abbreviation: HIV, human immunodeficiency virus.

Based on Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep.* 2015;64(3):1-137. Available at: https://www.cdc.gov/std/tg2015/tg-2015-print.pdf. Accessed March 31, 2017.[7]

Infections That Mimic Sexually Transmitted Infections in Genital Areas

Many primary care conditions produce symptoms in the groin region that can mimic STIs. For example, herpes zoster (commonly known as shingles) looks identical to HSV, except that the lesions are along one or more dermatomes. *Trombica* mite bites, commonly known as chiggers, cause itchy, uncomfortable lesions in the groin that may be a presenting concern. Other conditions, such as tinea cruris and other forms of dermatitis, can manifest on and around the vulva. While targeting the examination to the woman's chief concern, the clinician should not prematurely rule out primary care diagnosis that may have genital manifestations. **Table 14-23** lists some conditions that are not STIs, but may appear as such and should be considered in a differential diagnosis.

Table 14-23 Diagnoses That May Mimic Sexually Transmitted Infections That Are Not Sexually Transmitted

Diagnosis	Presenting Concerns and History	Physical Examination	Treatment Generic (Brand)
Chiggers (*Trombicula* mite bites)	Severe itching usually 3–24 hours after outdoor activity in hot, humid weather.	Small, grouped, excoriated papules along panty-line or in fold of groin, often found along a line of clothing constriction.	Irritation is self-limiting. Topical antihistamines and corticosteroids may provide relief. Oral antihistamines can be used in severe cases.
Herpes zoster ("shingles")	Open lesions that are painful superficially and have a deeper nerve pain component. Often occurs in elderly or immunosuppressed women. 10–15% of affected individuals will have postherpetic neuralgia following an initial outbreak.	Painful papules, or vesicles that rupture and crust over. Lesions may be in various stages of forming and healing. Found on L5 and S1 dermatomes. Indistinguishable from herpes by examination. Serologic tests will be negative for HSV infection.	Treatment within 72 hours is ideal to decrease incidence of postherpetic neuralgia: Acyclovir (Zovirax) 800 mg five times a day Famciclovir (Famvir) 500 mg three times a day Valacyclovir (Valtrex) 100 mg three times a day Appropriate pain control medications Lesions are contagious via the air and physical contact, and can cause varicella in previously uninfected individuals. Covering the lesions reduces transmission risk.

Abbreviation: HSV, herpes simplex virus.

Introduction

The quest for control of reproduction has a long and rich history. Many ancient and modern methods of contraception exist and are well documented. Indeed, there is even a museum dedicated to contraceptive methods.[1] During the mid-twentieth century, the first modern hormonal contraception was developed, and by early twenty-first century, available hormonal methods included new oral hormones, implants, and vaginal rings.[2]

The term *family planning* was chosen as the title for this chapter because this term is the broadest in scope. However, several approaches to presenting the family planning content can be utilized. The focus of this section of the text is primarily on reviewing pregnancy prevention. This material could be presented in different ways, each of which has its own advantages and disadvantages. For example, this material could be presented in order of effectiveness, moving from most to least effective methods. Effectiveness is a very important concept when counseling women about family planning. Alternatively, this content could be subdivided into the methods that are nonhormonal or hormonal, which allows areas of commonality, such as mechanism of action, to be easily identified to better facilitate understanding, especially of side effects such as the unexpected bleeding associated with progestin-only methods of contraception. This is the approach taken in this text, although organizing the chapters covering these issues—*Family Planning*, *Nonhormonal Contraception*, and *Hormonal Contraception*—in this manner is not perfect. For example, some intrauterine devices are nonhormonal and others hormonal; thus, they are covered in both the *Nonhormonal Contraception* and *Hormonal Contraception* chapters, which together provide detailed discussion of the various types of contraceptive methods.

The current chapter presents an overview of family planning, contraception counseling, and factors that affect a woman's choice of a birth control method. Information about options counseling (adoption and abortion) as well as types of surgical and medical (pharmaceutical) abortion are reviewed. New suggested methods in family planning are briefly discussed at the end of the chapter.

Common Terms and Definitions

Prior to discussing details about family planning, it is wise to address the common language used in this area of health care. Although the terms "birth control," "contraception," and "family planning" are often used interchangeably, they are not analogous in meaning, nor are they always used accurately. Some terms are integral to a discussion of family planning, such as "unintended pregnancy." **Table 15-1** provides some terms commonly used in this area and their definitions.[3-5]

Table 15-1 **Definitions of Terms Used in Family Planning**

Term	Definition
Birth control	Limitation of the number of children who are conceived, or ways to control reproduction via use of methods that improve or diminish fertility.
Contraception	Use of specific methods to prevent conception (or *contra-conception*); does not include methods that act after conception, such as interference with or after implantation.
Effectiveness	The success of a method in preventing pregnancy when used "typically," including pregnancies that occur because of incorrect or inconsistent use of a given contraceptive method; poor effectiveness for a contraceptive method usually is attributed to user failure.
Efficacy	The chance that conception will occur despite consistent and correct ("perfect") use of a specific method; poor efficacy for a contraceptive method often is termed true method failure.
Family planning	A broad term generally considered to include methods to assist an individual to plan if and/or when a pregnancy is desired. Most often this involves the use of various contraceptive or birth control methods, but not exclusively.
Long-acting reversible contraceptives (LARCs)	Contraceptive methods generally including implants and intrauterine devices that have high effectiveness and usually do not require direct control of the user. Typical and perfect use statistics are very similar.
Medical Eligibility Criteria for Contraceptive Use	Publication originally developed by the World Health Organization but adapted by different countries. Currently there exists one for the United States as well as a companion piece with recommendations for selective practices.
Pregnancy	"A physiologic state of a woman that follows implantation of a blastocyst(s)."[3] This definition was published by American College of Obstetricians and Gynecologists and has been widely adopted in healthcare publications and guidelines.
Reproductive life plan (RPL)	Similar to the term *family planning*; active planning of when and how many children an individual desires to have. RPLs are a component of general health care for women and men and are an important foundation for the choice of a contraceptive method.
Short-acting reversible contraceptives (SARCs)	Contraceptive methods including daily methods that have less effectiveness than LARCs, owing primarily to their being under the direct control of the individual (e.g., oral contraceptives) and subject to user error. Perfect use generally is much higher than typical use with SARCs.
Unintended pregnancy	A pregnancy that is mistimed or unplanned at the time of conception. This term does not automatically indicate that the pregnancy will not be accepted by the woman.

Establishing Efficacy and Effectiveness

The concepts of efficacy and effectiveness are used to describe how well a form of contraception works and often are thought to be synonymous, however, they are distinctly different. *Efficacy* is the chance that conception will occur despite consistent and correct ("perfect") use of a given method. *Effectiveness* describes the success of a method in preventing pregnancy when used "typically," including pregnancies that occur because of incorrect or inconsistent use of a given contraceptive method. To clarify these concepts, efficacy can be viewed as true method failure, while effectiveness is associated with user failure.[5] Certain methods are known to be efficacious, such as oral contraceptives when used perfectly. However, because of real-life factors such as missed pills and drug–drug interactions, their effectiveness may be less than that of other methods. Effectiveness is an important point to consider when the woman's goal is to avoid unintended pregnancy.

Unintended Pregnancy

It has been estimated that approximately half (45%) of all pregnancies in the United States are unintended.[4] Unintended pregnancies occur disproportionately to low income women and those of color. In addition, they are associated with higher risk of a variety of untoward perinatal outcomes and account for a number of the 926,200 abortions reported in 2014.[4,6]

Many women conceive when using a contraceptive method, especially when the method consists of short-acting reversible contraceptives (SARCs). Decreasing the likelihood of unintended pregnancy is a shared goal among many groups and individuals. Essential in assisting women in their choice of identifying an effective method is providing information about the risks of pregnancy associated with specific methods. Although seemingly easy, calculation of the risk of unintended pregnancy associated with a particular contraceptive method is not really simple, in that problems with estimates of efficacy and effectiveness have long been recognized.[7-9]

Calculation of Effectiveness of Contraceptive Methods

The Pearl index, also called the Pearl rate, has been used for more than seven decades in clinical trials to report the effectiveness of a contraceptive method. This calculation is defined as the number of method failures per 100 woman-years of exposure to the method.[8,9] The number of pregnancies that occur is divided by the number of months of contraceptive exposure and then multiplied by 1200 or 1300. When 1300 is used, it is because a menstrual cycle is typically 28 days, which occurs 13 times in a year (365 days ÷ 28 = 13). Based on the statistical formula used, a woman-year is defined by either the number 12 (1200 for the index) to designate months or the number 13 (1300 for the index) to designate average number of

menstrual cycles based on 28 days within a year. A lower Pearl index indicates a lower risk of unintended pregnancy.

Some studies report two Pearl indices, one of which is labeled as typical or actual use for a contraceptive method (effectiveness). The data from which this effectiveness index is calculated include all pregnancies, regardless of whether they involved user error or method failure. Other reports cite the second, "perfect use" Pearl index, which includes data limited to cycles in which there is assurance that the method was correctly and consistently used (efficacy).[8]

Major problems have been found when using the Pearl index to assess a contraceptive method. For example, some assumptions on which the method is based may be invalid. Because of the way the index is calculated, if all of the women became pregnant in the first year, the pregnancy rate would not be a logical 100% or an index of 1000, but rather either 1200 or 1300 depending on the definition of woman-year used in the calculation. Another problem is the mistaken assumption that a failure rate for a method is constant over time. In a large sample of individuals, the most fertile women will get pregnant earlier, and those with lower fertility will become pregnant later, regardless of the type of contraceptive method employed. Furthermore, for some methods such as the diaphragm, the longer the method is used, the more likely women are to become experienced with using it correctly. Conversely, the effectiveness of other contraceptive methods can expire, such as implants, such that these methods are associated with more pregnancies if they are used for periods beyond the recommended length.

In addition, the Pearl index does not recognize other confounding factors. For example, it does not incorporate reasons for self-discontinuation (e.g., side effects), dissatisfaction or change in desire to attempt pregnancy, and loss of women to follow-up who may continue to use the method correctly and successfully avoid pregnancy.

To compensate for some of the problems with the Pearl index, some researchers use life tables for statistical calculations of unintended pregnancy rates.[10] These tables present separate effectiveness rates for each month of study among a group of individuals using a specific contraceptive method over a set period of time (e.g., 12 months). When the results are subdivided by months, the assumption that contraceptive failure rates remain static is corrected. Other statistical analyses using life tables may differentiate between net effectiveness, which allows for comparison of reasons for dropping out of a study, and gross effectiveness, which enables comparison of one study to another. Studies today tend to use both the Pearl index and life table analysis, although many do not clearly designate which approach they use.

In addition to this statistical quagmire, research studies reporting data often are part of clinical trials undertaken for Food and Drug Administration (FDA) approval of a method. Trials involving contraceptives differ from the more traditional drug trials, as discussed in the *Pharmacotherapeutics* chapter. Phase 2 and 3 clinical trials are typically randomized, are often double blinded, and compare an agent to a placebo. In Phase 3 trials, the participants are individuals with a health condition that the new drug is likely to treat. Obvious ethical and methodological problems prohibit the use of this approach for investigation of new contraceptives. Therefore, most clinical trials include "typical" women who are healthy and

seeking a method to use for family planning. The concept of the “typical” participant in clinical trials is also problematic because females younger than the age of 18 years are minors who are subject to pediatric research policies and, therefore, are not included in contraceptive trials. In addition to eliminating most adolescents, clinical trials of contraceptives tend to enroll participants of average weight/body mass index (BMI), even though the United States is experiencing an epidemic of obesity. Exempting women from both of these populations is a limitation for generalizing the findings to all women using contraceptives in the United States.

Another problem is apparent in the manner in which contraceptive methods are compared to one another. The effectiveness of one method can usually be compared to the effectiveness of another method only by using results from previously conducted research, not by conducting a head-to-head study. For example, assume a new oral contraceptive was found to be associated with a 20% rate of amenorrhea in users. Previously published research about an older contraceptive will most likely be used as the basis for comparison with this new contraceptive. Therefore, the assumption is made that both of the studies in question, old and new, have similar methodological approaches and populations. In reality, reasonable comparisons cannot be guaranteed.

Because of the challenges in determining an exact risk of unintended pregnancies associated with a method, quoting statistics to women about the effectiveness of contraceptive methods is an imperfect science. Many midwives use generally agreed-upon ranges of effectiveness. Others present the information by ranking which methods are more effective than others without resorting to exact, and perhaps somewhat inaccurate, numbers. In any case, although the efficacy and effectiveness of methods are critical pieces of information, a woman’s choice of a contraceptive method will include a variety of considerations, including the simple but essential factor of whether she will use a method correctly and consistently.

Fortunately, most studies provide relatively similar results regarding effectiveness and efficacy, and rates found in this chapter are generally agreed upon by several references. **Table 15-2** provides a widely accepted list of effectiveness rates for typical and perfect use of contraceptives.[7]

Table 15-2 Percentage of Women Experiencing an Unintended Pregnancy During the First Year of Typical Use and the First Year of Perfect Use of Contraceptives and the Percentage Continuing Use at the End of the First Year, United States

Method	Women Experiencing Unintended Pregnancy Within the First Year of Use (%), Typical Use[b]	Women Experiencing Unintended Pregnancy Within the First Year of Use (%), Perfect Use[c]	Women Continuing Use at 1 Year (%)[a]
No method[d]	85	85	
Spermicides	28	18	42
Fertility awareness–based methods	24		47
StandardDays method		5	
TwoDay method		4

Mirena (LNG)	0.2	0.2	80
Implanon	0.05	0.05	84
Female sterilization	0.5	0.5	100
Male sterilization	0.15	0.10	100
The lactational amenorrhea method (LAM) is a highly effective, temporary method of contraception.[e]			

[a] Among couples attempting to avoid pregnancy, the percentage of who continue to use a method for 1 year.
[b] Among typical couples who initiate use of a method, the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.
[c] Among typical couples who initiate use of a method and who use it perfectly (both consistently and correctly), the percentage who experience an accidental pregnancy during the first year if they do not stop use for any other reason.
[d] The percentages becoming pregnant in columns 2 and 3 are based on data from populations in which contraception is not used and from women who cease using contraception so as to become pregnant. Among such populations, approximately 89% become pregnant within 1 year. This estimate was lowered slightly (to 85%) to represent the percentage who would become pregnant within 1 year among women now relying on reversible methods of contraception if they abandoned contraception altogether.
[e] To maintain effective protection against pregnancy, another method of contraception must be used as soon as menstruation resumes, the frequency or duration of breastfeeding is reduced, bottle feeding is introduced, or the baby reaches 6 months of age.

Permanent Versus Reversible Contraceptive Methods

The first categorization of contraceptive methods is permanent versus reversible. Male or female sterilization remains the most efficacious and effective of all contraceptive methods and is the method used by approximately 20.6% of women between age 15 and 44 years.[11] Different types of sterilization are discussed in the *Nonhormonal Contraception* chapter. However, millions of individuals of childbearing age desire a reversible contraceptive method.

The search to identify the most effective contraceptives has led to categorizing reversible contraceptive methods as either long acting (LARCs) or short acting (SARCs). Hormonal contraceptives are among the most commonly used forms of birth control in the United States. In contrast to nonhormonal contraceptives, which tend to be both coital and user dependent, hormonal contraceptive use is separate from sexual activity. Nevertheless, the effectiveness of some of the hormonal methods, such as oral contraceptives, rings, and patches, depends on a woman using them consistently and correctly. These user-dependent types of methods are categorized as SARCs because most failures with these methods are associated with user error, and the perfect use rate is considerably higher than the typical use rate. Depot medroxyprogesterone acetate (DMPA), a contraceptive injection, may be considered a SARC because the user needs to regularly return to a provider to receive injections. By comparison, LARCs, such as intrauterine devices (IUDs) and implants, require a healthcare visit for placement, but are neither coital nor user dependent; they offer years of effectiveness and, therefore, their typical use rates are similar to their perfect use rates. **Figure 15-1** compares the effectiveness of the most commonly used contraceptives; as can be seen in this figure, LARCs are the most effective options.[12]

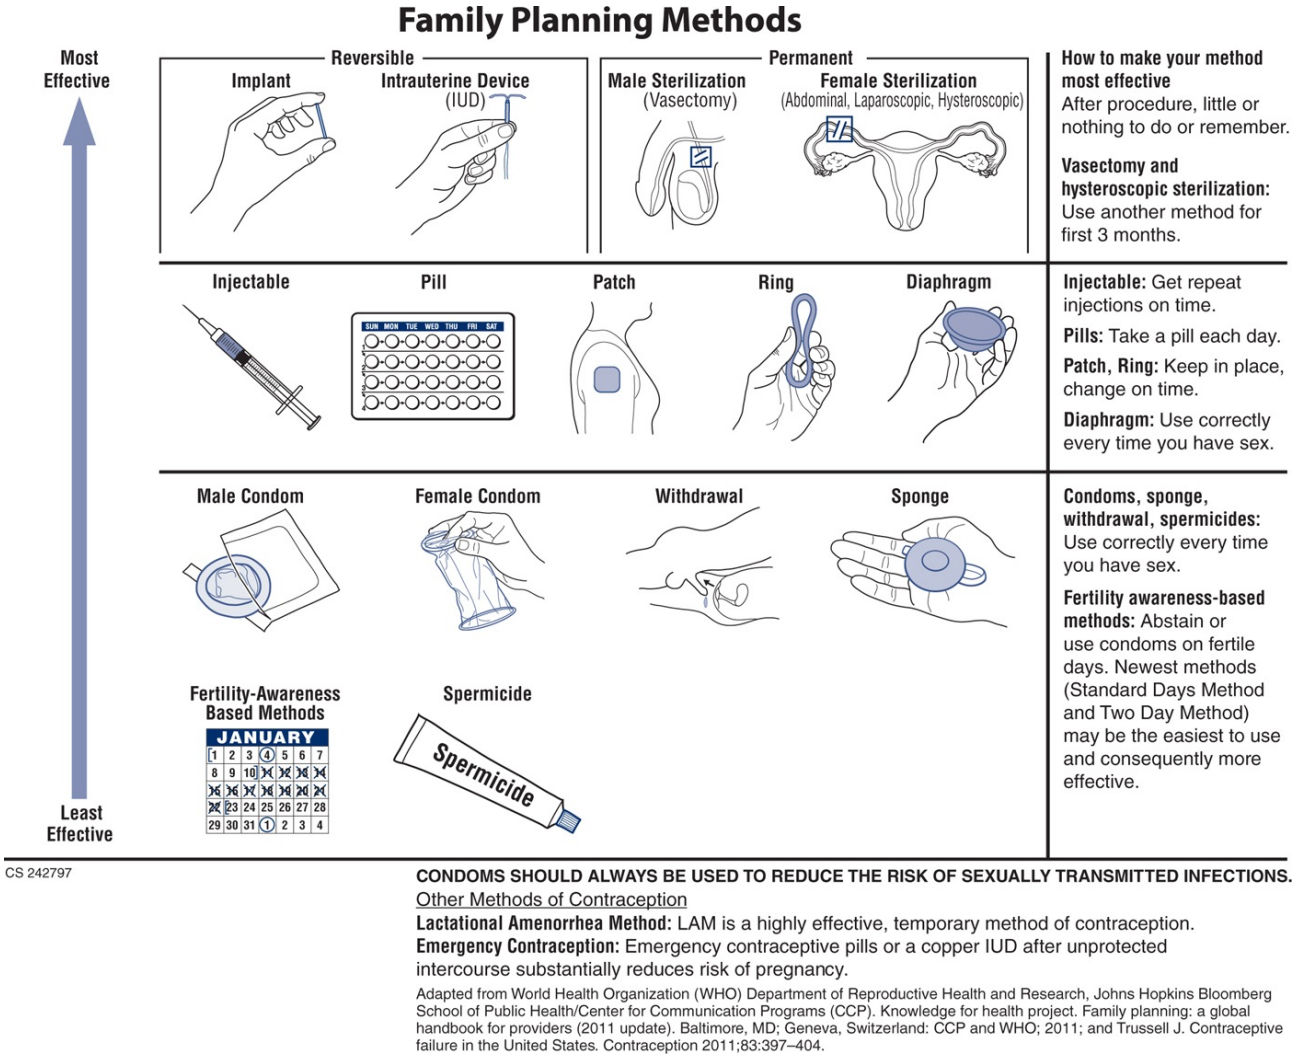

Figure 15-1 Comparing the typical effectiveness of contraceptive methods.

Modified with permission from Centers for Disease Control and Prevention. Effectiveness of family planning methods. Available at: https://www.cdc.gov/reproductivehealth/unintendedpregnancy/pdf/contraceptive_methods_508.pdf. Accessed September 15, 2017.[12]

The Centers for Disease Control and Prevention (CDC) has identified increasing access to LARCs as one of the top public health priorities for reducing adolescent pregnancy and unintended pregnancy in the United States.[13,14] LARCs have been advocated as a first-line recommended form of contraception for the majority of women, regardless of age or parity.[14] Guidelines published by the American College of Obstetricians and Gynecologists state that LARCs should be considered as a first-line option for most women, including adolescents.[15,16] In a 2014 policy statement and technical report, the American Academy of Pediatrics similarly recommended LARCs for adolescents, and subsequent studies have found that young women tend to continue to use the methods for several years.[17,18]

Initially, LARCs are the most expensive reversible methods owing to the healthcare costs incurred for both the devices and the visit for their insertion. However, once implanted or inserted, the annualized cost is the same or less than that for less effective methods. Several studies have found that state funding of free or low-cost LARCs decreases the costs associated with unplanned births and abortions and, therefore, that these methods are cost-effective.[19]

Like any contraceptive method, LARCs are not perfect, nor are they the best choice for every woman. Because they are provider dependent, lack of professionals in an area is a challenge for women seeking these types of contraception in some geographic locales.[20] The fact that major professional organizations are actively promoting use of LARCs has caused some individuals to voice concerns that a clinician might inadvertently urge a woman—especially one who is young or socioeconomically disadvantaged—to use a LARC without appropriately acknowledging her choice.[4,21,22] In addition, some relatively rare conditions exist that preclude the use of implants and intrauterine devices. Fortunately, national medical eligibility criteria for different contraceptive methods provides insight into the advisability of specific contraceptive methods.

Medical Eligibility Criteria for Contraceptive Use

In 1996, the first edition of *Medical Eligibility Criteria for Contraceptive Use* (WHO MEC) was published by the World Health Organization (WHO). This document is regularly updated based on new evidence.[23] The WHO MEC currently is in its fifth edition and is useful especially for midwives working internationally. WHO has encouraged countries to modify the MEC as needed.

In recognition that practice in the United States may differ in some respects from international care, the CDC has published nationally focused guidelines (**Figure 15-2**). Known as the *U.S. Medical Eligibility Criteria for Contraceptive Use, 2016* (U.S. MEC for Contraceptive Use), this publication is available as a free download and is closely related to the WHO MEC. The U.S. MEC for Contraceptive Use website is listed in the Resources section at the end of this chapter. It uses the same categories for eligibility as noted in **Table 15-3**.[24]

Summary Chart of U.S. Medical Eligibility Criteria for Contraceptive Use, 2016

Condition	Sub-Condition	Cu-IUD		LNG-IUD		Implant	DMPA	POP	CHC

Updated July 2016. This summary sheet only contains a subset of the recommendations from the U.S. MEC. For complete guidance, see: http://www.cdc.gov/reproductivehealth/unintendedpregnancy/USMEC.htm. Most contraceptive methods do not protect against sexually transmitted diseases (STDs). Consistent and correct use of the male latex condom reduces the risk of STDs and HIV.

Table 15-3 **Categories of Medical Eligibility Criteria for Contraceptive Use**

1 = A condition for which there is no restriction for the use of the contraceptive method.

2 = A condition for which the advantages of using the method generally outweigh the theoretical or proven risks.

3 = A condition for which the theoretical or proven risks usually outweigh the advantages of using the method.
4 = A condition that represents an unacceptable health risk if the contraceptive method is used.

Modifications of the WHO MEC for Contraceptive Use for women in the United States include exclusion of methods not available in the United States and inclusion of several additional health conditions of note in this country. In particular, modifications that address breastfeeding, intrauterine device use, valvular heart disease, ovarian cancer, uterine fibroids, and venous thromboembolism were made to the WHO MEC for Contraceptive Use to reflect the U.S. population and practice. The U.S. MEC for Contraceptive Use also added information about care of women with inflammatory bowel disease, history of bariatric surgery, rheumatoid arthritis, endometrial hyperplasia, history of peripartum cardiomyopathy, and history of solid-organ transplant that is not found in the WHO MEC for Contraceptive Use.[23,24]

A companion to the U.S. MEC for Contraceptive Use is a document focusing on selected practices that, although common, can be complicated. Titled *U.S. Selected Practice Recommendations for Contraceptive Use, 2016* (often abbreviated as SPR), this publication can be found on the CDC's website or downloaded as a free electronic book. The SPR focuses on frequently occurring conditions associated with controversial or complex interventions for women seeking contraception in the United States. The most recent changes to the SPR include guidelines on when to start a method after emergency contraception as well as medications to ease insertion of IUDs.[25]

The U.S. MEC for Contraceptive Use primarily focuses on the safety of use of various contraceptives, especially for both initiation and continuation. The midwife and the woman can quickly verify recommendations for use of a specific method by referring to multiple tables in the publication. Note that the U.S. MEC for Contraceptive Use is a set of guidelines—compliance with its recommendations is not mandatory. Thus, deviations from its recommendations may occur upon considering an individual woman's situation. Nevertheless, variations in practice are becoming rarer and the U.S. MEC for Contraceptive Use guidelines are used widely throughout the United States, augmented with information from the SPR.

Other factors that can be intertwined with eligibility for a contraceptive method include requirements for laboratory testing and physical examinations, both of which can be major barriers for women. Contrary to practices in the late twentieth century, however, such interventions are rarely necessary today. **Table 15-4** lists recommended examinations or tests based on the current SPR.[25]

Table 15-4 Examinations and Tests Recommended Before Contraceptive Initiation

	Copper IUD	LNG IUD	Implant	DMPA	CHC	POP

Abbreviations: CHC, combined hormonal contraception; DMPA, depot medroxyprogesterone; IUD, intrauterine device; LNG, levonorgestrel; POP, progestin-only pill.

Class A: Examination or laboratory test result is essential and mandatory in all circumstances for safe and effective use of the contraceptive method.

Class B: Examination or laboratory test result contributes substantially to safe and effective use, but implementation may be considered within the public health and/or service context; the risk of not performing an examination or test should be balanced against the benefits of making the contraceptive method available.

Class C: Examination or laboratory test result does not contribute substantially to safe and effective use of the contraceptive method.

[a] In instances in which blood pressure cannot be measured by a provider, blood pressure measured in other settings can be reported by the woman to her provider.

[b] Body mass index (BMI) is not needed to determine medical eligibility for any method of contraception because all methods can be used or generally can be used by obese women. However, measuring weight and calculating BMI at baseline might be helpful for monitoring any change and counseling women who might be concerned about weight changes perceived to be associated with their contraceptive method.

[c] Most women do not require screening for sexually transmitted disease (STD) at the time of intrauterine device insertion if they have already been screened according to CDC's STD treatment guidelines (http://www.cdc.gov/std/treatment). If a woman has not been screened according to guidelines, screening can be performed at the time of the insertion of the intrauterine device and insertion should not be delayed. Women with purulent cervicitis or current chlamydial infection or gonorrhea should not undergo insertion of the intrauterine device.

Modified with permission from Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. Selected practice recommendations for contraceptive use, 2016. *MMWR Recomm Rep*. 2016;65(4):1-66. Available at: https://www.cdc.gov/mmwr/volumes/65/rr/rr6504a1.htm. Accessed August 27, 2017.[25]

In summary, many factors are to be considered when providing care for a woman who desires to prevent pregnancy. Although the effectiveness and eligibility of specific methods are important considerations, counseling is a prerequisite to facilitating an informed choice. The best contraception for a woman is one she personally desires and can use correctly and consistently.

Family Planning Counseling and the Role of the Midwife

Hallmarks of midwifery care include concepts such as promoting family-centered care, facilitating empowerment of women as partners in health care, promoting public health, and advocating for shared decision making and the right to self-determination.[26] Responsibilities of the midwife in this area include identification of needs, health education, assisting in decision making, and provision of contraceptive methods. In some settings, midwives may also provide abortion services. To appropriately provide family planning care, midwives must be aware of their own feelings and attitudes about sexuality, gender roles, contraception, religious beliefs, and other beliefs that could affect family planning counseling. Counseling is one of the most critical aspects of family planning care, which has different components depending on the type of counseling provided.

Obtaining a comprehensive health history is the initial step in family planning counseling. This information will allow the midwife to assess for risk factors as outlined in the U.S. MEC for Contraceptive Use and tailor counseling to the individual. Some medical conditions may affect a woman's eligibility for some contraceptive methods. For example, combined hormonal contraceptives are not safe for a woman who has severe hypertension.[24]

Choice of a Specific Contraceptive Method

Not all women who are sexually active are at risk for pregnancy. For example, some have a partner of the same gender, or a heterosexual woman may be engaged in a monogamous relationship with a man who has had a vasectomy. Furthermore, among heterosexual couples who engage in sexual activity that involves vaginal penetration, one or both may be infertile. Despite these caveats, more than 60% of women between age 15 and 44 years use a contraceptive method.[11] To effectively provide any counseling, the midwife must be able to personally detach from the decision that the woman may make, acknowledging that her decision may not be the one the midwife would make or recommend. In fact, the woman's decision may even conflict with the midwife's personal beliefs.

The woman's preference is the major foundation for choice of a specific method.[27] Incorporation of a partner into the process of choosing a contraceptive method is a decision made by the woman. In some cases, midwives may provide education to couples; in other situations, the woman alone consults with the professional. Throughout this chapter, content regarding education and care may be extrapolated to include significant others when their inclusion is preferred by the woman.

Some women prefer not to share information about a chosen contraceptive method with their partners because of personal privacy concerns or fear of contraceptive sabotage. Contraceptive sabotage occurs when a partner or other exercises reproductive coercion over the woman either to conceive or to abort a pregnancy.[28] Women may seek contraceptives because they are anticipating exposure to pregnancy, voluntarily or not. For example, women in the military may be placed in positions where they are vulnerable to sexual violence, or where

a contraceptive-associated amenorrhea may be preferable because of deployment to areas with lack of hygienic conditions.[29,30] Women who have physical or intellectual disabilities also have unique needs in the area of contraception and menstruation.[31,32] These needs may be related to or separate from voluntary sexual activity.

A woman's preference for a specific contraceptive method also can be influenced by a variety of individual factors that should be acknowledged by the midwife. Desired family size and choices about contraceptive methods are strongly influenced by culture, attitudes, and religion.[33] Even though pregnancy is defined by implantation, some women may view pregnancy as starting at conception, and this belief may affect adoption of certain contraceptive methods that do not impede conception based on their mechanism of action. Some women believe exogenous hormones are unnatural and only opt for nonhormonal methods. A woman with several friends and family using one method may gravitate toward that method. Cost and insurance availability can cause women to discount certain methods. These examples are simply a few of the factors that a woman might consider.

Practice varies as to how the informed consent process is acknowledged and documented. Some practices require that women sign consent forms. In any case, informed decision making is essential, and written consent must always be obtained prior to initiation of any invasive method, such as an implant or intrauterine device.

Other Factors a Woman May Consider When Choosing a Contraceptive Method

Counseling should include sharing information about the noncontraceptive advantages of certain methods of which the woman might be unaware or does not readily consider. For example, condoms prevent transmission of sexually transmitted infections (STIs) in addition to their contraceptive action, and combined oral contraceptives (COCs) can decrease a woman's lifetime risk for ovarian cancer. The cost of the method, both for initiation and for long-term maintenance, should also be discussed with the woman. For example, some methods may be covered by health insurance, whereas other methods may result in higher out-of-pocket costs, precluding their use by some women who have lower incomes or lack insurance to defray the cost.

Some personal beliefs about the effects of a contraceptive method may be based on misinterpretation that may be clarified with scientific evidence. Others are deeply held beliefs based on culture or religion, which may in turn influence the woman's choices.

Any one single factor may be of more importance to a woman than another factor. For some women, the major concern is effectiveness of the contraceptive method, and they are willing to experience additional side effects to gain greater effectiveness. For other women, unintended pregnancies would be ill timed but not devastating; in such a case, factors such as cost, ease of use, and acceptability to their partner may contribute more to the decision about which contraceptive method to use.

The presence of or potential for transmitting genetic disorders to offspring may be an additional consideration, and for some women is a factor in choosing permanent sterilization. Of note, personal genetic risk factors may influence a woman's physiologic response to a contraceptive method as well as her personal risk factors. A woman with a strong family

history of coagulation disorders, for example, may choose an intrauterine device as opposed to a contraceptive patch because of the former's lower risk of triggering a thrombotic event. Such a decision recognizes the inheritable nature of the disorder even if the woman does not know her personal risk.

Special Populations

A woman's age can factor into her choice of contraceptive method. Adolescents may choose LARCs because they are discrete. Nonsmoking women in their 30s or 40s may choose oral contraceptives based on the noncontraceptive benefits. Other women who smoke and are older than 35 years should not take COCs based on the U.S. MEC for Contraceptive Use.[24,25] Perimenopausal women may not realize their risk for pregnancy until they receive health education.[34] Women with a mobility disability may have difficulty with insertion of a barrier method.[31,32] Women with intellectual disabilities may have a guardian who can be included in counseling, although every effort should be made to retain the woman's choice.[32]

Table 15-5 summarizes common factors that a woman may consider in the selection of a contraceptive method. Midwives are ideal providers to customize contraceptive messages and support women in their choices.

Table 15-5 Common Factors Involved in Women's Selection of Contraceptive Methods

Factor	Examples
Acceptance of critical aspects of method	View that a daily method or one that is coital dependent is inconvenient
Acceptance of unintended pregnancy	Failure of method is inconvenient but not troublesome to the woman and her family
Access to method and ability to use successfully	Inability of hands to manipulate diaphragm
	Expense of methods and no insurance to cover cost
Beliefs	Desire not to have device reside in the woman's body
	Wariness about using any exogenous hormones
Eligibility based on risk factors	Age and concomitant health conditions identified as Level 3 or 4 in the U.S. *Medical Eligibility Criteria*
Health benefits	Personal risk factors that can be ameliorated by specific methods
Need for discrete method/privacy	Desire not to let the partner or others know of sexual activity or contraception
Need for protection from sexually transmitted infections	Most methods provide contraception but not protection unless condoms are added
Opinions of partner/significant others	Family members' opinions about the benefits or complications of use of a specific method
Past history	Desire to restart or not restart a method
Pattern of sexual activity	Sexual activity infrequent
Side effects and tolerance	Interpretation/tolerance of intermenstrual bleeding; amenorrhea; other common side effects
Support and counseling from healthcare provider	Healthcare provider with a negative opinion about a specific method or about adolescents engaging in sexual intercourse

Time to return to fertility after discontinuation	Desires a pregnancy within a short period, which may preclude certain methods including LARCs

Counseling Women Who Have an Unintended Pregnancy

In most practices, a pregnancy test is performed as part of the standard protocol prior to prescribing or dispensing a contraceptive product. However, if such a laboratory test is not readily available, certain clinical criteria have a negative predictive value of 99% to 100% for the absence of current pregnancy (**Table 15-6**).[25] Even when a negative pregnancy test is obtained, the midwife may desire to document the clinical criteria listed in **Table 15-6** in the woman's health record. If a woman is unintentionally pregnant, options counseling is provided.

Table 15-6	How to Be Reasonably Certain a Woman Is Not Pregnant
A midwife can be reasonably certain that a woman is not pregnant if she has no symptoms or signs of pregnancy and she meets any one of the following criteria:	
Is ≤ 7 days after the start of normal menses	
Has not had sexual intercourse since the start of last normal menses	
Has been correctly and consistently using a reliable method of contraception	
Is ≤ 7 days after spontaneous or induced abortion	
Is within 4 weeks postpartum	
Is fully or nearly fully breastfeeding (exclusively breastfeeding or the vast majority [≥ 85%] of feeds are breastfeeds), amenorrheic, and < 6 months postpartum	

Reproduced with permission from Curtis KM, Jatlaoui TC, Tepper NK, et al. U.S. selected practice recommendations for contraceptive use, 2016. *MMWR Recomm Rep.* 2016;65(4):1-66. Available at: https://www.cdc.gov/mmwr/volumes/65/rr/rr6504a1.htm. Accessed August 27, 2017.[25]

Options Counseling

Options counseling is the process by which an individual who is undecided about available choices is provided with information about all available options.[35] When faced with an unintended pregnancy, a woman generally has the following options: She can continue the pregnancy and keep the baby; continue the pregnancy and place the newborn for adoption; or electively terminate the pregnancy. One of the Hallmarks of Midwifery identified by the American College of Nurse-Midwives (ACNM) addresses advocacy for informed choice, shared decision making, and the right to self-determination.[26] In addition, the ACNM Reproductive Health Choices position statement states: "Every woman has the right to access factual, evidence-based, unbiased information about available reproductive health choices, in order to make an informed decision."[26] These standards underscore the midwife's responsibility with regard to counseling, advising, and informing the woman of her options.

It is very important to understand the distinction between options and abortion counseling. The professional responsibility to present options does not mean the midwife must conduct abortion counseling for women who are interested in abortion. Rather, options counseling is a nonjudgmental description of the alternatives, which might be presented with values

clarification exercises, that can help the woman decide which choice is right for her. Principles of options counseling include the ability to actively listen to the woman, provide to her all necessary information from which to make her decision, and support her in evaluating her options.[35] Some midwives do not provide abortion counseling due to personal, religious, or moral conflicts. A delicate balance is involved between respecting the autonomy of the individual midwife who is morally opposed to providing termination counseling, and respecting the woman's right to be informed about all of her family planning options. A midwife whose conscience will not allow provision of abortion counseling needs to inform the woman of that fact, and facilitate the woman in finding another provider who will offer the counseling.

A midwife can therapeutically discuss options with a woman via use of open-ended questions with nonjudgmental verbal and nonverbal communication. It is imperative that the woman is guided through exploration of her own feelings and beliefs with regard to all appropriate options. Assisting her to understand the outcome of each option is important not only for her decision-making process, but also for her ability to accept the option she will eventually choose.

Pregnancy Counseling

Simply because a pregnancy is unintended, it does not mean the child is unwanted or will be unloved. Some women will opt for maintaining the pregnancy and raising the child. For those women, the midwife can provide counseling regarding the woman's health as well as the fetus. In many cases, the visit provides an opportunity to initiate some aspects of prenatal care and arrange for ongoing care. Details regarding antepartum counseling and care can be found in the *Prenatal Care* chapter.

Adoption Counseling

If a pregnant woman chooses to place an infant for adoption, the primary role of the midwife is to connect the woman with the appropriate resources to assist her in creating an adoption plan. Optimally, this activity would occur in collaboration with a social worker or other professional who has knowledge of the full range of services available in the area, though in some communities the midwife may need to personally provide these referrals. Thus, it is incumbent upon the midwife to become familiar with locally available adoption services. Adoption options include open, closed, or semi-open adoption.[36]

- *Open adoption* occurs when the birth mother and the adoptive family are known to each other and have varying levels of communication, ranging from visits to letters or phone calls, although the birth mother does not necessarily have any input about the way the child is parented. Women should understand that in most cases of open adoption, there is no legal requirement for the adoptive family to follow the terms of such an agreement and legal restrictions will vary by state.
- *Closed adoption* is an adoption in which birth records are sealed, and all identities are

concealed.
- *Semi-open adoption* is an adoption in which some identifying information is shared, and communication occurs at prearranged intervals, usually through an intermediary such as an attorney or adoption agency. The degree of communication and "openness" may change over time.

Making the decision to place a baby for adoption is a difficult one, and the woman will need emotional support, both during prenatal care and during the birth and the early postpartum period.

Abortion Counseling

One should never assume that confirmation of pregnancy will be either positive or negative news for an individual. The legalization of abortion means that every woman in the United States, upon becoming pregnant, has a choice to carry the pregnancy to its natural conclusion or abort the pregnancy. Since 1969, the CDC has gathered data regarding abortion. In 2013, the rate in the United States was 2.5 abortions per 1000 women between age 15 and 44 years, or a ratio of 200 abortions per 1000 live births. These statistics represent a decrease of approximately 5% in the number of abortions from the prior year and are the lowest level seen in the last decade. Approximately 60% of pregnancy terminations are obtained by women who have had at least one or more previous children, and 55% have never had an abortion before.[6]

A woman's decision to have an abortion is not made easily. Midwives who desire to provide abortion counseling need to be knowledgeable about local resources, the methods used, and ways to make appropriate referrals as needed. Components of abortion counseling include discussion of method-specific risks, benefits, informed consent, and gestational age limits. Gestational age limits will vary by setting, state regulations, and local availability of trained providers.

Induced Abortion

More than 90% of planned abortions occur in the first trimester. A small percentage (8.6%) are performed after 13 weeks' gestation.[6] In the first trimester, abortions are performed using pharmacologic agents or surgical interventions such as vacuum aspiration or dilation and curettage. After the first trimester, surgical dilation and evacuation is used, potentially requiring a 2-day procedure, with the insertion of osmotic dilators at least 24 hours before the termination of pregnancy. For women whose blood is Rh negative, Rho(D) immunoglobulin (anti-D serum; RhoGAM) is indicated prior to start of either medical or surgical termination.

Surgical Abortion

Manual vacuum aspiration (MVA) may be used for pregnancies that are up to approximately 12 gestational weeks. This method involves using a handheld syringe as the suction source for emptying the uterine contents.[37] MVA has been found to be equally effective as suction curettage for abortion during the first trimester.[37] The procedure takes 5 to 15 minutes, and can be performed in the office setting. It results in removal of the intact gestational sac, thereby enabling confirmation of pregnancy termination.[38] Studies have suggested that nonpharmaceutical methods can augment pharmacologic treatments to mitigate the woman's discomfort during this procedure.[39,40]

Termination using suction dilation and curettage (D & C) is accomplished by dilation of the cervix, followed by curettage to empty the uterine contents. This technique can be used up to 13 gestational weeks. The overall risk of complications is less than 1% for surgical termination. The main complications of surgical abortion are continued intrauterine pregnancy; heavy bleeding; infection, including endometritis; uterine perforation or injury to organs; and risk of retained products of conception, requiring further surgical intervention.[41,42]

Abortion Using Pharmacologic Agents

The number of medical abortions in the United States increased from 2012 to 2013 by 5%, with this technique accounting for more than 22% of legal abortions.[6] In some countries, medical abortion is considered the method of the future and already accounts for the vast majority of induced abortions.[43] Three agents currently are used for medical abortion: mifepristone (Mifeprex, RU-486), methotrexate (Rheumatrex), and misoprostol (Cytotec). A combination of mifepristone and misoprostol was FDA approved in 2000 for women seeking a medical abortion, and in 2016 the FDA released new information about use. According to the FDA approval, oral mifepristone should be administered as a dose of 200 mg. Then, 24 to 48 hours later, 800 mcg of oral misoprostol can be administered at home.[44] At 7 to 14 days post treatment, the woman should be evaluated to confirm that a complete termination has occurred.

Mifepristone inhibits progesterone, which is necessary for normal placental attachment, thereby preventing fertilization and sensitizing the uterus to the effects of prostaglandin.[45] Maximal sensitization occurs at approximately 24 to 48 hours following administration of mifepristone.[46] Misoprostol, a prostaglandin E_1 analogue, causes expulsion of uterine

contents.[23] The two-medication regimen of mifepristone followed by misoprostol has a 95% to 98% effectiveness rate when used by women whose gestations are 63 days or less after their last menstrual period.[47] When used alone, mifepristone is approximately 76% effective; hence it is rarely used as a sole agent.[47] The effectiveness of misoprostol alone varies widely, from 68% to 94%,[47] depending on whether it is used vaginally, it is inserted dry or moistened (most effective), or it is taken orally.[48] When used alone, misoprostol is associated with significantly higher rates of nausea, vomiting, fever, chills, and diarrhea. It has also been found to be a teratogen, being associated with the rare congenital neurological disorder called Mobius syndrome if the pregnancy continues.[49]

Although methotrexate has been used for pregnancy termination, it is not as effective as the other drugs. Methotrexate works by inhibiting dihydrofolate reductase, an enzyme necessary for DNA synthesis, and often is categorized as an antimetabolite or an antifolate agent.[50] Rapidly dividing cells, such as those found in the zygote, morula, or blastocyst, are not able to undergo normal mitosis when exposed to methotrexate. When used alone, this agent's effectiveness ranges from 60% to 84%.[50] This drug is also used for treatment of women with ectopic pregnancies as well as to stop the replication of other rapidly dividing cells such as those found in cancer, although many other chemotherapeutic drugs have replaced it for specific malignancies.

Women who plan a medical abortion are counseled to expect heavy bleeding and significant painful cramping. The bleeding will be heaviest in the first 6 hours after misoprostol administration. Approximately 50% of women report nausea following use of mifepristone. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be effective in mitigating pain, and they do not interfere with the effect of misoprostol. Because there is a risk of teratogenicity if pregnancy is not aborted, women should be counseled about a possible need for surgical abortion in the event of failure of the medical approach.

The contraindications to medical abortion are listed in **Table 15-7**.[50,51] Notably, women who are breastfeeding should avoid nursing their infant for 2 days after using mifepristone and for 4 hours after taking misoprostol. Complications of medical abortion methods may include minor conditions such as nausea and vomiting. Rarely, women experience incomplete expulsion of uterine contents and subsequent need for surgical procedure; uterine infection (less than 1%); and heavy bleeding that requires hemostatic curettage (0.3% to 1.3%).[46] Women should be counseled to notify their provider if they experience continuing heavy bleeding post abortion.

Table 15-7	Contraindications to Medical Abortion
General Contraindications	**Use with Caution**
Previous allergic reaction to one of the drugs involved	Long-term corticosteroid therapy (including in individuals with severe uncontrolled asthma[a])
Inherited porphyria	Hemorrhagic disorder
Chronic adrenal failure	Severe anemia
Known or suspected ectopic pregnancy (neither misoprostol	Preexisting heart disease or cardiovascular risk

nor mifepristone will treat ectopic pregnancy)	factors Intrauterine device in place; remove before beginning the regimen

[a] Severe asthma not controlled by therapy is a recommended contraindication by some organizations, but is not listed as a contraindication by others. According to the American College of Obstetricians and Gynecologists, asthma is not a contraindication because misoprostol is a weak bronchodilator. However, if the woman has severe asthma, a consultation is recommended before proceeding with a medical abortion.

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 143: medical management of first-trimester abortion. *Obstet Gynecol.* 2014;123(3):676-692[50]; World Health Organization. *Clinical Practice Handbook for Safe Abortion.* Geneva, Switzerland: WHO Press; 2014.[51]

Post-Termination Care

Regardless of whether a midwife is involved in the termination procedure or even the counseling of the woman, it is common for a midwife to care for women who have recently had a pregnancy termination. Women may have an IUD inserted immediately after an uncomplicated first-trimester abortion.[52] Other contraceptive methods are classified into category 1 or 2 by the U.S. MEC.[24] Women who experience sepsis should avoid insertion of an IUD until the infection has revolved. Women who have undergone either a surgical or medical abortion should be seen for a follow-up visit within 2 weeks. The follow-up visit assessment includes assessment for complications including incomplete abortion, evaluation of emotional status, and discussion of ongoing contraceptive needs.

A pelvic ultrasound, urine pregnancy test, or qualitative serum beta–human chorionic gonadotropin (β-hCG) measurement may be used to confirm expulsion of the products of conception. A systematic review of the literature revealed controversy about routine use of ultrasound to rule out retained products of conception. Although ultrasound has high sensitivity and specificity for this indication, it is expensive and not always available. The use of alternative modalities, such as standardized questioning of a woman's symptoms, telephone consultations, and urine hCG measurement, are effective strategies for follow-up. However, if there is a strong suspicion of an abortion failure, ultrasound remains the most common intervention.[53]

Role of Midwives in Performing Abortions

In 1971, ACNM issued a practice statement that prohibited certified nurse midwives (CNMs) from performing abortions based on the rationale that it was an operative procedure best performed by a physician. This statement preceded the U.S. Supreme Court's 1973 ruling in *Roe v. Wade*, which legalized abortion across the United States. The 1971 statement was the only prohibitive statement ever issued by the ACNM and, after discussion within the membership, it was retracted in 1992.[54]

The abortion care provided by midwives and other nonphysician providers has been demonstrated to be equal to that provided by physicians.[55,56] Because medical abortion is discrete, the numbers of midwives who may be providing such intervention is unknown. The

University of California–San Francisco has provided education for CNMs, physician assistants (PAs), and nurse practitioners (NPs) in the procedure of uterine aspiration evacuation for many years. Induced abortion is not found in the ACNM core competencies, but midwives who desire to add it to their scope of practice can follow the steps outlined to incorporate new procedures as found in the *Standards for the Practice of Midwifery*.[57,58]

Emergency Contraception

Misnamed as postcoital or “morning after” contraception, this family planning method is more appropriately termed *emergency contraception*. This form of contraception is not intended for use as a regular method of birth control. Rather, it is recommended either when there has been a method failure, such as condom breakage, or after unintended unprotected intercourse. Emergency contraception may be used anytime in the first 3 to 5 days after unprotected intercourse depending on the method chosen.[59,60] Women seeking contraceptive services should be counseled about the availability and correct use of emergency contraception.

Four methods of emergency contraception currently are available in the United States: (1) the Yuzpe method; (2) levonorgestrel (LNG) formulations (Plan B One Step, Next Choice One Dose, Take Action); (3) selective progesterone receptor modulators (ulipristal acetate [UPA; ella]); and (4) the copper intrauterine device (IUD). The dose, efficacy, timing, availability, U.S. MEC rating, and clinical conditions for these methods are summarized in **Table 15-8**.[24,25,59,61,62]

Table 15-8 **Emergency Contraception in the United States**

Brand Name	Estimated Efficacy[a]	Timing after Intercourse[b]	Availability	U.S. MEC[c]	Clinical Considerations
FDA-Approved Emergency Contraception					
Plan B One Step Next Choice One Dose Take Action My Way And a number of other generics	81–90% reduced pregnancy rate	Within 72 hours	No prescription No age restriction	1 or 2	May be less effective for women with BMI ≥ 30. Avoid use of CYP3A4 inducers at same time.
ella (Ulipristal acetate or UPA) (1 pill)	2.1% failure rate	Within 120 hours	Prescription only	1 or 2	May reduce the contraceptive action of progestin-containing hormonal contraceptive methods because of its affinity for binding to the progesterone receptor; SPR recommends hormonal contraception delay for 5 days with abstinence for 7 days post UPA, although depot medroxyprogesterone acetate can be started simultaneously with UPA. Avoid use of CYP3A4 inducers at same time. Discard breast milk for 24 hours after administration due to higher concentrations in milk.
Not FDA-Approved Emergency Contraception But Available					
Combined oral contraceptives	1.3–1.5% failure rate	Within 72 hours	Prescription only	1–2	Also known as the Yuzpe method. More than 25 brands can be used.[d]
ParaGard copper IUD	99% reduced pregnancy rate	Within 120 hours after ovulation	Prescription only	1–3	U.S. MEC level varies based on risk of sexually transmitted diseases.

Hormonal Emergency Contraception: Mechanisms of Action

The mechanism of action of hormonal emergency contraception methods is inhibition and/or delay of ovulation secondary to suppression, delaying, or blunting of the luteinizing hormone (LH) surge, depending on when in the menstrual cycle the contraceptive pill is ingested.[50] Oral contraceptive and LNG formulations of pregnancy prevention do not effectively prevent follicular rupture if used in the late preovulatory stage; thus, these two methods are most

effective if used prior to ovulation and as soon as possible after unprotected intercourse.[63] UPA does prevent follicular rupture if taken before the onset of the LH surge and reduces endometrial thickness, thereby making the endometrium less hospitable for implantation of an embryo. Hormonal emergency contraception methods do not interfere with a conceptus that has already implanted and present no risk to that embryo.[45,63-68]

Calculating effectiveness rates for emergency contraception is complex because accurately estimating when ovulation occurs relative to the timing of sexual intercourse is difficult, and because some of the research reports use different statistics to report estimated efficacy. In general, emergency contraception is most effective when the interval between intercourse and use is short. Longer intervals result in decreased effectiveness.[65]

The Yuzpe Method

The Yuzpe method, an eponymous regimen that was first published by a Canadian scientist in the 1970s, is the oldest of the current emergency contraception methods. This method involves the ingestion of a high dose of estrogen and progestin, which is accomplished by administering several combined oral contraceptive pills in a single dose so as to inhibit ovulation. More than 25 brands of COCs can be used with this method. Because the brands of COCs can vary, when the Yuzpe method is desired, a midwife can consult a website with current information, such as the emergency contraception website supported by the Office of Population Research at Princeton University and the Association of Reproductive Health Professionals.[62]

The pregnancy rate following use of the Yuzpe method is approximately 2% to 3%. This contraceptive method frequently causes nausea, vomiting, headache, vertigo, and breast tenderness. The woman may also experience irregular bleeding or spotting in the 3 to 4 weeks following treatment.[65] The Yuzpe method is not suggested as the first choice of emergency contraception particularly because of the associated nausea and vomiting.[69] If it is used, an over-the-counter antiemetic, such as meclizine (Antivert, Bonine, Dramamine II) in a dose of 25–50 mg, can be recommended for use 1 hour prior to taking the emergency contraception dose. There is conflicting information on whether either dose should be repeated if the woman vomits within 1 hour of ingesting the medication.

The Yuzpe method may be a good choice if a woman has difficulty obtaining other dedicated emergency contraception methods because of age or lack of availability in the area. It also may present an attractive option if the woman has COCs on hand.

Levonorgestrel: Plan B One Step and Next Choice One Dose

Although still available, the Yuzpe method has been largely replaced by the progestin-only formulations made of LNG. The LNG formulations are more effective and have fewer side effects than those that contain both estrogen and progrestins.[65,70] LNG primarily inhibits or delays ovulation by preventing the LH surge if taken before the LH surge occurs.[66] If taken close to or during the LH surge, it blunts and delays the surge and makes the ovum resistant to fertilization.[59]

LNG for emergency contraception is formulated under the brand name Plan B One Step as

well as a variety of other brand and generic names. When using a one dose product, according to the package insert, a single dose of 1.5 mg LNG is taken within 72 hours following unprotected intercourse.[61,62] If vomiting occurs within 2 hours of taking a single-dose LNG, a repeat dose should be considered. Previously a two dose LNG option was available, however the convenience of taking one dose rather than two tended to improve use and effectiveness so that the two dose products are no longer on the market.

Studies that have evaluated one dose LNG agents used for emergency contraception and ingested within 72 hours following intercourse, have found the effectiveness is approximately 84% for the single-dose regimen.[71] Pregnancy rates are approximately 2% and generally lower than the pregnancy rates following use of the Yuzpe method.[59]

Ulipristal Acetate

In 2010, UPA, a selective progesterone receptor modulator marketed under the brand name "ella," received FDA approval for use as emergency contraception; thus, UPA is the first—and to date only—selective progesterone receptor modulator agent available for emergency contraception in the United States.[59] Selective progesterone receptor modulators bind to progesterone receptors and inhibit or delay ovulation, depending on when the agent is taken during the menstrual cycle. If used during the midfollicular phase, UPA prevents follicular rupture.[59] When this agent is taken in the late follicular phase, it delays the normal LH surge, thereby delaying ovulation.[67,72,73]

UPA appears to be more effective as emergency contraception than either the Yuzpe method or LNG, and can be effective up to 120 hours after unprotected intercourse—an effect attributed to its ability to prevent follicular rupture, although its effectiveness does decrease with time.[69] Side effects are the same as those reported for the Yuzpe method and LNG, but occur less frequently. Because most of these side effects are also symptoms of pregnancy, it is not clear exactly which ones occur secondary to administration of the drug.

Contraindications to Hormonal Emergency Contraception

The major contraindication to the use of any method of emergency contraception is a known pregnancy. Oral formulations of emergency contraception are contraindicated in pregnancy because they are ineffective; the contraindication is not related to concerns about teratogenicity. Because these hormones are given in low doses for a short period of time, women with healthcare conditions for which oral contraceptives are contraindicated can use emergency contraception safely.[59]

Although adverse drug–drug interactions have not been reported by women using oral emergency contraception, adverse drug interactions are possible. Anticonvulsants such as phenobarbital (Luminal), carbamazepine (Tegretol), and phenytoin (Dilantin) induce the CYP450 system and could decrease effectiveness of the contraceptive. Other drugs that interfere with the metabolism of oral contraceptive agents include rifampin (Rifadin), topiramate (Topamax), and St. John's wort.[59]

Copper Intrauterine Device

The copper IUD (ParaGard) can be used as emergency contraception when inserted within 120 hours (5 days) following intercourse and is the most effective emergency contraception method currently available.[59] The IUD is not effective for emergency contraception if inserted after the fertilized egg has implanted in the uterus, which normally occurs 6 to 12 days after ovulation.[59] The technique for insertion is described in the *Procedure for IUD Insertion* appendix to the *Nonhormonal Contraception* chapter.

Pregnancy rates following insertion of a copper IUD are approximately 0.1%.[74] The copper IUD alters tubal transport, is toxic to ovum, and incapacitates sperm, thereby preventing fertilization.[59] Unlike oral formulations of emergency contraception, the copper IUD also creates an inhospitable uterine environment for implantation.[5] If a woman is a candidate for intrauterine contraception, placement of a copper IUD for emergency contraception offers the additional advantage of establishing an ongoing contraceptive method. Note that the levonorgestrel-releasing intrauterine system IUD is not indicated for emergency contraception.

Contraindications to Use of the Copper IUD for Emergency Contraception

General contraindications to use of a copper IUD are reviewed in detail in the *Nonhormonal Contraception* chapter. Insertion of a copper IUD for emergency contraception after rape is an important topic to review. The U.S. MEC for Contraceptive Use category for insertion of a copper IUD for emergency contraception is 3 if the woman has a high risk for being exposed to an STI, but is 1 if she has a low risk for being exposed to an STI.[25] There are no agreed-upon definitions for what constitutes “high risk” versus “low risk” for STI. In addition, the U.S. MEC for Contraceptive Use category 3 means that the theoretical risks generally outweigh the advantages. Thus, clinician judgment is needed to assess the history and circumstances for a woman who has been raped and to determine whether she is a good candidate for a copper IUD.

Special Considerations for Dispensing Emergency Contraception

Some pharmacies may opt out of dispensing emergency contraception methods and a number of states protect their right to do so, as well as the rights of midwives and other professionals who do not choose to provide contraception.[75,76] In such cases, the Yuzpe regimen may be recommended. Many healthcare professionals regularly prescribe emergency contraception for women using a SARC method in case of missing COCs, breakage of a condom, or other circumstances.

Many national women’s health organizations recommend that all women who are victims of sexual assault be offered emergency contraception.[77] Some states mandate that women must be offered emergency contraception after rape. State laws can change, however, so the clinician should determine the specific state rules that apply. In any case, the midwife who may have occasion to care for a woman post assault should discuss whether she has either received appropriate information or been treated with emergency contraception.

Follow-up Care

Women who need emergency contraception also should be offered screening for STIs including human immunodeficiency virus (HIV) infection.

Women using emergency contraception may be counseled to return for evaluation 1 to 3 weeks following use of this treatment, specifically to assess the result of emergency contraception and discuss ongoing contraceptive needs, although this follow-up visit is not considered a necessary component of emergency contraception care by all professional organizations. In most situations, a suitable method of contraception should be started as soon as possible after the woman has used an emergency contraception method. Women who use hormonal emergency contraception can initiate any contraceptive method immediately, but are advised to use a barrier method or abstinence for the next 7 days. Because ulipristal acetate has a unique mechanism of action, using a hormonal contraceptive simultaneously can decrease the effectiveness of both methods. Therefore, women using UPA should use a barrier method or abstinence until the next menses, although they can begin a hormonal contraceptive method 5 days after ingestion of UPA.[25,26] Women using a copper IUD have immediate and continuing contraceptive protection.

Health Education

Women using emergency contraception should be advised that the next menses may be delayed after using oral regimens. It is important to be evaluated for pregnancy if menses does not occur within 3 weeks after emergency contraception use. Women should also be counseled regarding signs of ectopic pregnancy and advised to contact a healthcare provider as soon as possible if they develop severe abdominal pain at any point after using the emergency contraception method. In addition, women using emergency contraception should avoid unprotected intercourse until a method of contraception has been initiated.

Emerging Trends and Future Contraceptive Methods

There is no “one size fits all” method of contraception. Therefore, the greater the variety of options, the more likely that women will be able to find a method that they can consistently and correctly use in concert with their lifestyles. Prediction of new methods of contraceptives is an uncertain act, especially since development of a new method often take years and during trials complications may be identified such that the method is never introduced to the U.S. market.

Some of the proposed methods could potentially resolve common problems with contraceptives. For example, among the new methods needed are additional vaginal spermicides with microbicidal properties, agents with new delivery mechanisms, lower-cost agents, and those with dual protection for STIs.[78] Injectables and implants that offer a longer duration of effects could improve the effectiveness of current LARCs. A biodegradable implant could be more acceptable to women if it avoids the need for removal.

Among the new methods currently being investigated for women is a monthly injectable composed of medroxyprogesterone acetate and estradiol. A vaginal ring that is effective for 1 year, and that contains ethinyl estradiol and nestorone, may be available someday. A new weekly patch containing ethinyl estradiol and levonorgestrel is being researched. Several COCs are under investigation, many of which represent variations of a current formulation and others based on newer progestins.

A myriad number of fertility apps already exist, and in the future, they may potentially provide the ultimate control for women over their reproduction, enabling them to abstain during days of risk or use a barrier method then.

Although these innovations are focused on women, development of male contraception methods other than male condoms is considered desirable, although few innovations have emerged on this front. Perhaps the most promising male development involves an injection of a gel that creates a type of a chemical mesh to trap and inactivate sperm in the vas deferens without harming the surrounding tissues. The procedure, which is known as reversible inhibition of sperm under guidance (RISUG), is not permanent, as another agent can be injected to reverse the process.[79]

Prediction of future developments in health care is always difficult, and forecasting is no different in the area of family planning. However, development of an effective and acceptable method could potentially bring billions of dollars in revenues to the manufacturer; this powerful lure to would-be developers is cause for optimism in the family planning realm.

Conclusion

The midwife’s role in assessing a woman’s needs, preexisting knowledge, and desire in regard to avoiding pregnancy is paramount so that a woman can choose her best options. Such choice is individualized based on a myriad of factors, including age, health, culture, desire, beliefs, relationships, and response should a method fail. Counseling women about the options of parenting, releasing a child to adoption, and pregnancy termination are within the scope of the midwife. New methods of contraception are welcome developments, as they provide more choices for women and can ultimately decrease the rate of unintended pregnancy.

CHAPTER

16

Nonhormonal Contraception

MARY C. BRUCKER

The editors acknowledge Michelle R. Collins, Sharon L. Holley, Tonia L. Moore-Davis, and Deborah L. Narrigan, who were authors of this chapter in the previous edition.

Introduction

Today, women who want to use a form of contraception have an array of both hormonal and nonhormonal methods available. Many choose a nonhormonal option, both in the United States and worldwide. Some choose a nonhormonal method because they have concerns about the use of exogenous hormones or want to avoid exposure to additional hormones. Others have preexisting health conditions, such as thromboembolic disorders that preclude the use of some of the hormonal types of contraception. Still other women use nonhormonal methods as secondary contraceptive methods while initiating or transferring between hormonal methods or as one of multiple contraceptive methods used simultaneously.

This chapter reviews the contraceptive methods that do not contain hormones for their mechanism of action. Nonhormonal reversible methods can be categorized as behavioral, spermicidal, barrier methods or copper intrauterine devices (IUDs). In addition, male and female sterilization are permanent nonhormonal methods of contraception.

Intrauterine contraceptive devices include a copper device that is similar to the IUDs containing levonorgestrel (LNG). Both copper and LNG-containing IUDs are highly effective long-acting reversible contraceptives (LARC) with multiple commonalities. General information that applies to both types of IUDs is found in this chapter. Because the copper type of IUD does not contain any hormone, it is discussed in depth in this chapter, whereas those IUDs containing levonorgestrel are reviewed in the *Hormonal Contraception* chapter.[1]

The contraceptives that are within the behavioral, spermicidal, and barrier categories are controlled by the user, are relatively inexpensive, and have few or minor side effects. Many nonhormonal methods do not require a prescription (e.g., foam, condoms), and most are used only when coitus is anticipated or during coitus. Behavioral methods use no device at all, relying instead on biologic processes such as breastfeeding or observing changes during the menstrual cycle for contraceptive effectiveness.

Most of the nonhormonal contraceptive methods are safe, and with a few exceptions, these forms of contraception have no absolute contraindications. Thus, they are listed as Category 4 in the Centers for Disease Control and Prevention (CDC) guidelines entitled U.S. Medical Eligibility Criteria (U.S. MEC) for Contraceptive Use.[2] Health risks associated with these products are detailed in the section specific to each method in this chapter.

The Effectiveness of Nonhormonal Methods in Preventing Pregnancy

Each individual has personal reasons to choose one contraceptive method instead of another. For the majority, effectiveness is a major consideration in the choice of a contraceptive method, albeit not necessarily the *most* important. For example, some women may consider effectiveness to be less important than other factors and view a pregnancy that ensues a bit earlier than planned not to be a major problem. For other women, effectiveness is a primary consideration. The best contraceptive method is the one the user desires and will use consistently and correctly.

If a woman or a couple uses no contraceptive method, approximately 85 of every 100 will have an unintended pregnancy in the first year of no contraceptive use.[1,3] Effectiveness rates for typical use of the nonhormonal reversible methods vary widely, ranging from fewer than 1 unintended pregnancy per 100 women who use the copper IUD to 28 unintended pregnancies per 100 women who use spermicide only. The lactational amenorrhea method is highly effective, but the duration of its effectiveness is only approximately 6 months; this method also depends on certain specific requirements that can be socially difficult to fulfill for some women in the United States. Fertility awareness methods have quite variable rates of effectiveness and are highly dependent upon health education and clear understanding and commitment by users. Ultimately, the decision about type of contraception (if any) belongs to the woman, and providers should be aware of their own beliefs to avoid injecting personal bias when counseling women about contraceptive methods.[4]

Behavioral Methods

Behavioral contraceptive methods focus on identifying the likely fertile time for an individual woman.[5] These methods are highly dependent upon the woman/couple's motivation, understanding of fertility, and presence of normal predictable menstrual cycles. Behavioral contraceptive methods may be particularly attractive to individuals who do not want artificial interventions. Behavioral methods can be used for pregnancy prevention, attainment of pregnancy, or pregnancy spacing. Globally, behavioral methods are among the oldest and popular methods, with more than 5% of couples who are contracepting worldwide using coitus interruptus or fertility awareness.[6]

Abstinence

When undertaken for the purpose of avoiding pregnancy, abstinence is defined as refraining from penile–vaginal intercourse. However, if abstinence is defined to include prevention of sexually transmitted infections (STIs), then abstinence includes not engaging in sexual contact that has a risk of STI transmission. For example, anal intercourse with an infected partner confers a higher risk of transmission of human immunodeficiency virus (HIV) than vaginal penetration. By comparison, oral intercourse confers a higher risk of transmission of human papillomavirus (HPV) and herpes simplex virus (HSV).

Abstinence is free of cost, available without a healthcare provider visit, and free of side effects. Complete abstinence is 100% effective and prevents exposure to STIs as well as pregnancy. Planned abstinence can be unrealistic for some couples, however, and may not be possible to achieve in coercive situations.

Coitus Interruptus/Withdrawal Method

With the coitus interruptus (withdrawal) method, the penis is completely removed from the vagina and away from the female external genitalia before ejaculation. In a survey of contraceptive usage among women from 2006 to 2008, approximately 5% of women reported current use of this method, but more than half reported they had used this method at a prior time.[6,7] In addition, some couples use this method interchangeably or in combination with other methods, such as fertility awareness or condoms.[7] Coitus interruptus is free, requires no contact with healthcare services, and has no side effects. With typical use, 12 of 100 women will experience an unintended pregnancy within the first year of use.[3]

Using coitus interruptus relies to a great extent on both the male partner's awareness of the sensation of imminent ejaculation and his ability to withdraw consistently and completely from the vagina in time to avoid semen coming in contact with the vagina during each act of intercourse. Of note, pre-ejaculate fluid may contain sperm, and could possibly result in pregnancy.[8] Interrupting the sexual response cycle also may diminish pleasure for either or both partners. Women also may not be comfortable with the idea of relinquishing control of contraception to their male partners.

Coitus interruptus, including correct use and estimated effectiveness, should be included in a

discussion of contraceptive methods, especially as rates of its use have been reported to be as high as 25% to 60% among adolescents in the United States.[9] However, coitus interruptus does not protect against STIs, nor does it have any noncontraceptive benefits.

Lactational Amenorrhea Method

The lactational amenorrhea method (LAM) relies on physiologic changes associated with breastfeeding for contraception. Breastfeeding confers a natural method of contraception in the initial postpartum period because the high levels of prolactin that occur during breastfeeding inhibit secretion of gonadotropin-releasing hormone from the hypothalamus, thereby preventing ovulation. Pumping or manual expression of breast milk may reduce the effectiveness of LAM.[10,11] To be successful as a means of contraception, LAM requires that three essential conditions be present, as outlined in **Table 16-1**.[10-12]

Table 16-1 **Criteria for the Lactational Amenorrhea Method**

1. The nursing infant is age 6 months or less.
2. The nursing infant receives all nutrition from suckling, with no more than 5% from food or formula supplementation, and is nursing on demand, with no more than 4 hours between feeds in the daytime and no more than 6 hours between feeds in the night.
3. Maternal menses has not resumed since the infant's birth.

Based on King J. Contraception and lactation. *J Midwifery Womens Health.* 2007;52(6):614-620[10]; Labbok MH. Postpartum sexuality and the lactational amenorrhea method for contraception. *Clin Obstet Gynecol*. 2015;58(4):915-927[11]; Kramer MS, Kakuma R. Optimal duration of exclusive breastfeeding. *Cochrane Database Syst Rev.* 2012;8:CD003517. doi:10.1002/14651858.CD003517.pub2.[12]

Globally, LAM is widely used as a birth spacing method. The major advantages of LAM include that it is immediately available, requires no healthcare visit, and is free, with effectiveness rates as high as 98% to 99.5% during the first 6 months postpartum when the three essential conditions are operational.[1,6] Unfortunately, this method has a limited lifespan because of the short period for which it is effective. In the United States, it also can be difficult to meet the three essential conditions, especially for women who return to work and are separated from their child for several hours each day.

Fertility Awareness Methods

Fertility awareness methods of contraception are occasionally referred to as "natural family planning."[13] These approaches are based on identifying the fertile days in the menstrual cycle when an ovum can be fertilized. However, the term "natural family planning" generally is reserved for a fertility awareness method in which couples use only abstinence during fertile periods; thus, this method is morally acceptable to the Catholic Church.

Fertility awareness methods have been characterized as an inferior method or "old" method

when compared to “modern” methods, perhaps causing individuals and providers to discount using them.[14] The most common concern about fertility awareness methods is poor effectiveness for pregnancy prevention. Reliable data for many of the fertility awareness methods are generally lacking because of the rarity of randomized controlled trials comparing these methods to each other or to other methods. The studies that have been published have been plagued by multiple protocol violations and high dropout rates.[15] For example, several reports have estimated that 24 in 100 women who use these contraceptive methods will have an unintended pregnancy in the first year of use, although the rate of perfect use has been estimated to be 5% or less.[16]

Fertility awareness methods are low-cost, user-controlled contraceptive methods that are available at any time. A multicountry survey of more than 2000 couples using fertility awareness methods reported that the majority were not only satisfied with the method, but also believed that the methods improved their sex lives.[17] Like many contraceptive methods, fertility awareness methods do not protect against transmission of STIs. **Appendix 16A** provides an overview of the various fertility awareness method options.

All of the fertility awareness–based methods are highly dependent on the couple’s motivation and desires; consequently, it is difficult to recommend one method over the others. Emerging technology may be used in combination with these methods, thereby potentially increasing their effectiveness. More than 100 apps are now available, but not all are equally accurate. In 2016, an analysis of the most popular apps listed those considered most appropriate, although the authors also cautioned that use of only an app without education about the contraceptive method may be insufficient to prevent pregnancy.[18]

Spermicidal Agents

Spermicides are chemical agents that kill sperm. Spermicidal agents are formulated as gels, creams, aerosol foam, suppositories, vaginal film, and sponges. The active agent in all spermicidal preparations available in the United States is nonoxynol-9, a surfactant that destroys the sperm cell membrane. This agent is combined with an inert base that creates the specific formulation, such as a cream or gel. The inert base material serves as a mechanical barrier to the cervical os and facilitates vaginal distribution and formation of a surface film that withstands coital activity. Effectiveness of any contraceptive method using the spermicide is directly related to the nonoxynol-9 dose: Products with at least 100 mg of nonoxynol-9 are more effective than preparations with lower doses.[19]

Table 16-2 provides detailed information on spermicidal products. Spermicidal preparations are relatively easy to use, are woman controlled, and are immediately effective. These agents are available widely in stores and online without prescription. **Figure 16-1** depicts the Today sponge, which is impregnated with nonxynol-9.

Table 16-2 Spermicidal Preparations

Preparation	Nonoxynol-9 (mg/dose)	Timing of Application[a]	Duration of Action	Comments
Creams	52–100	Up to 1 hour before coitus	1 hour[b]	Use alone or with a diaphragm
Film	280	Insert 15 minutes before coitus	3 hours[b]	Becomes a gel as it dissolves under body temperature Use dry fingers to place the film deep into the vagina
Foam	100–125	Insert immediately before coitus	1 hour[b]	Aerosol, under pressure in a container; apply with an applicator that is inserted into the vagina in a similar manner to a tampon applicator
Gels	3–4	Insert immediately before coitus	1 hour[b]	Use alone or with a diaphragm
Suppository or insert	100–125	Insert 15 minutes before coitus	1 hour[b]	Activated when melted; spermicide is embedded in cocoa butter or glycerin Remove the covering and insert the suppository deep into the vagina
Sponge	1000	Any time up to 24 hours before coitus	Leave in place for 6 hours after coitus, but no longer than 30 hours total to avoid the rare risk of toxic shock syndrome	Polyurethane "pillow"; moistening with water until suds appear prior to use activates nonoxynol-9 Fold the sponge by using the dimple; place it deeply within the vagina, with the string loop on the bottom for easy removal

[a] Insert another application of nonoxynol 9 for additional acts of intercourse.

[b] Do not douche for this method for a minimum of 6 hours post coitus.

Figure 16-1 Today sponge.

For this contraceptive method to be effective, the woman or couple must use the spermicide consistently with each act of vaginal intercourse. Also, for some preparations, as noted in **Table 16-2**, timing of initiating use is critical for effectiveness. For example, the contraceptive film and suppositories require 15 minutes in the vagina to become effective prior to being exposed to sperm. Women who are not comfortable inserting a finger into the vagina may find film and suppositories problematic, as both need to be placed deep into the vagina so as to cover the cervix. Some postcoital leakage is common with all of the spermicidal preparations except film, which some women consider esthetically unpleasing. Film melts at body temperature and does not result in any additional vaginal discharge.

Spermicidal preparations have a low effectiveness rate for typical use. Among typical users during the first year of use, approximately 28% will have an unintended pregnancy—a rate similar to that for the withdrawal method.[3] The one exception is the sponge, for which effectiveness rates differ according to women's parity: The rates of unintended pregnancy in the first year of use are 12% and 24% for nulliparous and multiparous women, respectively.[3] Even with this limited effectiveness, using any form of this contraceptive method is more effective than using chance or no method.

Side effects and adverse effects of nonoxynol-9 include a contact dermatitis local irritation of the vulva, vagina, or penis, which is often mischaracterized as an allergic reaction. Nonoxynol-9 is a surfactant with the potential to damage the vaginal epithelium, increasing risks of infections, including STIs. Spermicides are absolutely contraindicated (Category 4) for women at high risk for exposure to HIV per the U.S. MEC for Contraceptive Use.[2] The risk of microabrasions to vaginal epithelium increases with use more than twice a day, which in

turn increases the risk of HIV infection.[20] In addition, women who are HIV positive or who have acquired immunodeficiency syndrome (AIDS) likely should not use spermicides because the microabrasions caused by the spermicide also increase viral shedding, thereby increasing the risk of HIV transmission to an uninfected partner.[21]

A rare but serious side effect of sponge use is toxic shock syndrome—that is, an immunologic-mediated, potentially fatal, septic reaction to bacterial toxins of the species *Staphylococcus aureus* and/or *Streptococcus pyogenes*.[22] This condition was discovered in the 1980s to be associated with use of the contraceptive sponge as well as super-absorbent tampons that were composed of carboxymethylcellulose and polyester instead of cotton. Such factors as recent childbirth, use for more than 24 hours, difficult removal, or fragmentation of the aforementioned items appear to increase the risk of toxic shock syndrome.[23] However, the absolute risk of toxic shock syndrome is extremely rare.[24] This infection usually presents as 2 to 3 days of mild symptoms, such as low-grade fever, muscle aches, chills, and malaise. The symptoms worsen rapidly, and include fever higher than 38°C (101.4°F), with diffuse macular erythema and hypotension. Women using diaphragms or the sponge should be educated about the symptoms of toxic shock syndrome, and can decrease their risk of this rare disorder by removing the device within 24 hours of its insertion. Super-absorbent tampons are no longer available on the market.

Barrier Methods

Diaphragms, cervical caps, and condoms are among the oldest contraceptive methods. These methods usually are described as barrier methods because of their mechanism of action. To achieve the maximum effectiveness, spermicides must be used with these barriers so that sperm can be killed before conception occurs. The “barrier” refers to the combination of the physical product that traps ejaculate in the vagina and the chemical barrier supplied by the spermicide.[25] Effectiveness of barrier methods ranges from approximately 88% for diaphragms to an estimated 80% for condoms for women or men.[3]

Diaphragm

The diaphragm is a dome-shaped silicone cup with a flexible rim that permits compression of the device to facilitate insertion into the vagina, but regains its shape and fit so that it fits snugly against the vaginal walls. When properly positioned, the diaphragm rim rests against the anterior (posterior aspect of the symphysis pubis) and lateral vaginal walls, and extends posteriorly to completely cover the cervix. A diaphragm is used with a spermicidal gel or cream that is spread inside the dome of the diaphragm and lightly around the rim which is how the diaphragm provides both physical and chemicals barrier to sperm.[25]

Diaphragms come in three types, based on the presence or absence of a spring in the rim. Each type is available in several sizes, although all require a prescription. Advantages of diaphragm use include that this method is controlled by the woman herself. This method is not necessarily coital dependent, and insertion and removal can be done privately. Previously some diaphragms were composed of latex, but all of today’s diaphragms are silicon based.

Approximately 12% of typical diaphragm users will have an unintended pregnancy in the first year of use, making the diaphragm more effective than male condoms and all other female barrier methods.[3,26] Effectiveness appears to be inversely related to frequency of intercourse. Studies have shown that among individuals who are consistent diaphragm users, those who have intercourse at least three times weekly are almost three times as likely to have an unintended pregnancy.[26] Male condoms can be used simultaneously with the woman using a diaphragm, enhancing contraceptive effectiveness and adding protection against STI transmission.

The size of the diaphragm must be determined individually for each woman, because the distance from the posterior fornix to the posterior aspect of the symphysis pubis varies among women. Sizing is not specifically associated with parity. **Appendix 16B** describes the procedure for determining the right size of diaphragm for a woman.

Little evidence regarding timing of insertion and removal of diaphragms is available, but the usual instructions state that the diaphragm should be coated with approximately 1 teaspoon of a spermicide inside the dome and rim, inserted less than 3 hours before coitus, and left in place for at least 6 hours after intercourse (so that the spermicide remains effective), but no more than 24 hours.[27] If another act of intercourse occurs, the diaphragm should not be removed, but another application of spermicide is then applied intravaginally.

Side effects of diaphragm use include an increased risk for urinary tract infections as

compared to other contraceptive methods, perhaps due to pressure on the urethra exerted by the diaphragm's rim, causing incomplete bladder emptying, or from the spermicide altering the vaginal flora, which may increase the risk of *Escherichia coli* bacteriuria.[28] If the woman experiences recurrent urinary tract infections, the diaphragm may be too large or the rim too rigid, and refitting is indicated. If refitting does not resolve the problem, the woman can be counseled to select another contraceptive method.

Local irritation from the nonoxynol-9 spermicidal agent used may occur. If the diaphragm has been improperly fitted or is left in place longer than 24 hours after having intercourse, vaginal wall abrasions can occur. When recurrent vaginal or vulvar irritation occurs without evidence of an infection, these symptoms may indicate allergy to the diaphragm itself, especially if it is latex. Although latex diaphragms are no longer being produced, some women may have an older one that is made of latex. In such a case, the woman should be advised to discontinue use or switch to a nonlatex device. In addition, the risk of toxic shock syndrome may increase—though it remains low—if the diaphragm is left in place for more than 24 hours.

Contraindications to use of a diaphragm are the same as those to use of spermicide and are related to the spermicide component of this contraceptive method. Diaphragms are classified into the U.S. MEC for Contraceptive Use Category 3 for women with a history of toxic shock syndrome, because toxic shock syndrome has been associated with use of the device.[2] Occasionally a diaphragm cannot be fitted for a woman who has an anatomic abnormality such as pelvic organ prolapse or vaginal septum. The diaphragm does not protect against STI transmission.

A general consensus exists that a woman should be examined for a refit of a diaphragm if she experiences weight change of more than 15 pounds, has had a second-trimester abortion, or has had vaginal birth within 6 weeks, although these guidelines are empiric and not based on strong evidence.[25] The diaphragm should not be used after birth until uterine involution is complete and the vagina has regained its tone. All women using a diaphragm should be instructed about the symptoms of toxic shock syndrome.

Cervical Cap

The cervical cap is a dome-shaped silicone cap that resembles a sailor's hat (**Figure 16-2**).[30] The concave dome fits snuggly over the cervix and is held in place by the muscular walls of the vagina. The brim is slightly wider on the side that fits into the posterior fornix. The cap has a strap that stretches over the diameter of the dome, which facilitates removal. Spermicide is applied inside the dome, around the brim, and in the groove between the dome and the brim prior to insertion of the device.[29]

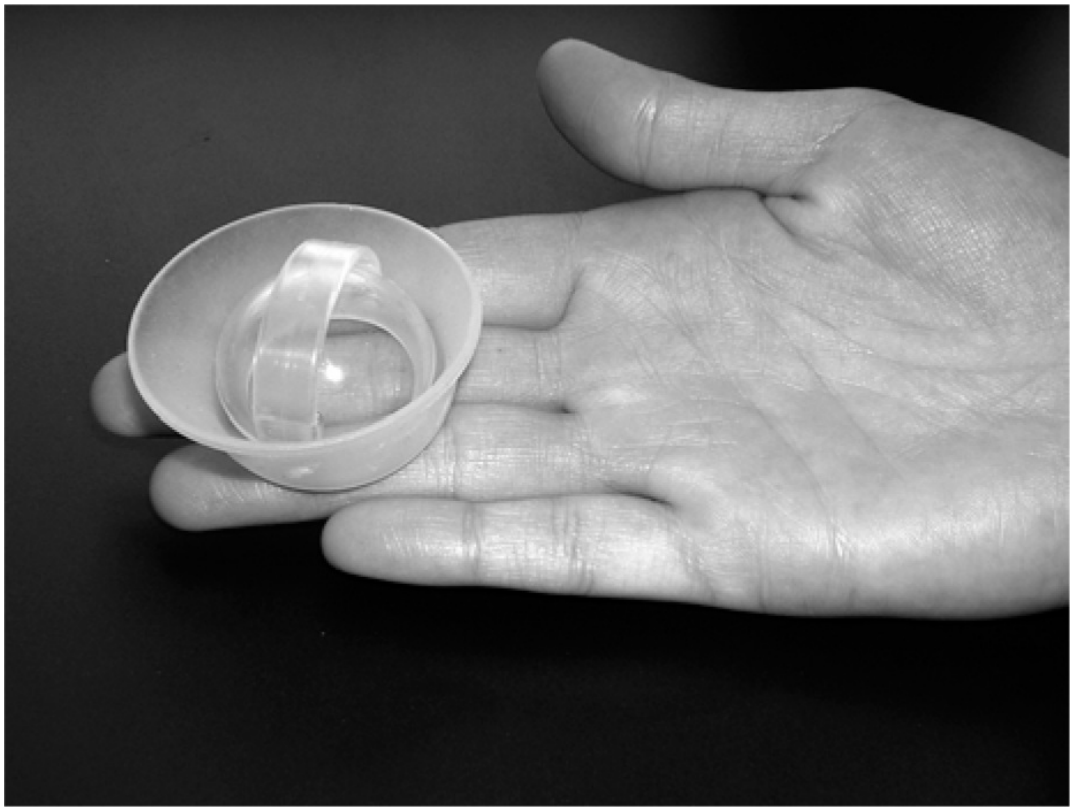

Figure 16-2 Cervical cap (FemCap).

Reproduced with permission from Cervical Barrier Advancement Society and Ibis Reproductive Health.

The only cervical cap currently available in the United States is marketed with the brand name FemCap.[30] Originally approved by the U.S. Food and Drug Administration (FDA) in 2003, it is available in three sizes, with size determined by a woman's pregnancy history: 22 mm if nulligravida, 26 mm if ever pregnant (nullipara), and 30 mm if the woman has had a full-term vaginal birth. A prescription is needed, and the device is available at selected sites or online. The advantage of the cervical cap is that it can be inserted as long as 42 hours before intercourse, thereby avoiding interruption of foreplay; it should be left in situ for 6 hours after intercourse.[29,31] When the cap is inserted more than 1 hour prior to coitus, an application of spermicide should be added without removing the cap.

In the original clinical trial reported to the FDA prior to approval of the originally designed cap, the 6-month effectiveness rate was 77% overall, but 86% for nulliparous women.[29,31] The current FDA-approved FemCap is a different design; only limited data on its effectiveness are available, and it is unclear whether it is as effective or even more effective than the diaphragm.[31]

Contraindications to use of a cervical cap are the same as the contraindications to use of spermicides and diaphragms, with a few additions. Women who have cervical cancer, cervical intraepithelial neoplasia, or a marked abnormally shaped cervix should be advised to use another form of contraception.[29] Using the cervical cap during menstruation may increase the risk of toxic shock syndrome and, therefore, should be avoided.[31] The cap does not protect against STI transmission, so using a male condom in combination with the cap adds this

protection.

While a pelvic examination is not needed to select the correct size, a clinician should insert and remove the device to illustrate proper technique for the woman, and then have the woman perform a return demonstration. **Figure 16-3** illustrates how a woman can insert a cervical cap in a manner similar to inserting a diaphragm (Appendix 16B). The mild suction exerted by the device allows it to fit snugly next to the cervix; it is properly placed when it does not move easily away from the cervix. The cap is most easily inserted before sexual arousal because sexual arousal can cause the cervix to become slightly soft. Removal is accomplished in a manner similar to removing a diaphragm: The woman inserts a clean finger into her vagina, firmly moves the cap off the cervix, and removes it by slipping it down the vagina and forward.

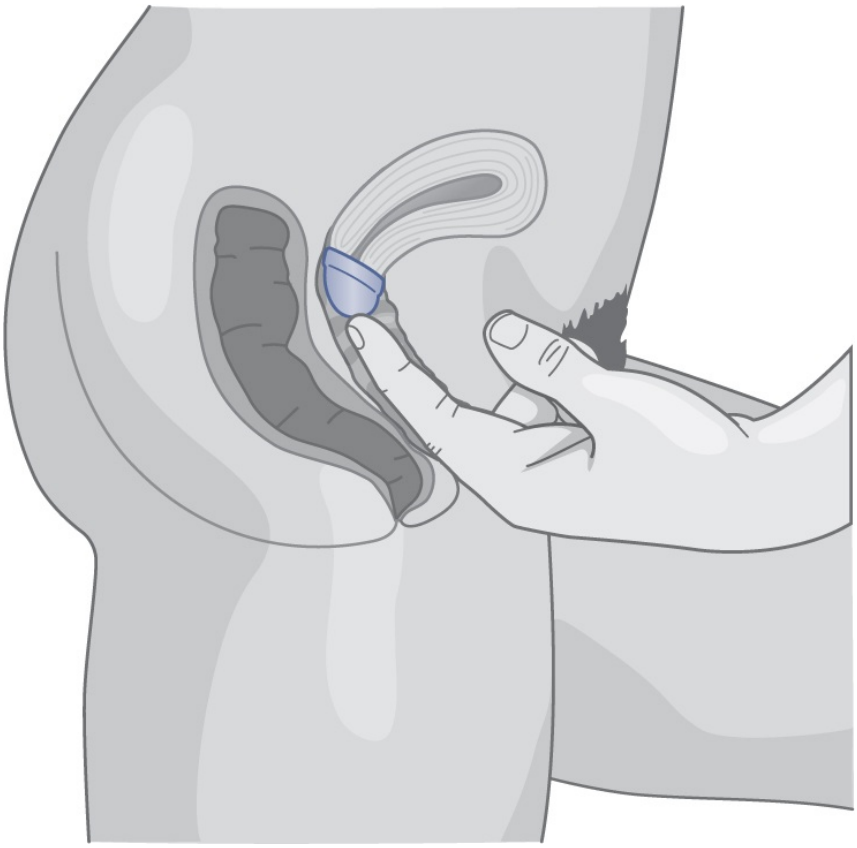

Figure 16-3 Proper insertion of a cervical cap by a woman.

Urinary tract infections occur less frequently in women using the cap compared to the diaphragm, and vaginitis at similar rates to those experienced by diaphragm users.[29] The cap should be replaced after each year of use.[29] The size should not need to be changed unless the woman's history changes—for example, she was nulligravid when the size was selected, but since last using it she has experienced a miscarriage, abortion, or given birth.

Male Condom

Contraceptives for men have long been a subject of research.[32],[33] Even so, only two methods are currently available: a barrier method, the male condom, and coitus interruptus. Male

condoms usually are sold over the counter and packaged inside a foil or plastic wrapper.

Many male condoms available in the United States are made of natural rubber latex. Condoms composed of polyurethane, a synthetic material, provide an option for individuals who are allergic to latex. Compared to latex condoms, the polyurethane condoms are odorless and colorless, fit more loosely, have a longer shelf life, and can be used with any lubricant.[34] Latex condoms are effective in preventing transmission of HIV and STIs; however, the effectiveness of nonlatex condoms in protection against HIV and STIs has not been established.[34]

Condoms come in a variety of colors, textures, transparencies, sizes, and shapes, although polyurethane condoms are more expensive than latex ones. Both types can be used either dry or with lubricants. Oil-based lubricants such as petroleum jelly or massage oils should not be used as they can cause breakage of the latex. Condoms used in conjunction with spermicides have enhanced effectiveness compared to those used either dry or with nonspermicidal lubricants. However, the spermicide should be used judiciously, as applying too much of the agent can cause slippage of the condom.

Male condoms remain the most widely available and commonly used barrier method in the United States. Approximately 16% of women using a contraceptive have reported that their male partners use condoms, making it a popular method for preventing pregnancy.[1,6] When used correctly and consistently with each coitus, during the first year of use among typical users, approximately 18% of couples would be expected to have an unintended pregnancy.[3] Most condom failures result from breakage or slippage during intercourse or while removing the condom. In a meta-analysis of 11 randomized trials that compared latex and synthetic condoms, failure rates were comparable for all latex and synthetic condoms, although most synthetic condoms had higher reported rates of breakage and slippage.[34]

Condoms can cause vaginal irritation or discomfort, with synthetic condoms reported to cause less vaginal irritation and discomfort than the latex versions.[35] Disadvantages include perceived reduced sensitivity and lack of spontaneity during sexual activity, especially during foreplay, when the condom should be worn, as well as latex allergy of either partner. Some men have difficulty maintaining erections while the condom is on, and some individuals may be embarrassed to use a condom or ask that one be used. Lastly, male condoms are male controlled. Women in relationships where they cannot negotiate condom use by their partner may be exposed to risks of unwanted pregnancy and/or STIs.

Condoms can be used as an adjunct to other contraceptives. For example, if a woman using combined oral contraceptives misses one or more pills, using a condom for the duration of the pill cycle provides protection from pregnancy. Dual use of condoms with another contraceptive should also be advocated for women with multiple or new partners to reduce risk of STIs, and for women seeking added protection against unintended pregnancy.[36]

Reviewing correct use is best done by demonstration, using a penile model or a substitute such as a banana. Basic instructions include the description that the male condom is a strong, thin, elastic sheath that is applied to the tip of an erect penis and unrolled to catch the seminal fluid during ejaculation and prevent it from being deposited in the vagina. Some space should be left in the tip of the condom to have a repository for semen; otherwise, the fluid can be

forced outside the base. In the event of condom breakage or slippage, emergency contraception is available as an option, as described in the *Family Planning* chapter.

Female Condom

The female condom is a soft, loosely fitting, thin sheath (**Figure 16-4**).[37] It has two flexible rings—one on the closed end of the sheath that is inserted into the vagina, and a larger ring on the open end that remains outside the vagina and covers the introitus. The female condom is available in only one size and does not need to be fitted by a healthcare professional.[38] Although the product may be prelubricated with a silicone-based, nonspermicidal agent, additional lubricants or spermicidal preparations may be used with it. Each condom is intended for one-time use. Current female condoms are made of nitrile, latex, or silicon to diminish the issue of crinkling sound with the previous generation of polyurethane-based female condoms.

Figure 16-4 Female condom.

Reproduced with permission from Cervical Barrier Advancement Society and Ibis Reproductive Health.

The effectiveness of the female condom is generally considered slightly less than that of male condoms, with approximately 79% of users in the first year of typical use avoiding unintended pregnancy.[3] The discrepancy in failure rates between perfect use and typical use may reflect problems mastering insertion as well as inconsistent use.[39] The female condom protects as effectively as male condoms against STIs and HIV transmission when used correctly, in part because the external portion provides a barrier between the labia and the

base of the penis during intercourse.[3,28]

The female condom can be inserted as long as 8 hours before sexual intercourse, but must be in place before the penis enters the vagina. Some couples prefer the freedom of movement and looseness of the female condom compared to the male condom. Some women have reported that the edge of the outer ring provides clitoral stimulation. Both partners may experience uncomfortable sensations, including feeling the inner ring, having the condom adhere to the penis, and feeling the outer ring press against the vulva during intercourse. Checking for correct placement and adding more lubricant can alleviate these problems. Learning the correct steps for insertion may be challenging, but can be achieved with close instruction. **Table 16-3** reviews the steps involved in correct use of the female condom. Most women need to practice two to three times to successfully place the condom.[39]

Table 16-3	General Instructions for Use of Female Condom
Insertion	
Lubricate the outside of the closed end with spermicide.	
Relax in a comfortable position (e.g., lie down, squat, stand with one foot on a chair).	
Squeeze the sides of the inner ring at the closed end together.	
Insert the condom deep in the vagina, in similar fashion as inserting a tampon.	
Slip the inner ring into the vagina as far as possible (until it reaches the cervix).	
Allow the outer ring to hang approximately 1 inch (2.5 cm) outside the vagina.	
Removal	
Squeeze and twist the outer ring to keep semen inside the pouch.	
Gently remove the condom directly out of the vagina.	
Discard the condom, but do not flush it down the toilet.	

The female condom usually moves from side to side in the vagina during vaginal intercourse. However, if the penis slips between the condom and the walls of the vagina, or if the outer ring is pushed into the vagina, the woman is at risk for contraception failure. As long as the male has not ejaculated, the condom can be removed, repositioned, and additional spermicide added. The female condom also has been used by some individuals for anal intercourse, but this use is not FDA approved. In the event of condom breakage or slippage, emergency contraception is available as an option, as described in the *Family Planning* chapter. The female condom does protect against STIs.

The Intrauterine Device

Several synonyms are used to describe IUDs, including intrauterine contraceptives (IUCs), intrauterine contraceptive devices (IUCDs), and intrauterine system (IUS). For consistency, the term IUD is used throughout this chapter. IUDs and contraceptive implants are the two types of long-acting reversible contraceptive (LARC) devices available in the United States. IUDs are the most commonly used reversible contraceptive globally, although in the United States among women using a birth control method, more continue to choose oral contraceptives.[40]

Rates of IUD use were increasing in the United States during the 1970s, but decreased significantly following highly publicized pelvic inflammatory disease (PID) episodes linked to the Dalkon Shield before this device's eventual removal from the market.[41] Thus, the current generation of reproductive-age women has been underexposed to IUDs as a method of contraception. Multiple factors have contributed to the lower prevalence of IUD use in the United States, including a lack of widespread marketing, especially compared to oral contraceptives; common misconceptions about IUDs' mechanism of action; misinformation about associated risks; and a history of negative publicity. Recent surveys of contraceptive preference, however, indicate that IUDs are increasing in favor among women of various age groups, perhaps indicating a resurgence of the method's acceptability in the United States.[3,6]

IUDs have been found to be among the most effective reversible forms of contraception. In addition to their effectiveness, an emerging body of research suggests that these methods may provide protection against cervical cancer.[42] Additional study needs to be conducted in the area to confirm this benefit.

Types of Intrauterine Devices

IUDs are classified as either hormonal or nonhormonal. Two types of T-shaped IUDs are available in the United States: one impregnated with copper (Copper T 380A [ParaGard]), and the other impregnated with levonorgestrel (levonorgestrel-releasing intrauterine system [LNG-IUS or LNG-IUD]). More commonalities exist for the two types than differences. Therefore, this chapter presents an overview of both types of IUDs and specific information about the nonhormonal copper IUD. Use of the copper IUD for emergency contraception is described in the *Family Planning* chapter. Information specific to the LNG-IUD is addressed in the *Hormonal Contraception* chapter.

Mechanism of Action of Intrauterine Devices

The primary mechanism of action of both types of IUDs is prevention of fertilization via inhibition of sperm mobilization and sperm viability as well as changes in transport speed of the ovum in the fallopian tube transport.[21] The two types of IUD have additional effects based on their major components.

Contraindications to Use of Intrauterine Devices

Contraindications to any IUD use and those specific for the copper containing IUD are listed in **Table 16-4**.[2] Contraindications for use of the LNG-IUD are listed in the *Hormonal Contraception* chapter. Any abnormal uterine bleeding should be evaluated for pathologic causes prior to IUD insertion. An IUD should not be used if the woman has a known hypersensitivity to any device component. The copper IUD is contraindicated for women with Wilson's disease—a condition that causes impairment of copper metabolism.

Table 16-4 **Contraindications for Use of Any Intrauterine Device: U.S. Medical Eligibility Criteria for Contraceptive Use Categories 3 or 4[a]**

Contraindications	Medical Eligibility Criteria for Contraceptive Use Category
Any IUD	
Cervical cancer awaiting treatment	4 for initiation; 2 for continuation
Distorted uterine cavity	4
Endometrial cancer	4 for initiation; 2 for continuation
Gestational trophoblastic disease with decreasing or undetectable beta-hCG levels	3
Gestational trophoblastic disease with persistently elevated beta-hCG levels or malignant disease	4
Immediately post septic abortion	4
Pelvic inflammatory disease	4
Pelvic tuberculosis	4 for initiation; 3 for continuation
Pregnancy	4
Puerperal sepsis	4
Sexually transmitted infections	
Chlamydia	4 for initiation; 2 for continuation
Gonorrhea	4 for initiation; 2 for continuation
Purulent cervicitis	4 for initiation; 2 for continuation
Increased risk for STI	3 if a woman has a very high risk of chlamydia or gonorrhea; otherwise 2
Solid organ transplant	3 for initiation; 2 for continuation
Unexplained vaginal bleeding that is suspicious for a serious condition	4
Copper IUD	
Allergy to copper	Listed in product label
Use for emergency contraception in case of rape	3 if high risk for STI; 1 if low risk for STI
Systemic lupus erythematosus with severe thrombocytopenia	3 for initiation; 2 for continuation
Wilson's disease	Listed in product label

Abbreviations: hCG, human chorionic gonadotropin; IUD, intrauterine device; STI, sexually transmitted infection.

[a] U.S. Medical Eligibility Criteria for Contraceptive Use Categories: Category 1: a condition for which there is no restriction; Category 2: a condition for which the advantages of using the method generally outweigh the theoretical or proven risks; Category 3: a condition for which the theoretical or proven risks usually outweigh the advantages of using the method; Category 4: a condition that represents an unacceptable health risk if the contraceptive method is used.

Modified with permission from Curtis KM, Tepper NK, Jatlaoui TC, et al. U.S. Medical Eligibility Criteria for Contraceptive Use, 2016. *MMWR*. 2016;65(3):1-106.[2]

The procedure for inserting and removing an IUD is described in **Appendix 16C**. This appendix includes discussion of timing and pre-insertion medication and side effects associated with insertion for both types of IUDs.

Adverse Effects Associated with Intrauterine Devices

Women should be counseled that use of IUDs may be associated with changes in menstrual bleeding patterns. The copper IUD often increases the amount of menstrual bleeding, whereas the LNG-IUD often decreases the amount of menstrual bleeding. Some inherent risks are related to the minimally invasive procedures of IUD insertion and removal. Bleeding, infection, perforation of the uterus, and pain can occur, although serious complications are rare. **Table 16-5** lists effects that should be considered for follow-up visits by using the mnemonic "PAINS."

Table 16-5 PAINS Mnemonic for Adverse Effects of Intrauterine Devices

Period	Amenorrhea, especially sudden onset; with the copper IUD, may be associated with pregnancy. Light bleeding and amenorrhea are side effects of LNG-IUDs.
Abdominal pain	General abdominal pain can suggest an ectopic pregnancy, sexually transmitted infection, or intolerance of copper.
Infection	Vaginal discharge, pelvic pain, history of exposure, or any suspicion of sexually transmitted infections.
Not feeling well	Malaise, fever, nausea, and vomiting suggesting infection or sepsis.
Strings	Strings or threads of the IUD changing in length or missing entirely.

Abbreviations: IUD, intrauterine device; LNG-IUD, levonorgestrel-releasing intrauterine device.

Intrauterine Device Expulsion

Expulsion rates are generally low (2–10%) following insertion of an IUD in a nonpregnant woman. Expulsion is most likely to occur during the first-year post insertion. Expulsion rates among devices are relatively similar, and adolescents were more likely to experience expulsion regardless of parity.[43] The rate of expulsion in the immediate postpartum period is typically higher than at other times, but women who receive immediate insertion of an IUD following childbirth are more likely to demonstrate continued use as compared to women who defer IUD insertion until a postpartum office visit.[44] Some researchers suggest that insertion after the 14th postpartum day is associated with an expulsion rate equal to that of insertion at 6 weeks or later.[45]

Encouraging regular string or thread checks can help detect expulsion. Education should include signs and symptoms of expulsion, including detection of the device at the os, pain and cramping, abnormal uterine bleeding, discharge, or fever.

Missing Intrauterine Device Strings

A clinician's inability to find IUD strings during an examination can be attributed to four possible causes: uterine perforation that leaves the IUD in the abdomen, spontaneous expulsion, strings cut too short, or, rarely, pregnancy in the second or third trimester when the uterus has enlarged and the device risen in the uterus.[46] Pregnancy should be considered whenever strings are not visible. Often strings have simply receded into the cervix, out of view, or the threads have curled behind the cervix and become difficult to palpate. Gentle cervical exploration with a cytobrush or cotton swab may be able to guide and straighten the strings—a technique colloquially termed "fishing" for the strings. Care should be taken not to pull on the threads and dislodge the device. If the strings are not apparent to the clinician during a clinical examination, it is possible that the device was spontaneously expelled and the woman is unaware of its loss. An ultrasound can identify whether the IUD is in situ. **Figure 16-5** provides an algorithm for managing the care of a woman with missing IUD strings.

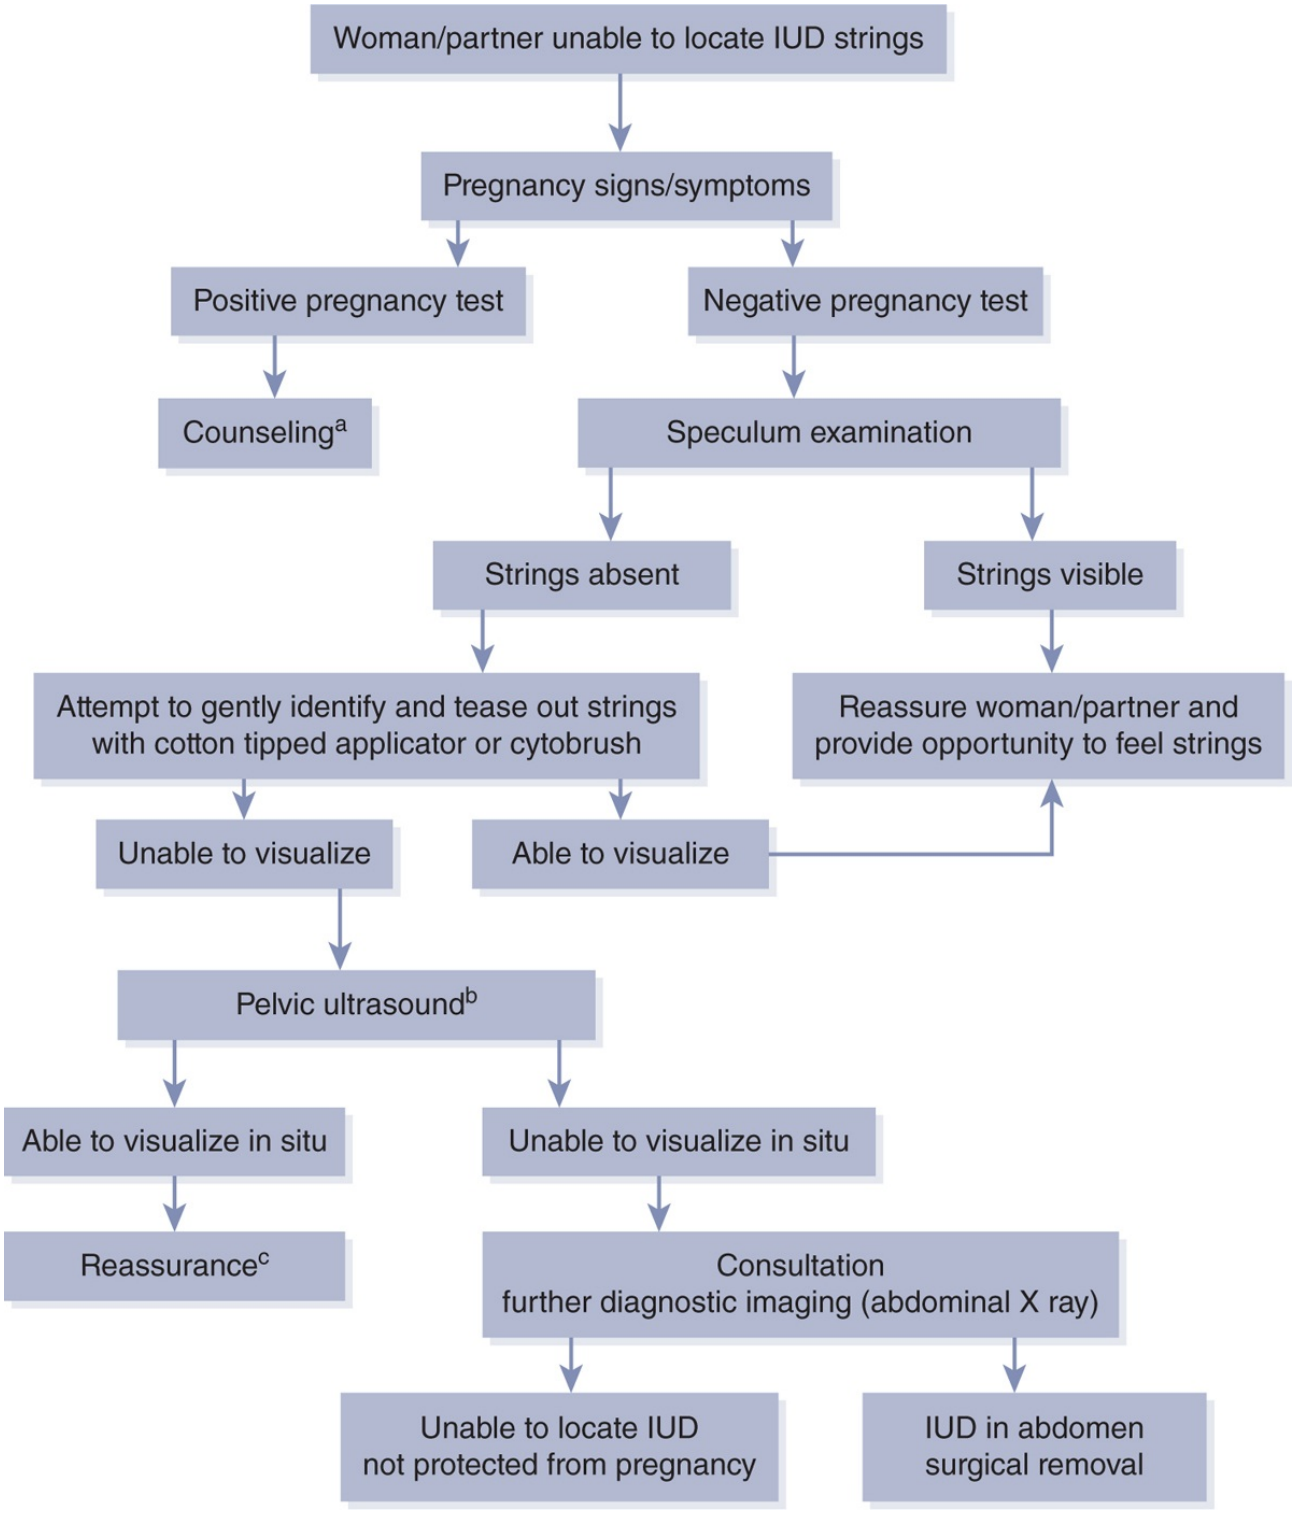

Figure 16-5 Algorithm for management of a woman with missing intrauterine device strings.

Abbreviation: IUD, intrauterine device.

[a] Counseling is required for shared decision making with risks and benefits outlined.

[b] Pelvic ultrasound may be ordered, or care may be transferred to a specialist based on practice policies at this point.

[c] Reassurance can be given that the IUD is providing protection from pregnancy, but some women may request a removal and replacement for regular reassurance by feeling strings.

In the unusual event of the IUD being appropriately positioned in the fundus but the threads are not palpable, the woman needs to make an informed decision regarding whether she wishes to have the IUD removed and replaced or to continue as is. Contraceptive effectiveness is not dependent upon the threads extending from the uterus into the vagina. If the ultrasound reveals that the IUD either is dislodged and no longer in the expected placement (e.g., in a fallopian tube) or has perforated the uterus and entered the abdomen, immediate referral is indicated.

Pregnancy with an Intrauterine Device in Situ

A woman who becomes pregnant with an IUD in place should be informed of the risks involved if the pregnancy is continued—namely, chorioamnionitis, spontaneous abortion, septic abortion, and preterm birth.[47] Although the risk of pregnancy is small with an IUD in place, women who become pregnant with an IUD in place should also be evaluated for ectopic pregnancy, as the risk of any pregnancy being ectopic is higher with an IUD in situ.

If pregnancy is confirmed, an ultrasound reveals the placement of the IUD, and the IUD strings are visible, the IUD should be removed to decrease the risk of spontaneous abortion. The incidence of spontaneous abortion is slightly higher if the IUD remains than if the device is removed.[47,48] This benefit is most apparent when the IUD is removed during the first 12 weeks' gestation. Removing the IUD for a woman who wishes to terminate the pregnancy reduces her risk of septic abortion.[48] The IUD is removed in the usual fashion as described in Appendix 16C. Often a woman who has an IUD in situ during pregnancy is referred to a physician, although midwives can accomplish the procedure as long as the woman understands the risks and benefits, she is in the first trimester of pregnancy, and the threads are visible.

When pregnancy is confirmed and the strings of the IUD are not visible, ultrasound may reveal that the device has been covertly expelled, such as with a heavy menses; the woman may not have been aware of its loss. If the ultrasound reveals the IUD placed abnormally (e.g., within a fallopian tube) or in the uterus but without strings visible the woman should be referred to a specialist.

Copper T 380A (ParaGard)

The only nonhormonal IUD currently available in the United States, known as ParaGard, is composed of polyethylene and an inert plastic material that is flexible, is non-inflammatory, and resumes its original shape easily after being flexed for insertion (**Figure 16-6**). The vertical stem of the polyethylene body is wrapped with 176 mg of copper wire, while each of its horizontal arms has a 68.7-mg copper collar attached.[49] The copper components of ParaGard release ions into the endometrial cavity that affect tubal and endometrial fluids, and subsequently incapacitate sperm. The ParaGard IUD has a length of plastic thread attached to the lower segment that extends through the cervix into the vagina when the IUD is in place. The string facilitates removal and enables the midwife and the woman to confirm the presence of the device. Embedded within this IUD's polyethylene body is a small amount of barium sulfate, which allows the device to be localized with standard X-ray imaging. ParaGard provides contraception for as long as 10 years after insertion.

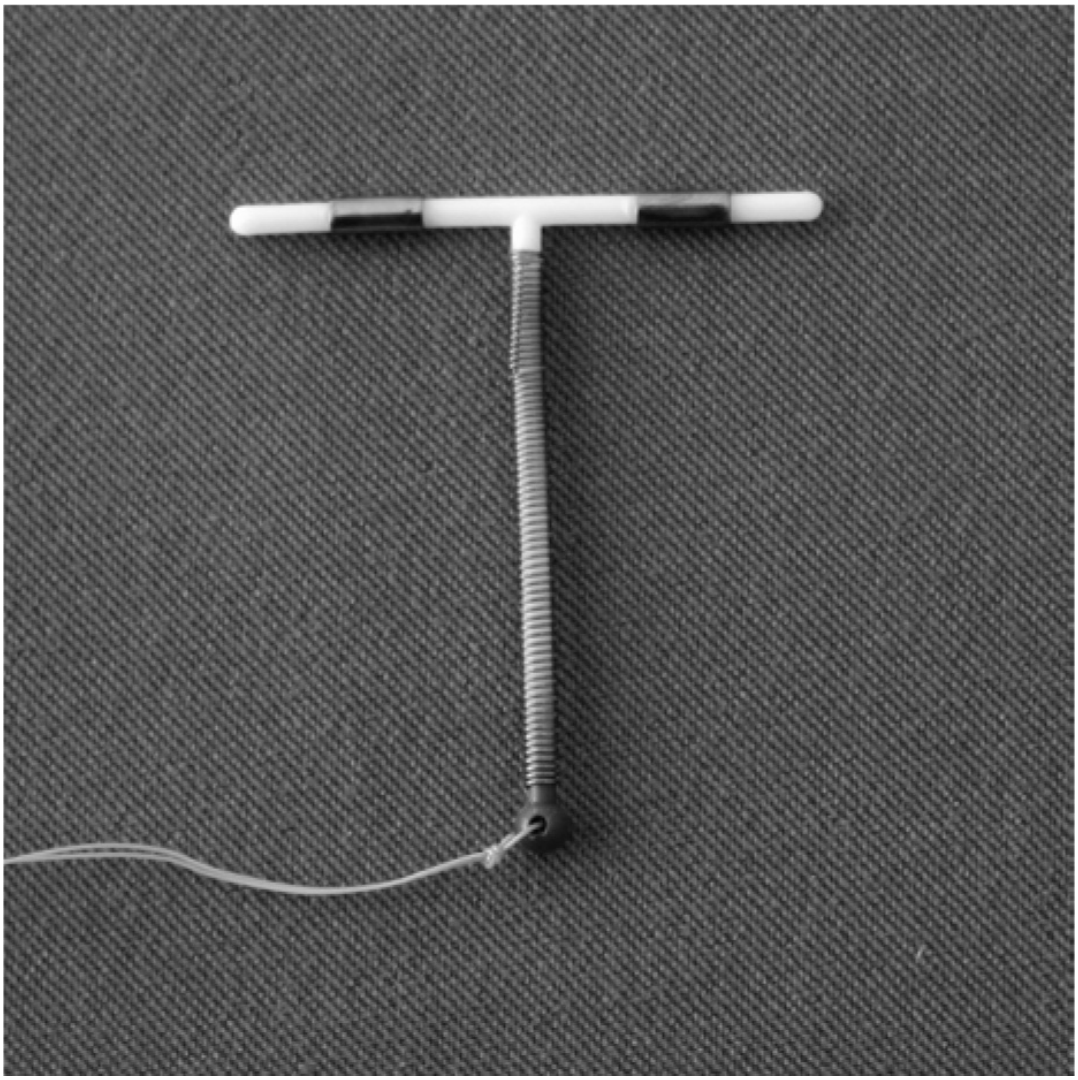

Figure 16-6 ParaGard intrauterine device.

© Jones and Bartlett Publishers. Photographed by Kimberly Potvin.

The effectiveness rate for ParaGard is high, with fewer than 1 in 100 users experiencing an unintended pregnancy in the first year of use.[2] The copper in the IUD alters sperm tubal transport, has toxic effects on the ovum, and impairs normal sperm activity by slowing motility, reducing sperm capacitation, and increasing sperm destruction. In addition, the copper creates a localized reaction[50] in the endometrial tissue that renders the uterine endometrium unfavorable for implantation.[51]

The copper IUD is associated with menstrual changes such as 1 to 3 more days of bleeding per cycle, increased severity of dysmenorrhea, and potential increase in blood loss, which can exacerbate iron-deficiency anemia. Consequently, ParaGard is not a good choice of contraception for women who have heavy menstrual bleeding (menorrhagia). Copper-bearing IUDs appear to convey protection against endometrial cancer (odds ratio [OR], 0.54; 95% confidence interval [CI], 0.47–0.63), although the mechanism of action has not been elucidated.[52]

Use of a copper IUD is noncoital dependent, does not require further consideration of cost

after the initial insertion, and is effective for as long as 10 years. Some women find the IUD-associated side effects such as bleeding too discomfiting, and others do not like the idea of having a foreign object inside their body. When these concerns are not a consideration and for women who do not desire any hormones for contraception, the copper-containing IUD may be a good choice.

Permanent Contraception: Sterilization

Sterilization is the surgical interruption or closure of pathways for sperm or ova to unite, which prevents fertilization. Since the 1970s, female sterilization has become an increasingly available and acceptable contraceptive choice.[53] Sterilization, an elective procedure, is considered a safe, highly effective, and permanent form of contraception. Overall, both female and male sterilization (vasectomy) are more than 99% effective in preventing pregnancy.[2]

Methods of female sterilization include: (1) laparoscopy tubal ligation, (2) tubal interruption, (3) hysteroscopy (transcervical) sterilization, and (4) the chemical agent, quinacrine (Atabrine) that is not available in the United States. Male sterilization, or vasectomy, is both a safer and simpler procedure compared to female sterilization. Vasectomy is also, approximately half the cost of female sterilization, although female sterilization is more common in the United States.[54] In fact, in the United States, female sterilization is one of the most frequently performed surgeries for a woman. The term “tying tubes” is a common phrase, but this wording should be avoided as it may incorrectly connote that the fallopian tubes could later be untied. Fallopian tubes may be surgically cut and ligated with or without a section of the tube being removed, mechanically blocked using clips or rings, electrically coagulated, or blocked by a fibrotic reaction induced by chemicals or micro-inserts. Reversal of a tubal ligation is actually a complicated and costly procedure with a high failure rate. Female sterilization procedures can be performed soon after a vaginal birth (postpartum sterilization), in conjunction with a cesarean section, immediately following an uncomplicated first-trimester abortion, or independent of pregnancy (interval sterilization).

Female Surgical Sterilization

There are two common approaches to female surgical sterilization: laparoscopy, or transcervical. Female sterilization may also be accomplished via a mini-laparotomy but this technique is not commonly used in the United States. Sterilization via laparoscopy is the standard approach for women who desire postpartum sterilization. Women who desire interval sterilization may chose laparoscopy or hysteroscopy tubal interruption

Only 0.5% of women experience an unintended pregnancy within the first year following surgical sterilization, which translates into a 99.5% effectiveness rate.[2] This number includes those women with an unsuspected pregnancy at the time when the procedure is performed. Failure can also happen many years after the procedure is performed. Because spontaneous pregnancy after tubal ligation is rare, the overall risk of ectopic pregnancy is lower in women who undergo surgical sterilization than in the general population. If pregnancy does occur after tubal sterilization, approximately one-third are ectopic.[53]

Overall, there are few, if any, contraindications to sterilization for the individual who desires this form of contraception. Sterilization is a surgical procedure that requires the surgeon’s consent to perform the procedure. It has been reported that some surgeons have personal requirements of age or parity prior to offering sterilization to women. Requirements based on age or nulliparity are not justified.[53] Conversely, reports of specific requirements for male sterilization have not been identified.

Counseling prior to informed consent includes a review of alternatives, risks associated with the procedure and use of anesthesia, permanency of contraception, and the risk of ectopic pregnancy should a pregnancy occur after the procedure. Women also should be informed that sterilization does not prevent transmission of STIs or HIV.

Sterilization is not coital dependent, nor does it require partner agreement or purchasing of supplies. Some studies show a positive effect on sexuality, which is possibly related to reduced worry about unintended pregnancy.[54] Complications are those associated with any surgical procedure.

Regret that a sterilization procedure was performed has been reported.[55] Various studies indicate that the percentage of women who regret their decision to undergo sterilization ranges from 1% to slightly less than 30%.[2,55,56] Higher rates of regret are found in women who were younger than age 30 years at the time of sterilization, are in an unstable relationship, have experienced the death of a child, and are of low parity.[55,56]

Historically women of color were sterilized without consent in some locales. Today, black women are more likely to undergo sterilization than are white women even when confounding factors such as parity and age are controlled for. Although the reasons for this difference have not been fully elucidated, there is some thought that black, Hispanic, and Native American women may be more likely to receive counseling and education about sterilization. Despite a lack of full understanding of these statistics, it is a reminder that healthcare provider overt or implicit bias must not be present in contraceptive counseling.[56]

The midwife must be aware of applicable federal and state regulations about sterilization. Because of abuses related to forced sterilization in the past, strict criteria must be met to verify informed consent, including the requirement that the consenting woman is an adult. Consent is to be obtained within a specified time period (usually 30 days) before giving birth, and the time interval may differ by state, facility, and payer.[53] As with any shared decision-making discussion, the woman should receive information that is at the appropriate health literacy level, in her native language, and she should be informed that she can decline the sterilization even after the consent form has been signed.

Reversal of sterilization is expensive, requiring either costly assisted reproductive technology or highly technical microsurgery, and results cannot be guaranteed. Successful pregnancy following sterilization reversal varies with the type of tubal occlusive method used and with the age of the woman. Rates of successful reanastomosis following reversal procedures range from 30% to 70%. The long-term effects of tubal sterilization on menstrual pattern (post-tubal ligation syndrome) appear to be negligible. Most recent studies have not found any difference in menstrual patterns between women before and after sterilization.[53]

Laparoscopy Sterilization

Early studies conducted when tubal occlusion techniques were relatively new found electrosurgery and micro-clips were associated with higher pregnancy rates compared to tubal ligation. However, recent studies have found all the techniques for occluding or cutting the Fallopian tube have similar effectiveness. Thus, the technique chosen is based on the surgeon’s preference and skill.

Hysteroscopic Sterilization (Transcervical Sterilization)

The transcervical female sterilization method involves gaining access to the fallopian tubes via hysteroscopy that is introduced through the cervix. This method can be accomplished on an outpatient basis under local anesthesia.[53,57] The only currently available transcervical method is marketed under the brand name Essure. The Essure system consists of stainless steel coils that are soft and flexible because they are wrapped in polyethylene terephthalate covered with a nickel–titanium alloy. The small metal springs are placed into the proximal end of each fallopian tube. Upon release, they expand and anchor to the tube, creating scar tissue.[53] Thus, the mechanism of action involves irritation and growth of new tissue that results in permanent occlusion of the fallopian tubes as the tubes respond to the polyester fibers within the micro-inserts. Tubal occlusion occurs approximately 3 months after the procedure is performed. The tissue response has been found to be localized to the insert.

Sterilization does not occur immediately after the procedure, so women need to use additional contraception for 3 months until permanent tubal occlusion is verified by hysterosalpingogram. If this confirmation hysterosalpingogram reveals there is still tubal patency, the woman is instructed to use an alternative contraceptive method. Other methods for verification of tubal occlusion have been suggested, such as ultrasound, but the gold standard for confirmation remains the hysterosalpingogram.

Long-term data on safety, effectiveness, and pregnancy rates for Essure remain controversial, as many of the existing studies were funded by the manufacturer.[57] U.S. and worldwide literature indicates that this sterilization technique has a greater than 98% effectiveness.[57] Other clinical trials and reviews have reported unintended pregnancies that appear to be related to failure to strictly comply with the follow-up protocol, failure to perform a urinary pregnancy test on the day of the procedure, or failure to instruct the woman to return for the hysterosalpingogram follow-up visit to confirm bilateral occlusion via the injection of radiopaque contrast material into the uterus to detect fallopian tube patency.[57] Studies have underscored the importance of the 3-month follow-up, as some women may not develop tubal occlusion until later. In addition, expulsion of the micro-inserts has been observed and can lead to contraceptive failure.[58]

In 2017, the FDA mandated a black box warning for Essure based on reports of adverse effects such as chronic pelvic pain, irregular bleeding, allergic reactions, and autoimmune-like reactions.[53,58-60] Additional study is warranted regarding these reports. Because the Essure coil contains nickel, a known hypersensitivity to nickel confirmed by skin test is a contraindication to placement of the micro-inserts.[58]

Transcervical sterilization may be an option for women who have comorbidities, such as obesity, cardiorespiratory disease, or complex abdominal issues that make other forms of permanent sterilization difficult to accomplish or contraindicated.[59] Like all permanent sterilization options, this procedure is not coital dependent, does not require partner agreement, and avoids the need to buy further supplies, enhancing the convenience factor.

Female Chemical Sterilization

Quinacrine, which was originally approved as an antimalarial drug, is the best-studied chemical agent used for female sterilization. This agent is most commonly used in low-resource countries because it is inexpensive and does not require expensive equipment for placement. However, particularly because of an association with cancer, the World Health Organization (WHO) recommended that until totality of the safety, effectiveness, and epidemiologic data has been reviewed, quinacrine should not be used for nonsurgical sterilization in women.[61] Quinacrine pellets are not currently available in the United States for sterilization.

Male Surgical Sterilization (Vasectomy)

Vasectomy is one of the few contraceptive options currently available for men. Sterilization is achieved by cutting or occluding the vas deferens so that sperm can no longer pass out of the body in the ejaculate. This procedure can be done in an outpatient setting under local anesthetic by a trained provider. Advantages of this method include the short procedure time and the reduced risk of hematoma, infection, and postoperative discomfort when compared to female tubal ligation.[62]

Vasectomy is a highly effective and relatively low-cost permanent method of sterilization with a low morbidity rate and an extremely low mortality rate. The incidence of pregnancy 5 years after the procedure was performed is less than 1%.[2] Vasectomy is not immediately effective, however: It may take 12 weeks or more, or between 12 and 20 ejaculations, before the ejaculate is sperm free. Alternative contraception needs to be used until azoospermia is confirmed.

Individuals should be informed that recanalization does occur, albeit infrequently. Regret about undergoing a vasectomy has been reported among approximately 5% of men who have the procedure done.[62] The majority of men who report regret had the procedure when they were younger than age 30 years, were in an unstable marriage, had no or very young children, or made the decision to have a vasectomy during a time of financial crisis or for reasons related to a pregnancy.[62]

Conclusion

This chapter reviewed currently available nonhormonal methods of contraception for both women and men in the United States. Options for contraception change frequently, as do aspects of a woman's life; therefore, midwives need to remain informed of the latest options so that the persons for whom they provide care can engage in meaningful shared decision making. Each individual has individual needs and a different lifestyle, which make decision making unique. For many, nonhormonal methods can provide the primary or secondary contraceptive method that they desire.

Fertility Awareness Methods

MARY C. BRUCKER

© hakkiarslan/iStock/Getty Images Plus/Getty

Although fewer than 1% of women who use contraception in the United States employ fertility awareness methods, in some areas of the world these methods are the predominant form of birth control.[1,2] Some reasons that may account for the limited use of these strategies in the United States include the complexity of the methods, lack of available education about fertility awareness methods, and personal beliefs of consumers and providers that these methods are not effective.[3]

Formal education programs exist for both clinicians and couples. Many midwives complete certification courses for a particular type of fertility awareness method, whereas others prefer to refer interested individuals to a specialist in the area. This appendix provides general information about fertility awareness methods and discusses the five most common types.

Assumptions

Fertility awareness methods are based on regularly occurring biologic events during the menstrual cycle that should be understood by the clinician and the consumer:

1. Ovulation occurs once, approximately 14 days before menses begins. It is important to note that 14 days before menses begins is more reliable than 14 days after the last menstrual period starts because the secretory phase of the menstrual cycle is generally more regular than the follicular phase.
2. The maximum lifespan of the ovum is 12 to 24 hours.[4]
3. Sperm are viable after ejaculation for approximately 3 to 5 days.
4. The most likely time for pregnancy to occur is during the fertile window, which spans from approximately 5 days prior to ovulation until the day after ovulation, for a total of 6 days each month.[5]

Considerations for Use

Table 16A-1 lists the main criteria that a couple should consider before adopting a fertility awareness method for contraception. Although there are no devices required, a strong dedication to consistently and correctly using the fertility awareness method chosen is needed.

Table 16A-1	Considerations for Use of Fertility Awareness Methods
Commitment by both sexual partners to consistently use the method month after month	
Comfort in observing for signs of fertility, including personal touching	
Commitment to recognize and document even subtle signs of fertility	
Ability to practice abstinence for at least one month, during which time baseline signs of fertility are observed and documented before initiating the method	

Contraindications

Relative contraindications to fertility awareness methods include conditions that result in irregular menstrual cycles, including recent childbirth, onset of menarche, perimenopause, breastfeeding, frequent anovulatory cycles, and recent discontinuation of hormonal contraceptives. Women with the following conditions also may have difficulty using fertility awareness methods: persistent vaginitis or other infections that may disrupt signs of cervical changes (for some methods); not being comfortable examining cervical mucus (for some methods); intermenstrual bleeding; and inability to correctly interpret the signs of fertility.

Types of Fertility Awareness Methods

Currently, several fertility awareness methods are in common use. **Table 16A-2** summarizes the majority of these methods using available data.[5-8] Fertility awareness methods can be generally categorized as either calendar methods or ovulation methods. Both are discussed in this section. For methods that are considered proprietary, their developers usually charge and/or restrict use of their educational materials, including provider and consumer charts, to maintain integrity and accuracy. Many of the proprietary organizations also have educational programs for accreditation or certification.

Table 16A-2 **Description, Observations, Fertile Day, and Estimated Effectiveness of Selected Fertility Awareness–Based Methods**

Method	Signs or Symptoms Used by Method	Observations	Days to Avoid Unprotected Intercourse	Efficacy, First Year of Typical Use	Unintended Pregnancies, First Year of Use with Perfect Use[a]
Calendar	Day of cycle	Record cycle lengths for 6–12 cycles Identify shortest and longest cycles Shortest number of cycle days minus 18 = beginning of fertile window Longest number of cycle days minus 11 = end of fertile window	Days identified as fertile by calculations (repeat calculations every cycle) Total: Depends on cycle length variability	87%	3–5
Standard Days	Day of cycle	Track cycle days beginning with first day of menses Note days 8–19 of cycle	Days 8–19 of cycle Total: 12 days per cycle	88%	5
Ovulation	Cervical secretions	Monitor cervical secretions daily Assess quality and quantity of secretions Record data	Menses Preovulatory days following days with intercourse All days with fertile-type secretions Until 4 days past "peak" day Total: Approximately 14–16 days each cycle	80%	3–5
Two-Day	Cervical secretions	Note presence or absence of cervical secretions Record data	All days with secretions One day following days with secretions Total: Approximately 10–14 days each cycle	86%	4
Symptothermal	Cervical secretions Vaginal mucus BBT	Monitor cervical secretions daily Assess quantity and quality of secretions Take BBT daily Record observations on chart	Menses Preovulatory days following days with intercourse All days with fertile-type secretions Until 3 days of higher temperatures, or 4 days past peak Total: Approximately 14–16 days each cycle	80%	2–5

Abbreviation: BBT, basal body temperature.

[a] Number of pregnancies per 100 women per year of use with perfect use.

A fixed formula to define the fertile window of the menstrual cycle as the basis of a simple method of natural family planning. *Contraception.* 1999;60(6):357-360[5]; Jennings VH, Burke AE. Fertility awareness–based methods. In: Hatcher RA, Trussell J, Nelson A, Cates W Jr, Stewart F, Kowal D, eds. *Contraceptive Technology*. 20th ed. New York, NY: Ardent Media; 2011:432[6]; *Family Planning: A Global Handbook for Providers.* WHO Press; 2011. Accessible at: http://apps.who.int/iris/bitstream/10665/44028/1/9780978856373_eng.pdf. Accessed November 28, 2017[7]; Kambric R, Lamprecht V. Calendar rhythm efficacy: a review. *Adv Contracept.* 1996;12:123-128.[8]

Calendar Methods

Two calendar fertility awareness–based methods are available. The "rhythm" method, also known as the calendar method, is the oldest fertility awareness–based methods method, and was developed in the 1930s. A calendar method, the Standard Days Method, is a more recent adaptation.

Rhythm Method

This method attempts to predict the days in a menstrual cycle during which time a woman is most likely to become pregnant based on the projected time of ovulation. This interval is determined by calculations made from recording the length of the last 8 to 12 menstrual cycles. To use this method, a woman keeps a record of the date on which her menstrual cycle starts for several months to identify the longest and shortest cycles so that all possible fertile days may be projected. Although extremely popular decades ago, the rhythm method is the least used of the fertility awareness–based methods available today.

Standard Days Method

The Standard Days Method is based entirely on tracking the days of the menstrual cycle for women with regular cycles that range from 26 to 32 days.[9-12] The user notes the first day of menstruation and abstains from intercourse or uses another birth control method between days 8 and 19 after the first day that menses start during each menstrual cycle.[10]

The Standard Days Method has been promoted globally, although there is some question regarding standardization and effectiveness of the educational programs. These educational programs often advocate use of a bead-like device called CycleBeads, whose colors a woman uses to determine whether she should be considered fertile or infertile on a particular day. CycleBeads and Standard Days Method programs are proprietary, with the former device being marketed by a for-profit company. A number of apps using Standard Days Method are available.

Ovulation Methods

The three ovulation methods focus on using physical signs that indicate ovulation to identify the days of fertility and infertility for a specific cycle. These signs include changes in amount and characteristics of cervical mucus, basal body temperature (BBT), and the position and consistency of the cervix (**Figure 16A-1**).[11] Although cervical mucus is to be assessed, it is most commonly determined by wetness of the vulva. Ovulation methods that use a BBT require use of an appropriate thermometer—one of the few devices associated with fertility awareness methods.

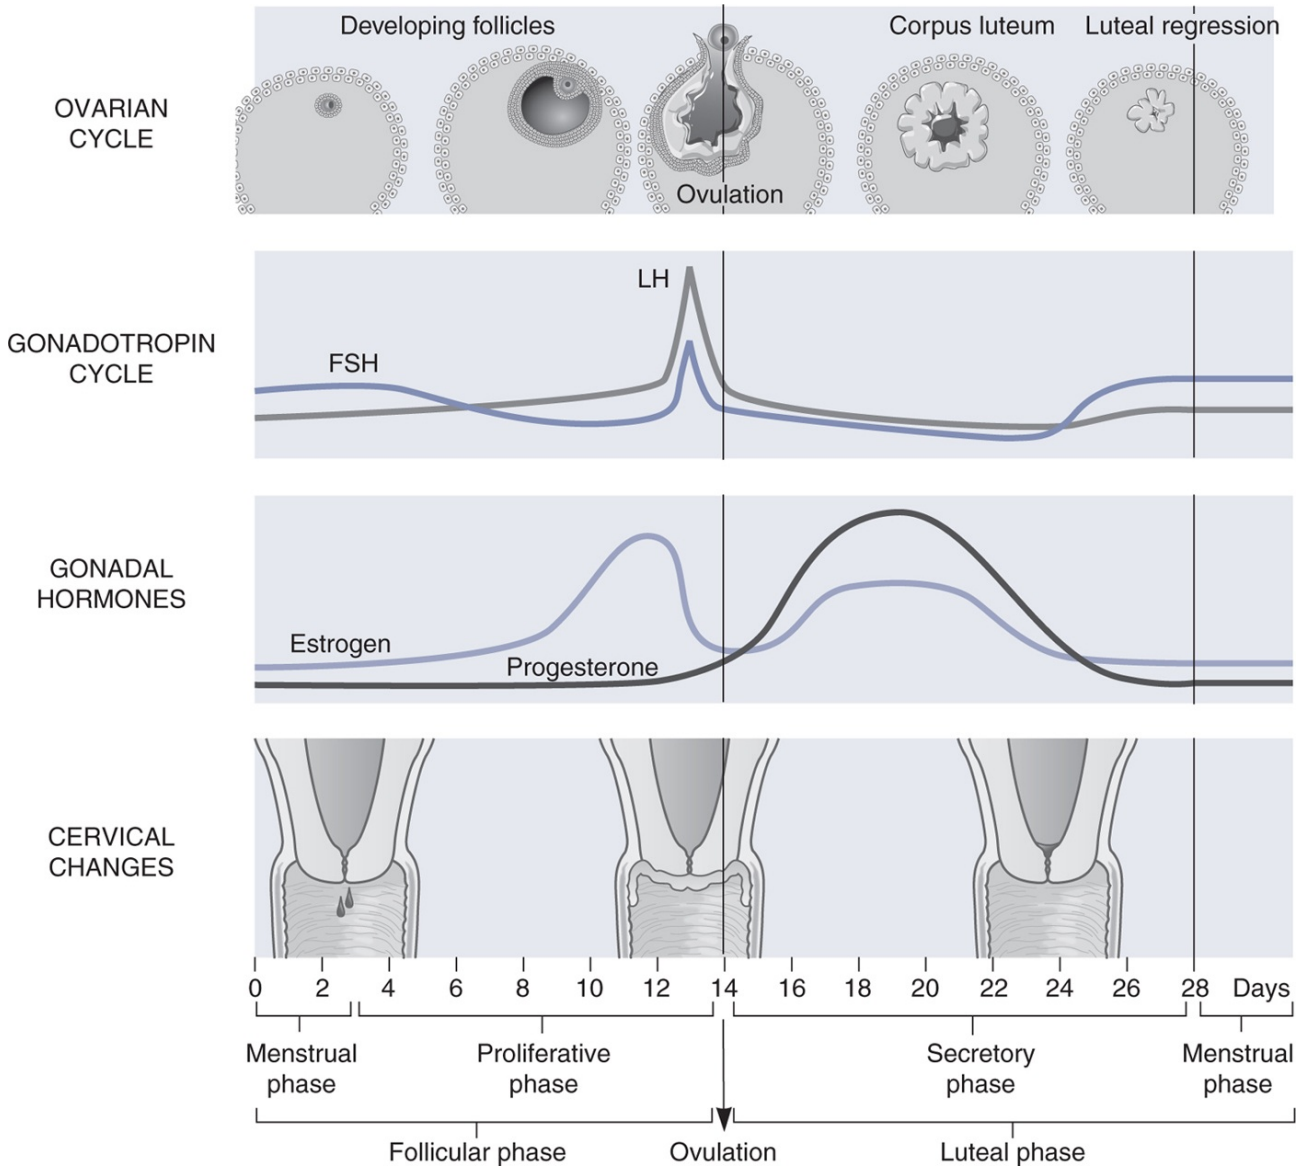

Figure 16A-1 Hormonal, follicular, temperature, secretions, and cervical changes during the menstrual cycle.

Billings Ovulation Method

The Billings Ovulation Method focuses on changes in the cervical mucus. During the infertile period in both the preovulatory phase and the postovulatory phase of the cycle, cervical mucus is absent or results in no sensation of wetness at the vulva. Fertile days are signaled by vulvar wetness or slippery cervical mucus. The woman observes the sensation of wetness at the vulva and the presence of mucus throughout the day and records her observations at the end of the day. During the entire first cycle of charting, abstinence is necessary for her to become familiar with her pattern of cervical mucus and sensations of vulvar wetness. The Billings Ovulation Method uses two patterns to describe monitoring cervical mucus (**Table 16A-3**).

Table 16A-3	**Billings Ovulation Method**

Cervical Mucus Pattern	Comments	Fertility
Basic infertile pattern (BIP)	Days immediately after menstruation Consistent dryness at the vulva	Intercourse every other day to avoid confusing seminal fluid with mucus
Peak pattern	Change in vulvar sensation from wet to slippery Under the influence of estrogen, the mucus increases in volume and becomes clear and stretchy, with an egg-white consistency (spinnbarkeit) Last day of peak is also called “peak day”	Avoid intercourse during peak and for 4 days after the peak day

Use of spermicides, lubricants, vaginal treatments, or barriers using spermicides may interfere with use of this method. Women are also advised to refrain from intercourse on days with heavy menstrual bleeding because it masks the signs of mucus associated with ovulation.

Creighton Model FertilityCare System

This fertility awareness method is a modification of the Billings Ovulation Method, yet a separate method. The Creighton Model FertilityCare System has a standardized teaching plan, is trademarked, and relies on a code system for charting.[13]

Two-Day Method

The Two-Day Method simplifies observation of cervical mucus.[14] This particular method does not require distinguishing the quality of the mucus. Instead, a woman using this method asks herself two specific questions (**Table 16A-4**). Women with irregular cycles can use this method because it relies entirely on observing one physical sign of fertility.

Similar to the Standard Days Method, the Two-Day Method is proprietary. The app associated with this method is available for a free download for a device using an iOS platform.

Table 16A-4	Two-Day Method
Question	**Fertility**
1. Did I note secretions today? 2. Did I note secretions yesterday?	Both questions must be answered. If the answer is “yes” to either one, it should be assumed the woman is fertile.

Symptothermal Method

The symptothermal method combines observation of three physical signs of ovulation: basal

body temperature, cervical mucus, and changes in the cervix itself. **Table 16A-5** lists physical signs of ovulation that suggest fertile days on the basis of ovulation.

Table 16A-5 Patterns of Ovulatory Temperature Rises

Physical Signs of Ovulation	Description	Comments
Rise in basal body temperature (BBT)	BBT rise of at least 0.4°F above the previous six daily BBT measurements	Rise is characterized as a sustained elevation or a plateau of the temperature for 3 days, or when there have been 5 days of progressive increase
Abrupt rise pattern	Rise over 1–2 days	
Saw-tooth pattern	Rise and fall over several days, with overall increase	For example, an increase of 0.4°F, decrease of 0.2°F, increase of 0.4°F, and so on
Slow rise or staircase pattern	Gradual rise over several days	
	Sharp dip in temperature followed by a rise	Occasionally occurs with ovulation but is not required
Changes in cervical mucus	Increase in volume and change to clear and elastic consistency	Same as peak pattern in Billings Ovulation Method
Cervical changes	From firm to soft and moves higher into vaginal canal	

The rise in BBT occurs as more progesterone is released by the corpus luteum, signaling that ovulation has occurred. The pattern of the rise in temperature may vary both from woman to woman and from cycle to cycle for the same woman and can be altered by inconsistent schedules or illness. Observing cervical mucus changes augments the BBT pattern to help identify fertile and infertile days. As with the Billings Ovulation Method, fertile days are characterized with elastic, thin, clear mucus.

In addition to BBT and cervical mucus observation, the third component of this method is changes in the cervix itself, which can be felt by palpating the cervix. As ovulation approaches, the cervix softens, the os dilates slightly, and the cervix is positioned higher in the vaginal canal. After ovulation, the cervix returns to being firm, closed, and lower in the vaginal canal. Detection of the cervical position is an optional sign. A woman using this method documents observation of the three parts of the method—BBT, cervical mucus, and cervical characteristics.

APPENDIX

16B

Fitting Diaphragms

MARY C. BRUCKER

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

A diaphragm is a soft silicone dome that covers the cervix during intercourse. The rim has a spring inside that ensures the diaphragm fits between the posterior symphysis and the posterior vagina, covering the cervix. This appendix describes how to fit or verify the fit of a diaphragm. The diaphragm is always to be used with a spermicide. The spermicide is placed in the dome, which is designed directly to face the cervix, and spread upward to around the rim of the diaphragm.

The contraceptive mechanism of action for a diaphragm is twofold: (1) The spring in the rim forms a seal against the vaginal wall, providing a physical barrier to prevent sperm from entering the cervix, and (2) during vaginal intercourse, the diaphragm moves slightly and coats the cervix and vaginal wall with spermicide. Current types of diaphragms are listed in **Table 16B-1**. A silicon wide-seal diaphragm is illustrated in **Figure 16B-1**, and a one-size diaphragm is depicted in **Figure 16B-2**.

Table 16B-1 Types of Diaphragms

Type	Description	Indications
Wide-seal rim	Has a flexible 1½-cm-wide "skirt" extending from the inner edge of the rim	Latex-free diaphragm composed of silicon. The small skirt is designed to hold gel in place and improve the seal. May have one of two springs.
	Arcing spring	Strongest type of rim. May be used by women who have cystocele, rectocele, uterine prolapse, retroverted uterus, or an anteverted or retroverted cervix.
	Omniflex	Has a distortion-free spring that provides arc no matter where the rim is compressed. This type of rim is proposed to provide increased suction for added protection.

		The wide-seal rim omniflex replaced the “all-flex” diaphragm, which was once the most popular diaphragm but was discontinued by the manufacturer in approximately 2014. However, it folds on only two axes.
Silicon single size	Purple diaphragm with rim dimples for gripping during insertion and a finger dome for ease of removal	Marketed with the “Caya” brand name, this silicon diaphragm is designed to fit most women. It is a single size and no measuring is required. Like all diaphragms, it is available by prescription only. Some providers suggest that proper placement should be verified by a clinician because the diaphragm is not marketed as fitting all women.

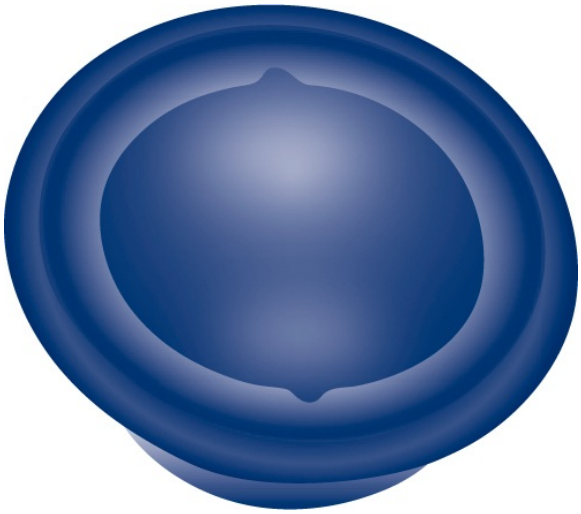

Figure 16B-1 Wide-seal diaphragm.

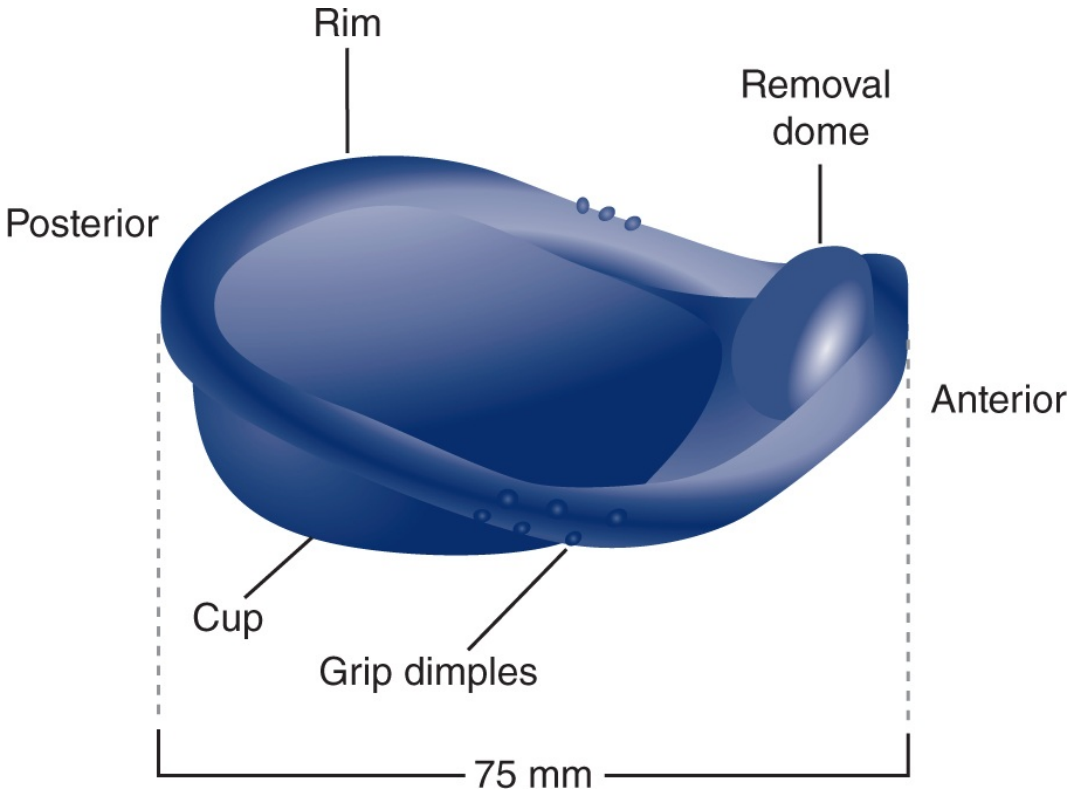

Figure 16B-2 Single-size contoured diaphragm.

Contraindications (U.S. MEC for Contraceptive Use Category 3 or 4)[1]

- History of toxic shock syndrome
- High risk for human immunodeficiency virus (HIV) infection
- HIV infection or acquired immunodeficiency syndrome (AIDS)

Procedure for Fitting for Diaphragms That Have Different Sizes

Equipment and Supplies

- A complete set of fitting rings or fitting diaphragms, from 50 mm to 95 mm
- Nonsterile gloves
- Lubricant

Preparation

1. Encourage the woman to have an empty bladder prior to examination.
2. Gather all needed equipment and arrange it so it is in easy reach.
3. Perform a pelvic examination to rule out any infections or abnormalities.
4. The initial choice of a fitting diaphragm or fitting ring usually begins with a size in the center of the probable range for the woman's parity. Generally a nulliparous woman will be fitted with size 65, 70, or 75, and a multiparous woman with size 75, 80, or 85.

Procedure[2]

1. Insert a gloved index and middle finger into the vagina until the middle finger reaches the posterior wall of the vagina, to determine the distance between the posterior symphysis and the posterior vagina behind the cervix.
2. Mark the point at which the index or middle finger touches the posterior inferior sympthysis pubis.
3. Remove the fingers and place a diaphragm rim on the tip of the middle finger. The opposite rim of the correct size of diaphragm should lie approximately in front of the place on the examiner's finger that touched the posterior inferior symphysis pubis.
4. Lubricate or moisten the diaphragm or fitting ring, compress the sides together with the fingers and thumb of one hand, and introduce it into the vagina (**Figure 16B-3**). Be certain to direct the diaphragm or fitting ring downward and inward, thereby applying pressure against the posterior vaginal wall and avoiding the more sensitive anterior structures.
5. Once the diaphragm is inserted, check its placement with a gloved finger. It is the

correct size if:

a. The rim is behind the cervix in the posterior fornix.
b. The circumference rests easily against the lateral vaginal walls.
c. A fingertip can be inserted between the diaphragm and the posterior surface of the symphysis pubis.
d. The cervix is covered.

6. The diaphragm is *too small* if:
   a. There is more than enough space for the flat portion of a fingertip to be inserted between the rim of the diaphragm and the posterior surface of the sympthysis pubis.
   b. It moves about freely in the vagina.
   c. It dislodges when the woman coughs or bears down.
7. The diaphragm is *too large* if:
   a. It fits tightly against the symphysis pubis.
   b. The rim buckles forward against the lateral vaginal walls.
   c. It dislodges or protrudes out the vagina when the woman performs a Valsalva maneuver.
   d. The woman feels discomfort when the diaphragm is in place.
8. Many midwives will verify the appropriate size by inserting diaphragms of successive size until the correct size is ascertained and then inserting one size larger for confirmation, although this last step is not required.
9. Return demonstration:
   a. Have the woman wash her hands. Remind her in real life she should verify the integrity of the device before inserting it.
   b. Have the woman assume a comfortable position that will allow her to insert two fingers into her vagina and reach her cervix. Optional positions include the following:
      i. Lying supine with head elevated and knees flexed
      ii. Standing with one leg on a stool, bending forward
   c. As she inserts her fingers into her vagina, verbally guide the woman to locate and feel the symphysis pubis and then her cervix.
   d. Have the woman hold the lightly lubricated diaphragm in one hand, dome side down. Then have her compress the sides of the diaphragm between her thumb and fingers, with her hand on top of the diaphragm, and spread her labia with her other hand and introduce the end of the folded diaphragm into her vagina in a downward and backward direction.
   e. Once the diaphragm has been introduced into the vagina, the woman can use the hand that has been separating the labia to complete insertion until the rim is under the posterior symphysis pubis. Instruct her to then use a finger to tuck the rim upward, behind the pubis.
   f. Have the woman check the placement, feeling the rim behind the pubis and the cervix covered by the diaphragm.
   g. The midwife may ask the woman to walk around the room to note any sensation or discomfort. When correctly fitted, the diaphragm will not be felt.

h. Have the woman lie down in modified lithotomy position; insert a gloved finger into the vagina and check that the diaphragm is fitted correctly.

i. To remove the diaphragm, have the woman resume the position she chose for insertion. She inserts a finger into her vagina, bears down, grasps the rim behind the symphysis pubis with two fingers or thumb and index finger, and gently slides the diaphragm down and out.

j. Have her repeat this practice insertion and removal until she is confident she can insert the diaphragm, check its correct placement, and remove it.

k. Demonstrate use of the spermicide. Squeeze 1 to 2 teaspoons of the gel from the tube into the dome, spreading it evenly over the inside and around the rim of the diaphragm.

For a woman who is using a single-size diaphragm, some providers suggest that the return demonstration as outlined here be performed to verify correct placement.

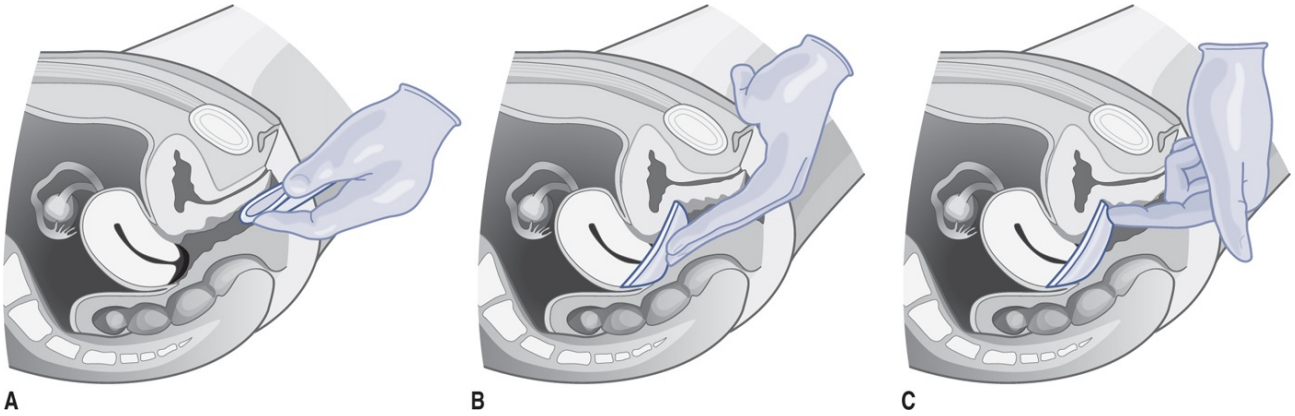

Figure 16B-3 Diaphragm fitting. **A.** Insert the folded diaphragm into the posterior vaginal fornix. **B.** Place the anterior wall behind the symphysis pubis. **C.** Check placement of the diaphragm posteriorly, anteriorly, and laterally to confirm it fits without undue pressure or too much space between the rim and the vaginal walls.

Health Education: Key Points

1. The diaphragm ensures the best protection when inserted correctly and used consistently with a spermicide.
2. Always wash hands and check for integrity of the diaphragm before using it. Even pinholes in the device invalidate this barrier method.
3. The diaphragm can be inserted up to a maximum of 6 hours prior to intercourse, although evidence-based data on timing are lacking. Some clinicians suggest an additional applicator of spermicide be inserted if more than 1–3 hours have passed after the initial insertion.
4. It is recommended that the diaphragm be left in place a minimum of 6 hours after intercourse, although there are no studies that document the optimal time needed for full contraceptive protection. Additional spermicide should be added without removing the

diaphragm before another act of coitus.

5. Do not leave the diaphragm in situ for more than 24 hours after intercourse, secondary to the theoretical risk of toxic shock syndrome.
6. When a diaphragm fits correctly, the woman will not feel it inside her vagina.
7. Symptoms of toxic shock syndrome—sudden high fever, muscle aches, chills, and malaise—should be reported to the midwife immediately.

APPENDIX

16C

Intrauterine Device Insertion and Removal

MELICIA ESCOBAR

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

Intrauterine devices are long-acting reversible contraceptive (LARC) agents that require little, if any action, by the woman after they are inserted, resulting in a very effective contraceptive method. For the purposes of this appendix, the terms "intrauterine device" and "IUD" will be used throughout. Five different brands of IUDs are currently available in the United States, one of which is wrapped in copper (copper IUD) and four of which are impregnated with levonorgestrel (LNG-IUD). More information about the effectiveness and use of these devices is found in the *Family Planning*, *Nonhormonal Contraception*, and *Hormonal Contraception* chapters.

This appendix can be used as a guide for insertion of any of the current IUDs. In addition to its use as a contraceptive, the LNG-IUD can be used for the treatment of women with menorrhagia; more information about this non-contraceptive usage is found in the *Menstrual Cycle Abnormalities* chapter.

Health Counseling for Women Considering an Intrauterine Device

In advance of IUD insertion, the clinician should examine personal biases toward contraceptive options, as this is essential to providing evidence-based information that is free of judgment.[1] A thorough reproductive life plan and health history, health education, contraindications, risks, contraceptive and noncontraceptive benefits, side effects and adverse effects are reviewed as part of a shared decision-making process.[1-7] These topics are presented briefly in this appendix. The reader is referred to the chapter on *Hormonal*

Contraceptives, resources and references for a more detailed description of health counseling prior to IUD insertion.

A written consent form granting permission to the clinician for IUD insertion, signed by the woman either on paper or by electronic means, is part of the shared decision making and legal informed consent. Health education should include the costs involved with IUD insertion. Although the initial cost may be higher than for other contraceptive methods, the IUD becomes cost neutral after three years of continuous use and has the added cost savings associated with reduction in unintended pregnancies.[6,7] For women without insurance coverage, some financial support for IUD use may be available directly through the pharmaceutical companies or their associated philanthropic programs.

Contraindications for Intrauterine Device Insertion

The initial step prior to consideration of an intrauterine device is to determine if the woman has any contraindications as listed in **Table 16-4**. In brief, absolute or relative contraindications for IUD use include: pregnancy, unexplained vaginal bleeding, solid organ transplantation, cervical cancer awaiting treatment, distorted uterine cavity, endometrial cancer, gestational trophoblastic disease, and infections such as pelvic tuberculosis, pelvic inflammatory disease (PID), post-septic abortion, sexually transmitted infections (STIs) (e.g., chlamydia, syphilis, gonorrhea), purulent cervicitis, or high risk for STIs.[3,4]

Contraindications specifically for use of the copper-containing IUD include Wilson's disease, allergy to copper, or systemic lupus erythematosus with severe thrombocyteopenia.[3,4]

Contraindications specifically for use of the LNG-IUD are current breast cancer, history of breast cancer, current heart disease, history of heart disease, systemic lupus erythematosus, and liver disease such as cirrhosis.[3,4] The LNG-IUD is not recommended for use as an emergency contraceptive, perhaps because of ethical issues in conducting a rigorous study or lack of compelling need because the copper IUD has well recognized spermicidal effects, and has been on the market for approximately four decades with a body of research demonstrating effectiveness as an emergency contraceptive.

Risks and Benefits Associated with Intrauterine Devices

The benefits of IUDs include ease of use in that these are non-coital dependent, long-acting reversible method, and a limited number of side effects. IUDs are associated with a decreased risk of cervical cancer. The copper-containing IUD is associated with menstrual regularity and possibly a decreased risk of endometrial cancer. The LNG-IUD is associated with amenorrhea, reduction of symptoms of dysmenorrhea and heavy menstrual bleeding, symptoms of endometriosis, and a reduced risk for PID.

Side Effects and Adverse Effects Associated with Intrauterine Devices

Many myths and misconceptions exist regarding IUDs that can be addressed during pre-insertion counseling.[5] IUDs are not associated with an increased risk for infertility, ectopic

pregnancy, or infections such as PID or HIV. Side effects are primarily changed vaginal bleeding patterns. The copper-containing IUD is associated with increased menstrual flow and menstrual cramping. In contrast, the LNG-IUD gradually induces amenorrhea. Adverse effects include a vasovagal response and uterine perforation, which are associated with insertion.

Vasovagal Response

During IUD insertion, some women may experience a vasovagal reaction secondary to cervical manipulation. Common symptoms include syncope, hypotension, bradycardia, tunnel vision, vertigo, dyspnea, nausea, and diaphoresis. This response usually resolves spontaneously if the clinician stops any manipulation and waits for the symptoms to resolve. Usually insertion can be resumed without incident. It is rare that an IUD cannot be inserted due to a vasovagal reaction.

Uterine Perforation

Perforation of the uterus at the time of IUD insertion is a rare event with an incidence estimated at 0.4 per 1000 insertions. If uterine perforation occurs during placement of the IUD, the clinician may find that during fundal placement, the IUD continues to travel beyond the original uterine depth and the threads begin to travel upward. Women most at risk for perforation are those who are breastfeeding, who have recently given birth, or both.[8] When perforation is suspected, the IUD should be removed, physician consultation obtained, and the woman should be evaluated closely. Most perforations are small and require little treatment.[9],[10] Any woman demonstrating symptoms of bleeding or shock post insertion should be transferred to an appropriate care facility for prompt treatment.

Choice of an Intrauterine Device

Several IUDs are currently available in the United States. Both the copper and levonorgestrel (LNG) IUDs provide highly effective contraception, can be identified on ultrasound if needed, and are easily reversible. Nevertheless, certain differences between them must be taken into consideration.

The copper IUD (ParaGard) is a nonhormonal option and has been available for decades in the United States. This IUD is associated with irregular bleeding, dysmenorrhea, and heavier menses, which on rare occasions may lead to anemia. Although the copper IUD is currently approved by the U.S. Food and Drug Administration (FDA) as having 10 years of effectiveness, emerging research suggests a longer duration of effectiveness exists.

Four LNG-IUDs (Mirena, Liletta, Skyla, and Kyleena) exist; they are described in more detail in the *Hormonal Contraception* chapter. While all of these devices contain the same hormone (levonorgestrel), they differ in size, duration of effectiveness, and dose of hormone. Additionally, Mirena and Liletta each have unique FDA approvals: Mirena is approved for the treatment of individuals with heavy menstrual bleeding who also desire an IUD, whereas Liletta is approved specifically for use in nulliparous women. When considering side effects

and the therapeutic benefit of amenorrhea conferred by the presence of LNG in these devices, it may be helpful to consider the person's baseline menstrual flow. Those who report light to moderate bleeding may be more likely to experience amenorrhea within the first year of use.[11]

Timing of the Intrauterine Device Insertion

IUDs may be inserted at any time if the clinician is reasonably sure that the woman is not pregnant, including postpartum (including after cesarean birth) and post abortion (either spontaneous or induced).[3] In both cases, sepsis precludes use of the method until resolution of infection. In an effort to reduce the number of unplanned pregnancies, insertion in the immediate postpartum period is becoming more common in the United States, despite an increased rate of expulsion associated with this timing.[12,13] Postabortion insertion continues to be a common practice and has been found to be safe and effective.[3] The copper IUD also can be used as a type of emergency contraception; its use for that indication is discussed in the *Family Planning* chapter.

In years past, IUDs for contraceptive use were almost exclusively inserted during menses to assure that the woman was not pregnant at the time of insertion. This practice was also based on the belief that insertion would be easier during menses. A theory existed that the cervix might be slightly open and softer at this time. In reality, little evidence exists to support this timing.[14] Current guidelines state that insertion can occur at any time for those women without preexisting contraindications to the method, assuming there is reliable evidence that the woman is not currently pregnant.

For a woman who already is using a hormonal contraceptive method such as combined oral contraceptives, the IUD can be inserted at any time during the cycle but should be in place 7 days before the pills are discontinued when an LNG-IUD is inserted and 5 days before the pills are discontinued if a copper IUD is used.

Screening for Sexually Transmitted Infections

According to national screening guidelines, screening for STIs should be conducted on a regular basis.[15] However, requiring that negative results of recent STI screening be available prior to IUD insertion imposes an unnecessary barrier to access for this method. Studies have found that the rate of PID is no different in women who screened positive for chlamydia infection or gonorrhea at the time of insertion versus those for whom IUD insertion was deferred.[16] An exception is those women who have active disease or signs and symptoms of purulent cervicitis, chlamydia, or gonorrhea infection; in these women, insertion should be deferred until the infection is resolved.[3,4,17] Screening for human papillomavirus infection or cervical cancer is not necessary and, therefore, is not required.[18]

Day of Intrauterine Device Insertion

The insertion procedures for copper IUDs and LNG-containing IUDs have minor differences based on the configuration of both the inserter and the device. Insertion in the immediate postpartum period also requires a different set of steps. In all cases, the intention is to place the IUD in the fundus of the uterus. If the IUD placement is not fundal, there is a higher likelihood of unintended pregnancy as well as expulsion of the IUD.

Several training programs are available in which clinicians can learn how to insert an IUD. Most of these programs are sponsored by the manufacturers of the devices, and these vendors may restrict use of their products until such education is completed. Multiple resources for IUD insertion procedures exist online, including video recordings that help the clinician review the process. In addition, the FDA-approved prescribing information and package label for each device include insertion instructions and images. The following steps for insertion are general guidelines and cannot replace hands-on experiences.

Premedication

It is common practice to administer a prophylactic nonsteroidal anti-inflammatory agent such as ibuprofen to women prior to insertion of an IUD. These drugs effectively treat the pain associated with IUD use, such as copper IUD–associated dysmenorrhea, but there is no evidence suggesting that they diminish discomfort at the time of IUD insertion.[3,19] Anesthesia such as topical lidocaine may or may not decrease pain, but published studies on this topic lack enough rigor to draw any conclusion.[3,19] By comparison, lidocaine, when delivered as a paracervical nerve block, may reduce pain associated with tenaculum placement or IUD insertion.[3,19] Only limited evidence supports the use of nitrous oxide as a possibly effective analgesia option for women during an IUD insertion; however, high satisfaction rates among users were noted.[3,19]

Using misoprostol (Cytotec) to soften the cervix does not significantly improve ease of IUD insertion and may even increase pain.[3,19] Thus, misoprostol is not recommended for regular use as part of the insertion procedure. However, there may be some benefit to using this agent when attempting a second insertion after a previous failed attempt.[20]

The use of antimicrobial agents has been shown to have limited effectiveness in reducing infection, including PID and endocarditis, despite a theoretical risk of these complications.[16,21] Although the overall risk of IUD-related infection is low, one systematic review found a small, but significant, reduction in infections among women receiving such treatment; the authors cautioned that the number of women in the studies was small and routine use was likely not to be cost-effective.[22]

Required Equipment for Intrauterine Device Insertion

General equipment includes the following items that are clean, albeit not necessarily sterile:

- Clean, nonsterile gloves for a bimanual examination.

- Lubricant for a bimanual pelvic examination.
- Adequate lighting for visualization.
- Speculum of appropriate shape and size.
- Scissors to cut the IUD threads after insertion.
- Antiseptic solution (povidone–iodine or 4% chlorhexidine gluconate).
- Cotton-tipped swab (drumstick swab) and/or a cotton ball or 4 × 4 gauze pads. These may be used to apply the antiseptic to the cervix. The swab may also be inserted to the level of the cervix against the uterine sound and then removed simultaneously for easy visualization of the measurement.
- Ring forceps to hold the 4 × 4 gauze pads if utilized, to remove the IUD if needed, or to remove the cut strings from the vaginal vault.
- A sanitary pad for the woman in the event of post-procedure spotting or bleeding.

A *sterile field* includes the following sterile equipment:

- Uterine sound to verify the size of the uterine cavity and the appropriateness of a specific size of IUD.
- Tenaculum (single tooth) to grasp the cervix, straighten the cervical canal, and stabilize the uterus during insertion. Some evidence suggests that an Allis clamp may be equally effective and reduce the risk of tenaculum-related bleeding.[23]
- Sterile gloves of appropriate size.

Optional Equipment for Intrauterine Device Insertion

- Os finder or other such dilator
- Monsel's solution or silver nitrate sticks to control tenaculum-related bleeding
- Supplies for administering a paracervical block, including trumpet, needle, syringe, and anesthesia
- 1% lidocaine, to be injected 3–5 minutes prior to IUD insertion
- 10-cc syringe with 22-gauge needle with extender or a spinal needle for the lidocaine

The IUD of choice may be placed on the field or handed to the clinician by an assistant. At some sites, a secondary IUD may be available should contamination occur with the first one. At other sites, consumers must purchase their own IUD. In those situations, it is likely that only one device will be available.

Key Points for Insertion of Any Intrauterine Device

1. Optimally the clinician should have another individual to assist with the procedure.
2. A bimanual pelvic examination is performed to ascertain the position of the uterus, rule out any abnormalities, and determine the position of the uterus. Note that a woman immediately postpartum or breastfeeding who has a softer uterus may have a higher risk

of perforation, but these conditions are not contraindications to the procedure.

3. The woman should have signed legal consent for documentation and verification of understanding of the procedure.
4. The woman is assisted into a physical position of comfort for the procedure. The examiner establishes adequate light for visualization of the vagina and cervix.
5. The woman is reassured that the procedure can be stopped at any time should she make this request.
6. The insertion is begun using sterile technique. Insert the speculum so that the cervical os is visualized.
7. The cervix and vagina is cleansed with the antiseptic. Cervical anesthesia administered if indicated.
8. Apply the tenaculum to the anterior lip of the cervix, with the teeth placed parallel to the plane of the speculum blades. If the uterus is retroverted, it may be more effective to place the tenaculum on the posterior lip. Gentle traction is exerted toward the clinician to straighten the cervical canal in alignment with the uterine cavity. Usually the clinician uses the nondominant hand to hold the tenaculum.
9. While performing these actions, the clinician should observe for a vasovagal response caused by manipulation of the cervix. If the woman feels faint or nauseated, stop the procedure and wait. Usually the second attempt at insertion is successful, assuming several minutes have elapsed.
10. While the clinician's nondominant hand holds the tenaculum in place, the dominant hand gently slides the uterine sound into the uterus to measure the depth of the uterine cavity (**Figure 16C-1**). Caution must be taken not to aggressively force the sound. Most of the currently available IUDs are designed for a uterine cavity that sounds between 6 and 9 cm, while the minimal sounding depth for Liletta is lower, at 5.5 cm. Skyla and Kyleena are physically smaller and may be appropriate for the uterine cavities of nulliparous women which are typically smaller than the uterine cavity in a multiparous woman. The depth of the uterus in centimeters is noted. If the sound does not confirm a depth within the required range, the insertion procedure should be aborted and an alternative method of contraception discussed.
11. At this point, the steps for the insertion vary based on the device. However, for all IUDs, the clinician maintains sterile technique. The device is not opened until it has been deemed appropriate for immediate insertion.

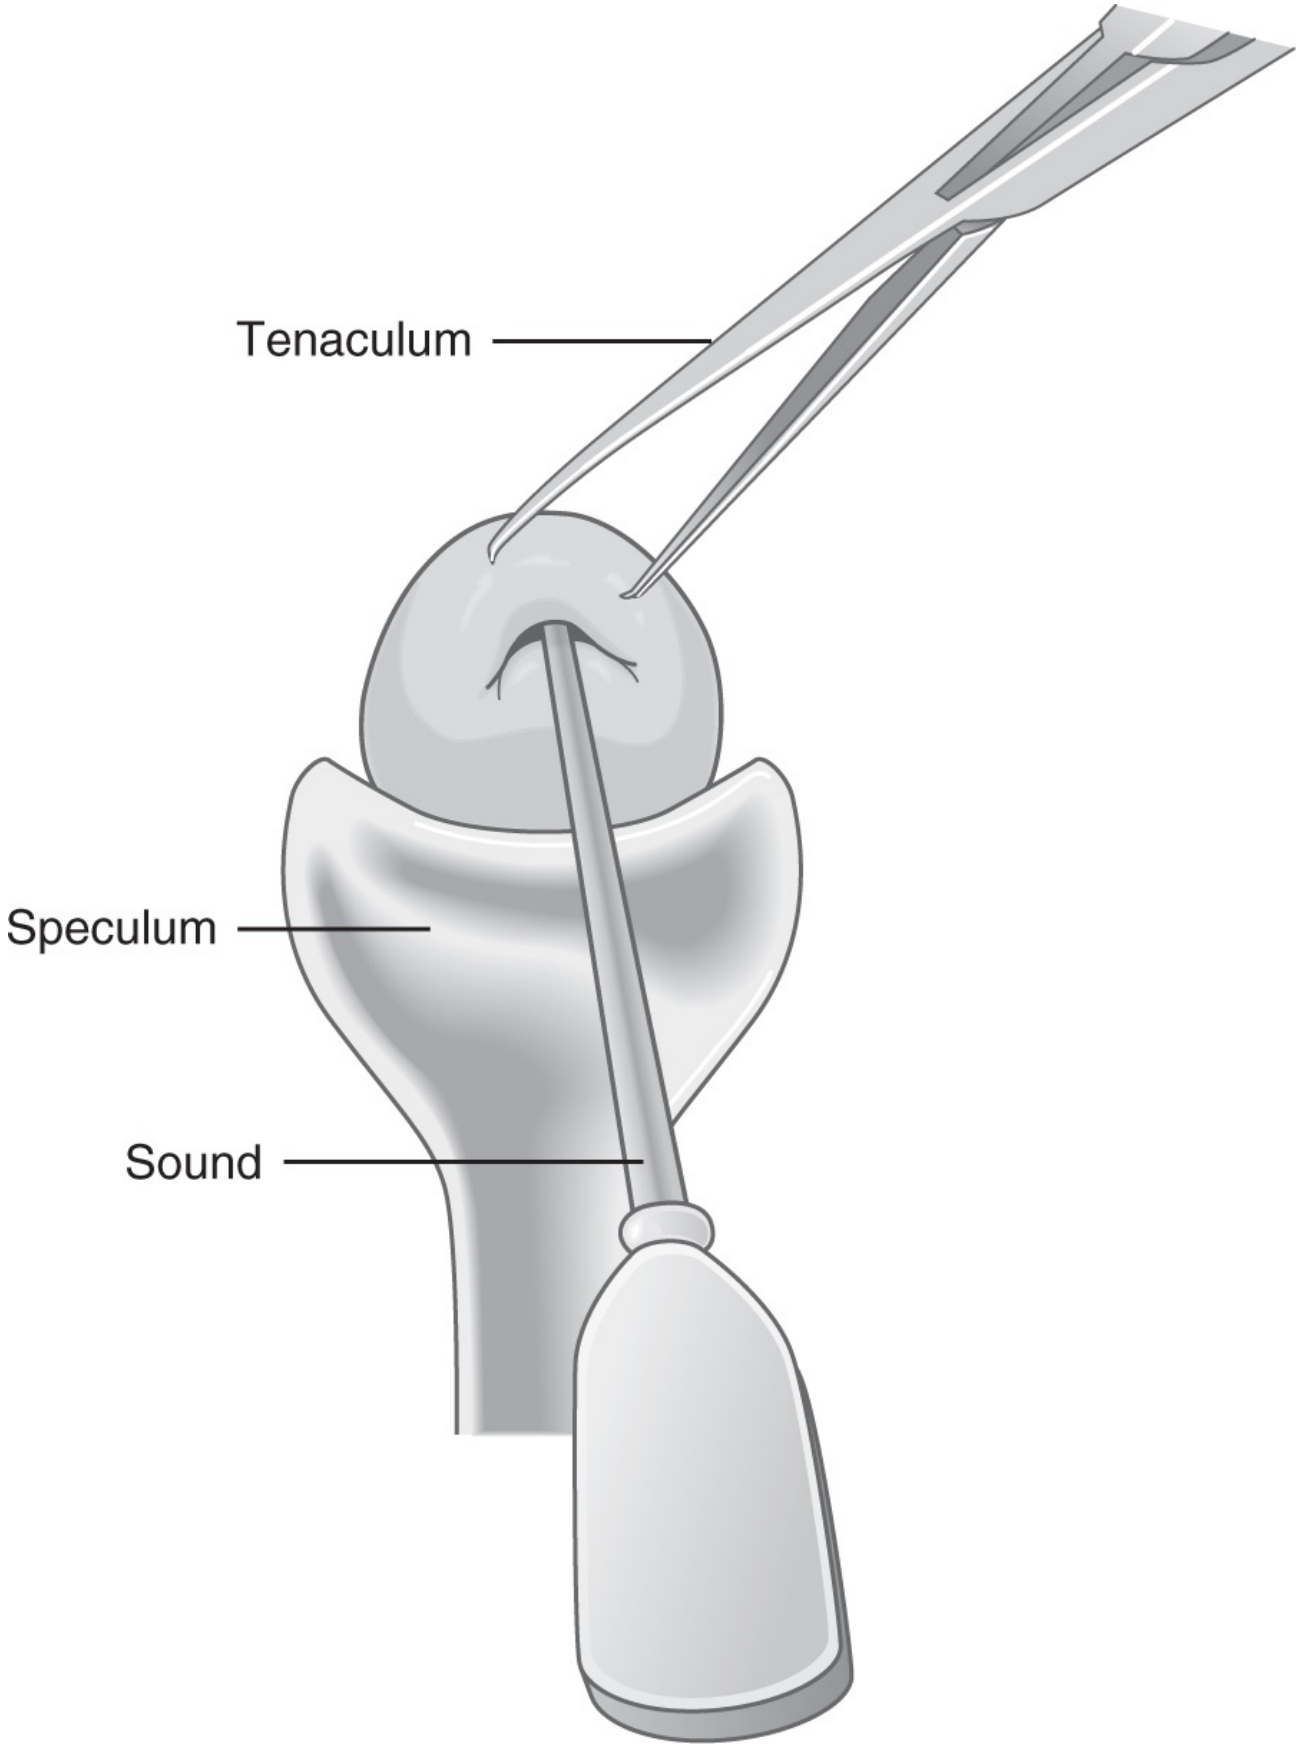

Figure 16C-1 Cervix with tenaculum and uterine sound.

Insertion of an LNG-IUD

The Mirena, Skyla, Kyleena, and Liletta IUDs are inserted in a similar manner. However, the anatomy of the Liletta device differs, particularly the loading mechanism and slider.

1. The IUD package is opened, usually by the assistant, and the clinician reaches for the device in a sterile manner. Alternatively, the entire package can be opened by the clinician and placed on the sterile field, who then dons sterile gloves and proceeds with the insertion. **Figure 16C-2** provides an illustration of the device in the packaging and the anatomy of the various LNG devices.
2. The threads of the Mirena, Skyla, and Kyleena are self-contained within the device. The threads of the Liletta are secured on the handle of the inserter and are ultimately released from the groove so they can hang freely.
3. Placement of the clinician's thumb or forefinger on the slider will stabilize the inserter and should be maintained until the insertion is complete. The slider should *not* be moved downward at this time, as this action may prematurely release the threads of the IUD. This is particularly relevant to the Mirena, Skyla, and Kyleena IUDs: Once the slider is moved below the mark, the IUD cannot be reloaded. The Liletta, however, may be reloaded.
4. The arms of the device should be in a horizontal position. If they are not, they can be realigned on a flat sterile area, such as the inside of the sterile package (**Figure 16C-3**).
5. To load the strings into the Mirena, Skyla, and Kyleena, push the slider forward until a "click" is heard or felt, indicating it is in place, while maintaining forward pressure on the slider. For Liletta, while continuing forward pressure on the blue slider, pull both strings straight back toward the clinician until a hard stop is achieved. This two-handed action retracts the IUD arms in the tubing (**Figure 16C-4**). The Liletta may be reloaded by releasing the thread from the cleft and pulling back on the blue slider until the groove becomes aligned with the green. By returning the blue slider to the forward position, the loading steps can be repeated. Do not load the IUD too far in advance of insertion so as to allow the device to retain its memory and allow optimal expansion of the arms to occur; prolonged time in the inserter may cause the device to lose structural memory.
6. Based on the uterine size determined by the sound, the flange on the insertion device is set at that number by sliding the flange over the marked increments on the IUD insertion tube. Sterile gloves must be used when touching the flange. The Liletta packaging has a built-in tray notch that enables the clinician to adjust the flange without touching it (**Figure 16C-5**).
7. The clinician's nondominant hand exerts gentle traction on the tenaculum or Allis clamp. Simultaneously, the clinician applies continued pressure to the slider on the IUD handle. These actions place the insertion tubing into the vagina at the level of the external cervical os.
8. Gently advance until the flange is approximately 1.5 to 2 cm from the external cervical os. The IUD will be into the uterus but should not be in the fundus at this time (**Figure 16C-6**).
9. For Mirena, Skyla, and Kyleena, the slider on the handle is pulled back toward the

clinician until the level of the raised mark on the insertion handle is reached. For Liletta, pull the blue slider back until resistance is reached; a common thumb recess is created once merged with the green slider. At that time, the IUD arms are expelled from the insertion tubing (**Figure 16C-7**). The clinician must wait 10 to 15 seconds to allow the arms to open completely.

10. Advance the insertion tubing until the flange is at the external cervical os. At that point, the IUD is in the uterine fundus (**Figure 16C-8**).
11. Move the slider(s) toward the clinician to release the IUD. A green indicator in the thread cleft of Liletta will confirm that the threads have been released (**Figure 16C-9**).
12. Gently remove the IUD handle and insertion tubing from the uterus and cervix and appropriately dispose of them.
13. The threads will remain in place.

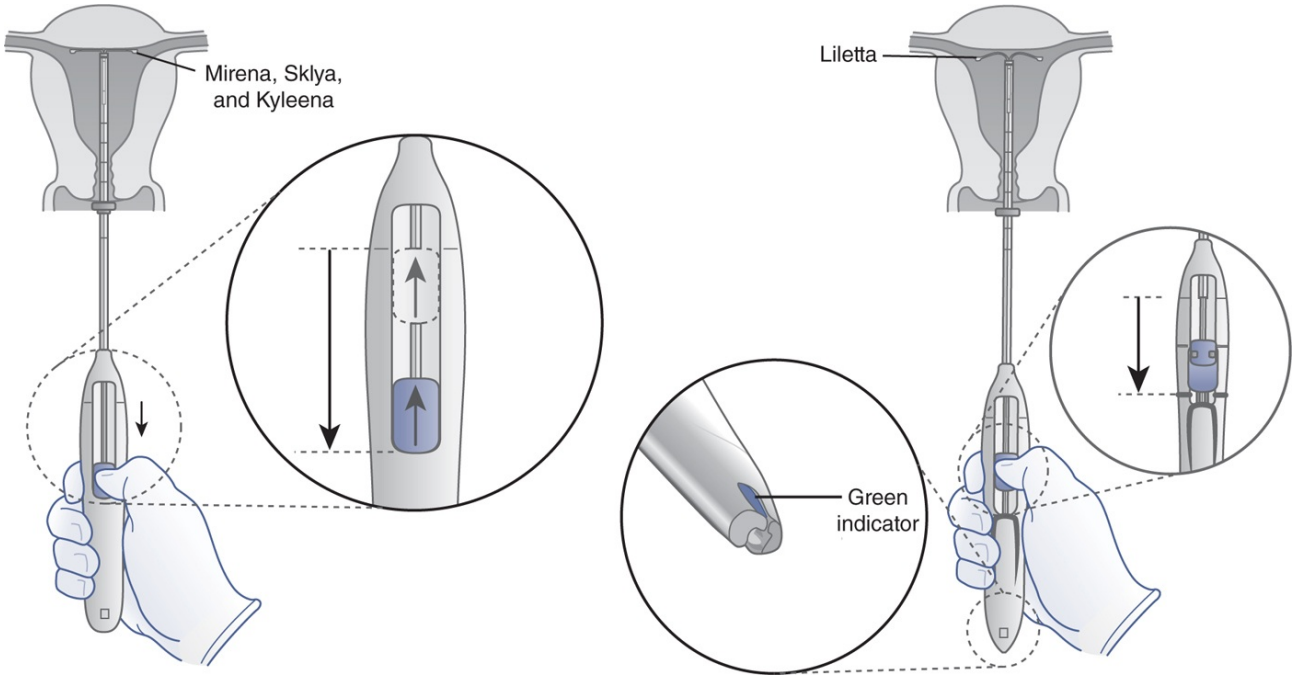

Figure 16C-9 Release of the LNG-IUD slider.

Insertion of a Copper Intrauterine Device (ParaGard T CU 380A IUD)

1. The IUD package (**Figure 16C-10**) is opened in the same manner for any IUD, usually by the assistant, and the clinician reaches for the device in a sterile manner. The clinician should be aware of the components of this IUD (**Figure 16C-11**).
2. Load the IUD into the insertion tubing by slightly withdrawing the insertion tubing and folding the horizontal arms of the IUD down along the vertical arm using the thumb and forefinger. This can be accomplished through the packaging (**Figure 16C-12**) or by using an open sterile technique (**Figure 16C-13**). Take precautions to ensure that the arms are not bent into the tubing until immediately before insertion. If the arms are folded for more than 5 minutes, the device may lose its memory and may not completely unfold in the uterus.
3. Advance the insertion tubing so that the horizontal arms sit securely within the insertion tubing.
4. Place the solid white rod into the bottom of the insertion tubing, advancing it until it touches the bottom of the IUD.
5. Grasp the insertion tube at the open end, and set the flange to the centimeter level predetermined by sounding the uterus.
6. Rotate the insertion tubing so that the horizontal arms of the IUD are parallel to the long axis of the flange.
7. Use a tenaculum or Allis clamp to stabilize the cervix. This stabilization usually is accomplished by the clinician's nondominant hand holding the tenaculum or Allis clamp as the loaded insertion tube is passed through the cervical canal guided by the dominant hand. When resistance is met at the uterine fundus, the flange should be at the external

cervical os (**Figure 16C-14**).

8. While the clinician's nondominant hand stabilizes the solid white rod, withdraw the insertion tubing with the clinician's other hand for a distance of approximately 1 cm. At this time, the IUD is released from the inserter.
9. Gently advance the insertion tube to ensure the IUD is placed in the fundus (**Figure 16C-15**).
10. Gently, the insertion tubing is withdrawn (**Figures 16C-16** and **Figure 16C-17**), and both the rod and the tubing are appropriately discarded.

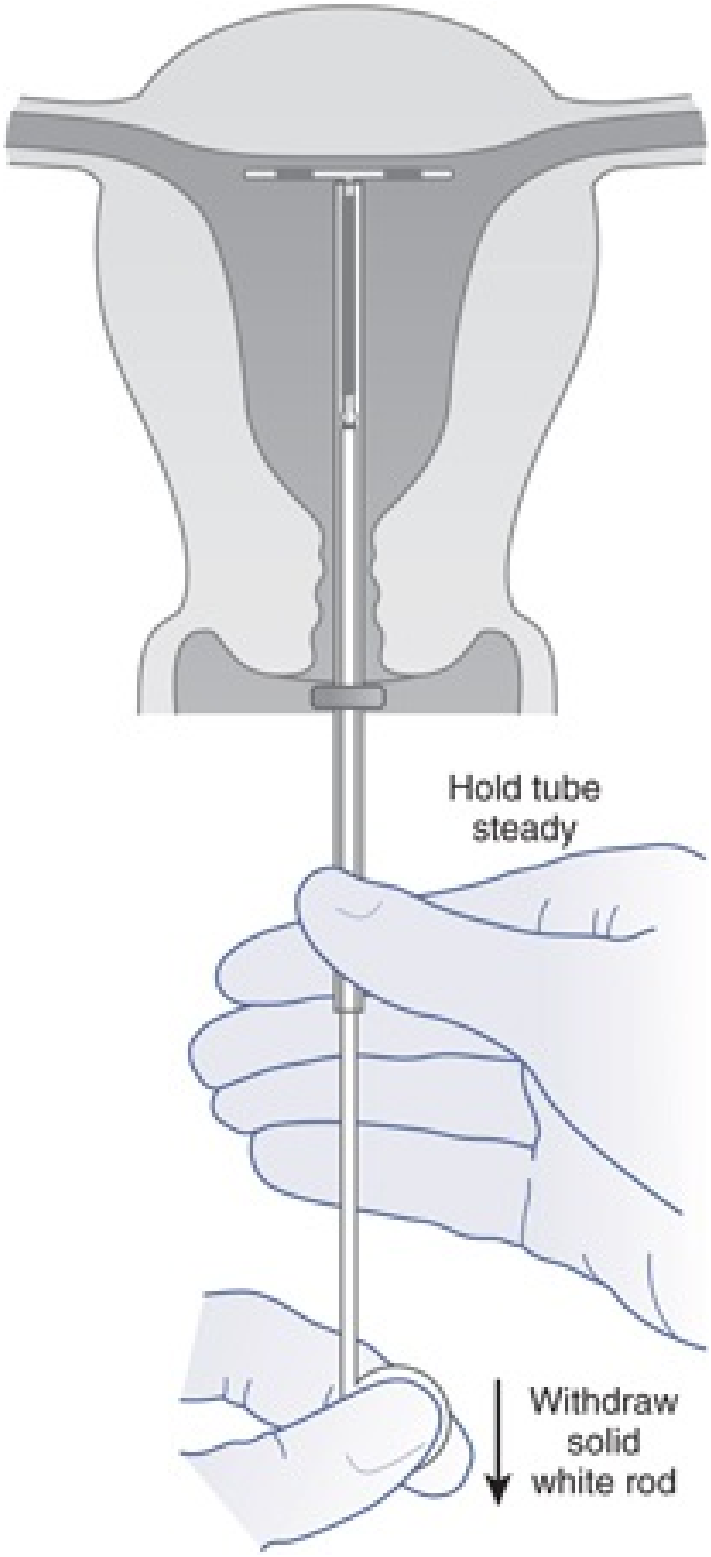

Figure 16C-17 Withdrawal of rod and insertion tubing for a copper IUD.

Postinsertion Care

The clinician should be able to visualize the IUD threads or strings in the vagina after IUD insertion is complete and the inserter materials removed. Using sharp scissors, threads are

trimmed to a length of approximately 3 cm from the external os after which the speculum can be removed. If the woman is overweight or obese, she may need a longer thread length than 3 cm to assure that she can easily feel the strings. Caution should be taken not to cut the threads too short, as they may migrate into the os, whereas longer strings can be shortened at a subsequent visit (**Figure 16C-18**). The exception to post-insertion cutting of the threads occurs when inserting an IUD in the immediate postpartum period, as discussed in that specific section of the *Nonhormonal Contraception* chapter.

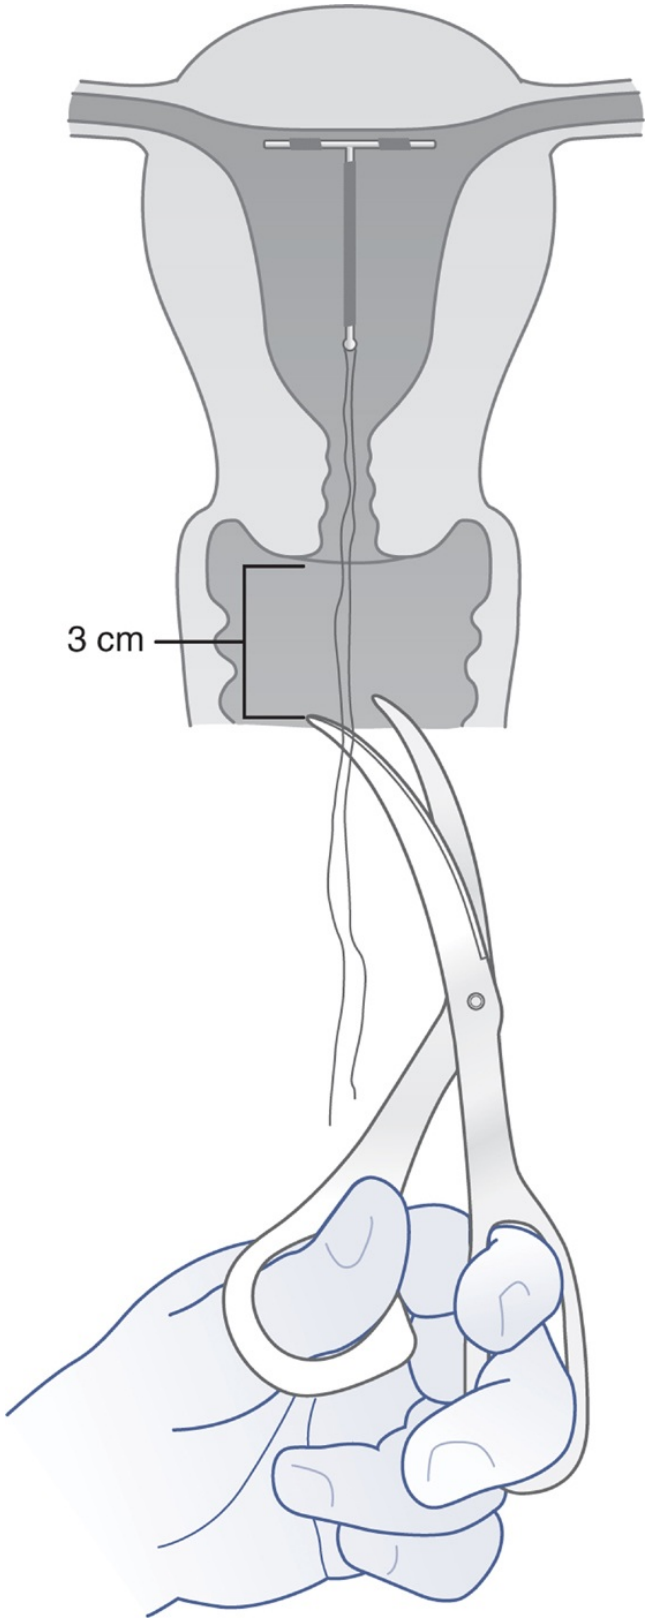

Figure 16C-18 Cutting threads for any IUD.

Immediate Postpartum Insertion of an Intrauterine

Device After Vaginal Birth

Placement of an IUD in the immediate postpartum period is contraindicated for women with peripartum chorioamnionitis, endometritis, or puerperal sepsis.[12] Alternative methods of contraception should be considered and placement of the IUD deferred in such a case. As with any contraceptive method, a woman should be engaged in shared decision making and the decision should be made prior to labor.

Ring Forceps Technique

1. Ensure that the device is placed within 10 minutes of when the placenta is expelled.
2. Clean the external genitalia and apply sterile drapes over the abdomen and under the buttocks.
3. Retract the vagina with a gloved hand, speculum, or retractor.
4. Swab the cervix and vagina with an antiseptic if desired; similarly, anesthesia can be administered as appropriate.
5. Using a ring forceps, stabilize the cervix by grasping the anterior lip. Do not use a tenaculum to avoid tearing the cervix.
6. Remove the IUD from the inserter and grasp the device by the vertical arm, with the horizontal arms slightly outside the ring but on the same plane (**Figure 16C-19**).
7. Cut the strings to 10 cm in length. Note that this is in contrast to cutting strings after insertion among women who are not postpartum.
8. Apply gentle traction to the ring forceps to stabilize the cervix.
9. Insert the device through the cervix and into the lower uterine segment (**Figure 16C-20**).
10. With the clinician's nondominant hand placed on the fundus to stabilize the uterus, advance the device to the uterine fundus, with ring forceps still grasping it, in an upward angle toward the umbilicus (**Figure 16C-21**).
11. If desired, confirm that the device is in place. This may be done under ultrasound guidance.
12. Release the IUD by opening the ring forceps and carefully remove the forceps from the uterus and vagina. Reduce the risk of inadvertently removing the newly device by leaving the forceps slightly open and sweeping laterally to avoid pulling the threads.
13. Examine the cervix and remove the ring forceps.

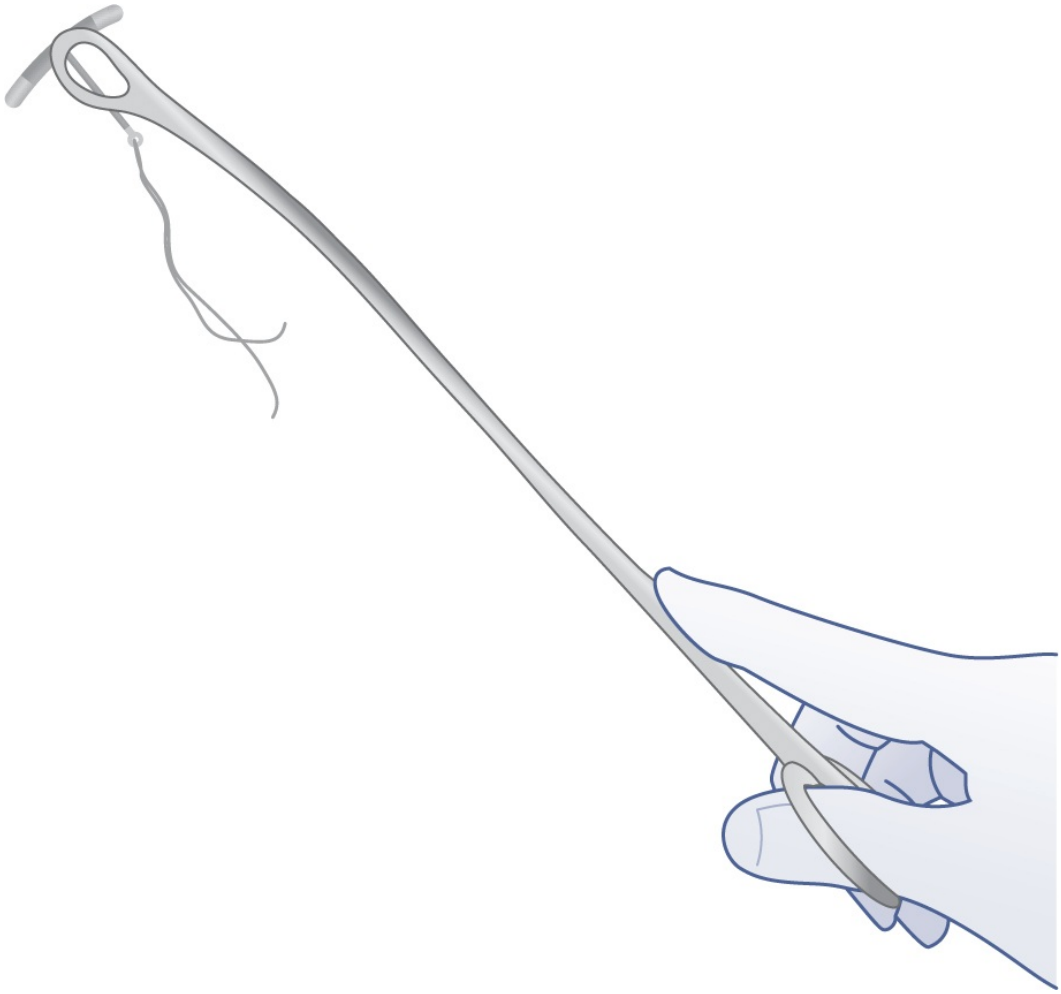

Figure 16C-19 Grasping the IUD with ring forceps.

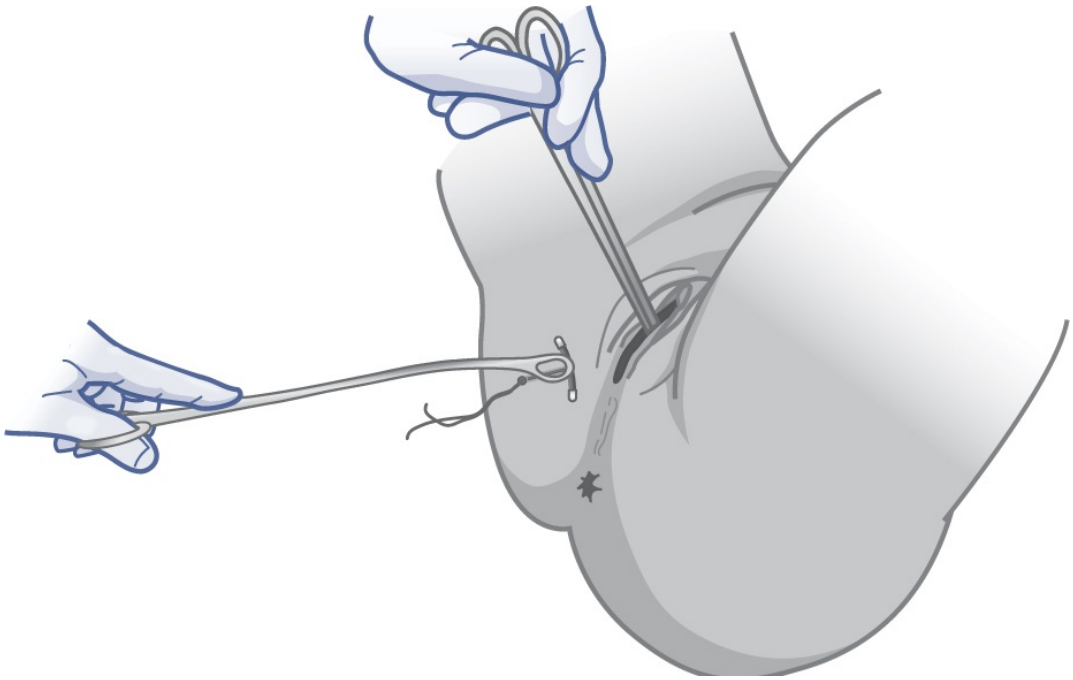

Figure 16C-20 Inserting the IUD with ring forceps while placing traction on the cervix.

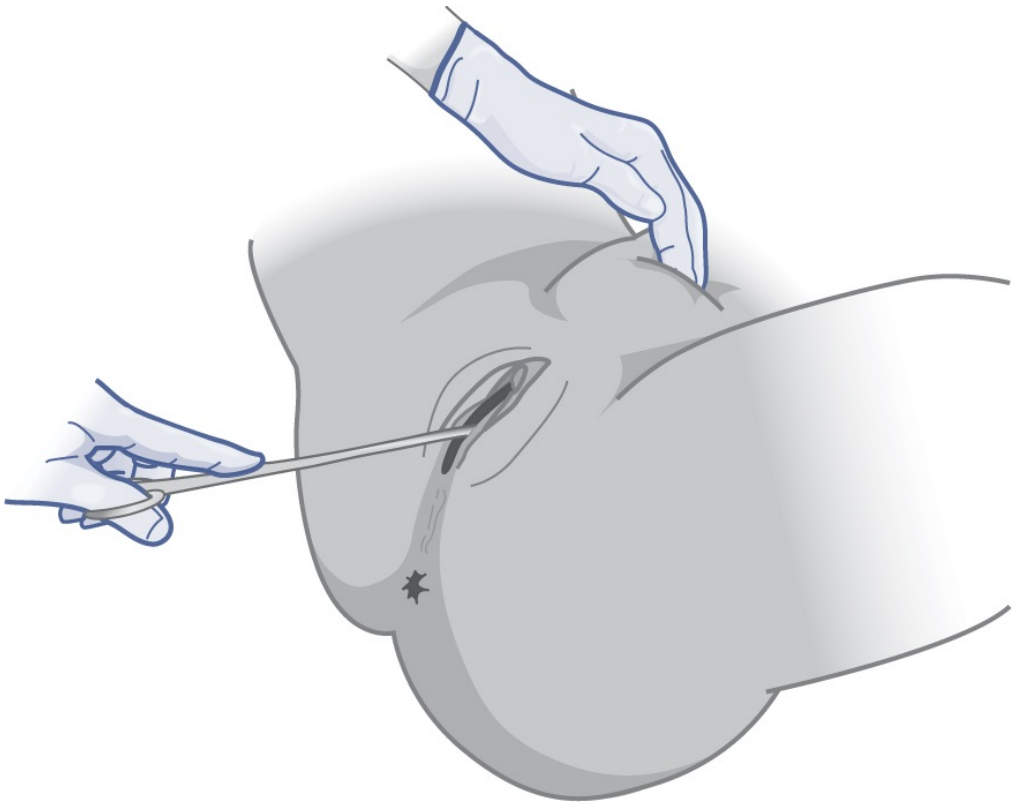

Figure 16C-21 Stabilizing the uterus while placing the IUD in the fundus.

Manual Technique

1. Ensure that the device is placed within 10 minutes of the birth of the placenta.
2. Clean the external genitalia and apply sterile drapes over the abdomen and under the bottom.
3. Swab the cervix and vagina with the antiseptic if desired; similarly, anesthesia can be administered as appropriate.
4. Visualize the cervix with a gloved hand, speculum, or retractor.
5. Remove the IUD from the inserter and grasp the vertical rod between the index and middle fingers of the dominant hand, noting the plane of the horizontal arms (**Figure 16C-22**).
6. Cut the strings to 10 cm in length. Note that this is in contrast to cutting strings after insertion among women who are not postpartum.
7. Insert the device through the cervix and into the lower uterine segment (**Figure 16C-23**).
8. With the clinician's nondominant hand placed fundally to stabilize the uterus, advance the device to the uterine fundus manually at an upward angle toward the umbilicus (**Figure 16C-24**).
9. If desired, confirm that the device is in place. This may be done under ultrasound guidance.
10. Release the IUD and carefully remove the dominant hand from the uterus and vagina, avoiding dislodging the device or inadvertently applying traction on the threads.

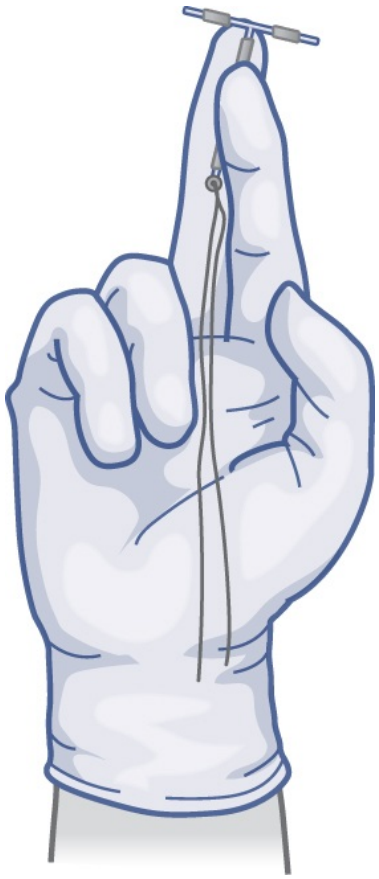

Figure 16C-22 Grasping the IUD prior to manual insertion.

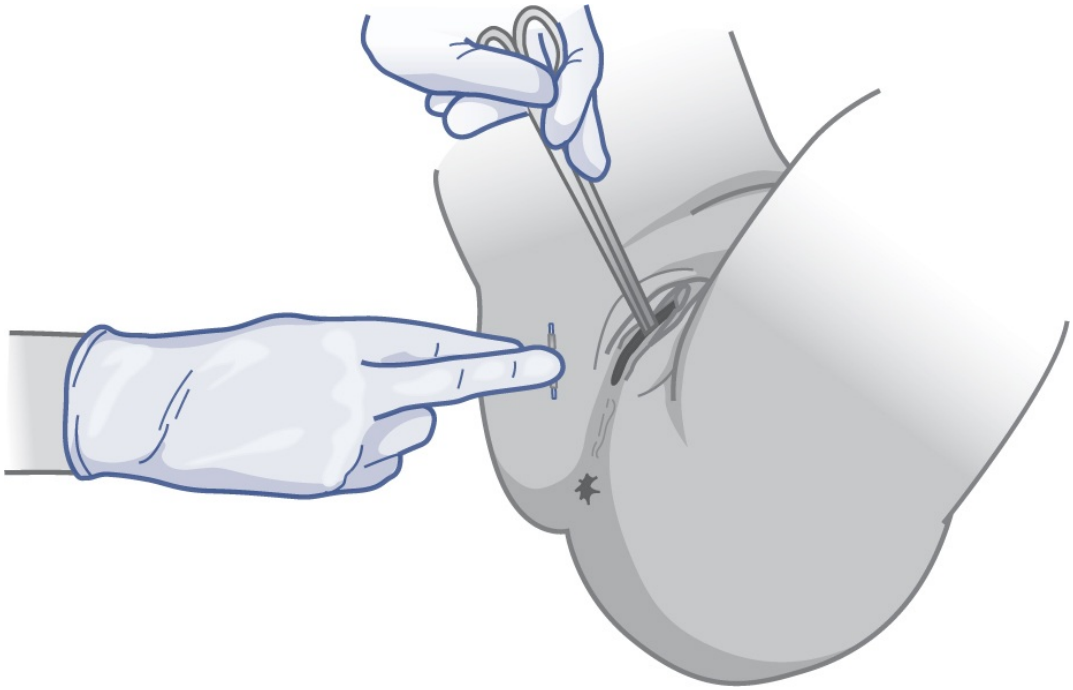

Figure 16C-23 Manually inserting the IUD with a retractor in place if needed.

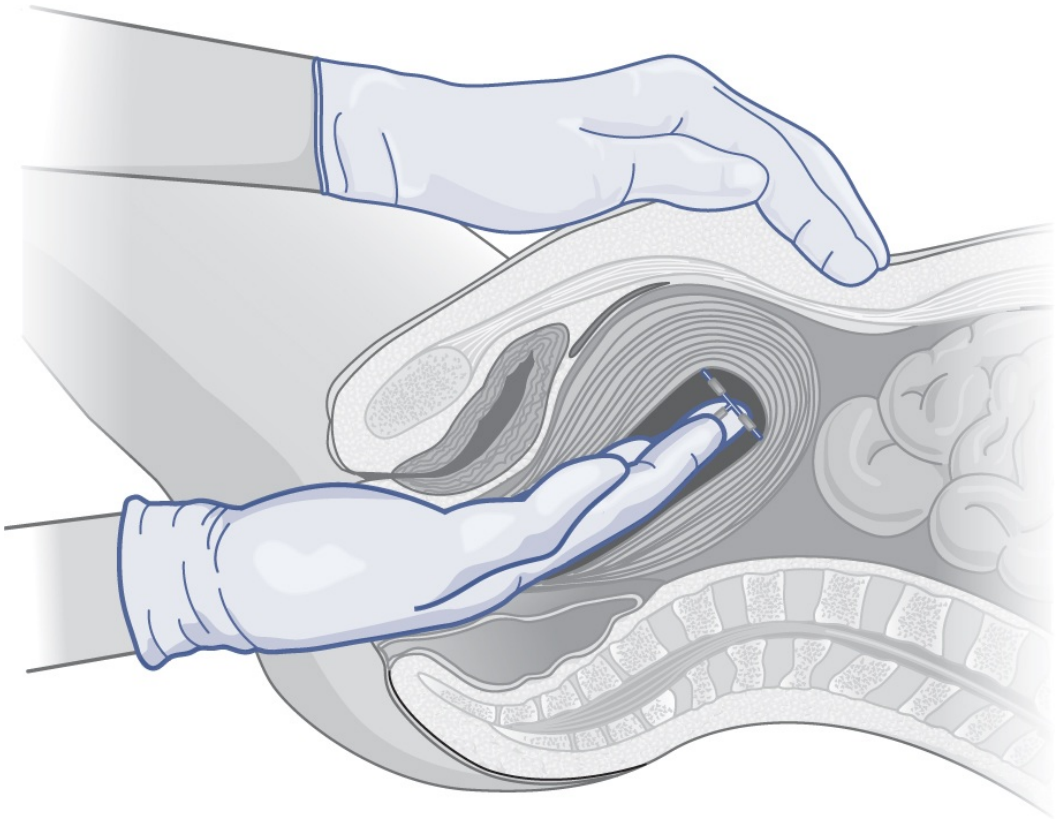

Figure 16C-24 Stabilizing the uterus while manually placing the IUD in the fundus.

Health Education

After insertion of an IUD, health education includes teaching about how to feel for and identify the threads in the vagina (**Figure 16C-25**). A sample IUD with strings the woman can feel may be used as a teaching aid. Any significant variations such as unusual lengthening of the strings, which may indicate nonfundal placement, or feeling any part of the plastic of the device should be reported, as these findings may suggest partial expulsion of the IUD. Some new IUD users may be concerned that either tampon or menstrual cup use will increase the rate of expulsion, though this has not been found to be the case.[24]

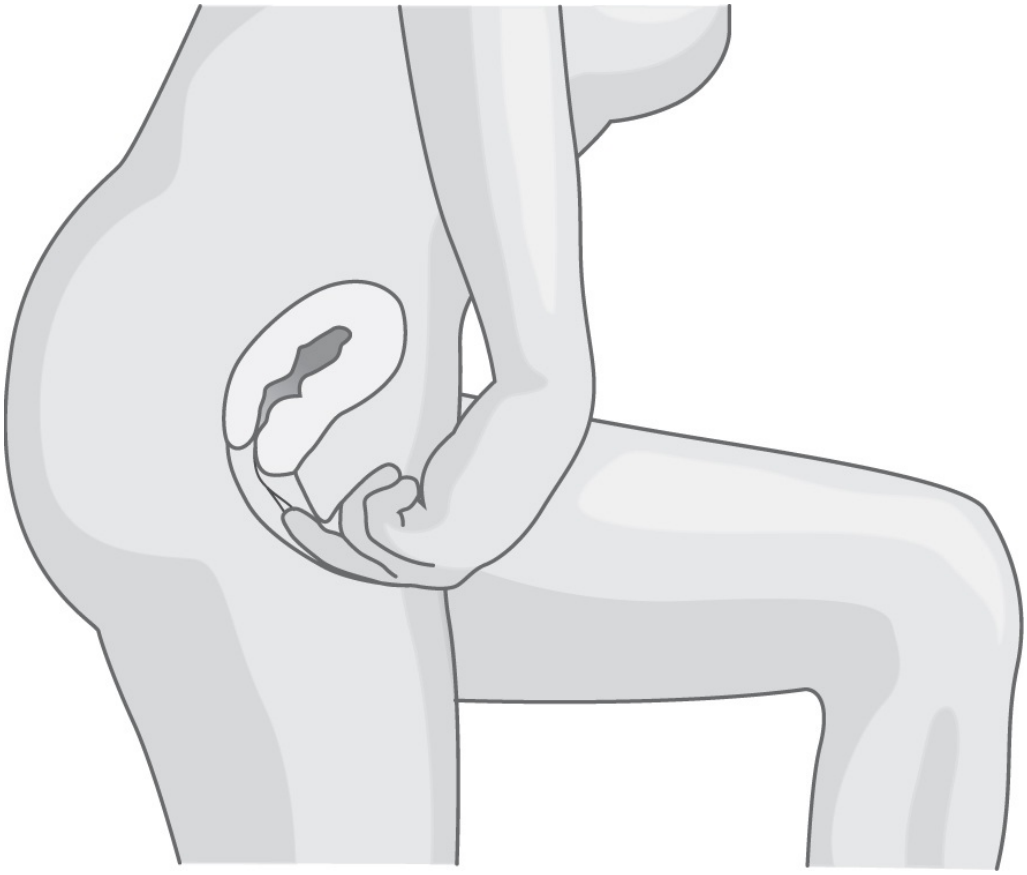

Figure 16C-25 How to feel for IUD threads or strings.

After insertion of the copper IUD, no no additional contraception is required, as this method is immediately effective.[3] The same is true for the LNG-IUD if inserted within 7 days of the onset of menses. However, abstinence or additional contraception should be used for 7 days after initiation of LNG-IUD if inserted more than 7 days after the onset of menses.[3] All women should be counseled that IUDs do not provide protection from STIs.

The mnemonic "PAINS" is often shared after IUD insertion as an easy-to-use reminder of potentially significant deviations that should be reported (**Table 16-5**). In all cases, women should be encouraged to contact their provider with questions or concerns, although most women using an IUD do not experience major side effects. Among the most common side effects of all IUDs are menstrual irregularities. In some women, especially those using a copper IUD, dysmenorrhea or heavy bleeding may occur; the use of nonsteroidal anti-inflammatory drugs (NSAIDs) provides relief from either or both of these symptoms. Conversely, those women using an LNG-containing IUD may experience decreased menstrual flow or amenorrhea. However, sudden amenorrhea for any woman with an IUD suggests pregnancy, and she should be evaluated for this condition.

Follow-Up Care

Usually a follow-up visit is scheduled for women 4 to 6 weeks post IUD insertion. At that

time, any concerns the woman has can be addressed and a speculum examination can be performed to confirm that the threads are visible. After the initial post-insertion visit, future appointments are made based on routine screening guidelines or other risk factors. The only other IUD-related visit should be at the time when the duration of the IUD expires (e.g., Skyla at 3 years); at that point, a new device can be inserted if desired.

Removal of an Intrauterine Device

Common reasons for requesting removal of an IUD include desire for a pregnancy, unnecessary troublesome side effects of menstrual irregularities, establishment of menopause, or end of duration of effectiveness. The removal procedure is the same for all of the IUDs.

Procedure for Removing an Intrauterine Device

1. Removal of an IUD requires clean, but not sterile technique.
2. Removal is a rapid procedure.
3. Constant communication should occur between the clinician and the woman during the removal.
4. After the woman assumes a lithotomy or dorsal position of comfort, perform a bimanual pelvic examination to determine the position of the uterus. Next, insert a speculum; it may be warmed and/or lubricated prior to insertion.
5. Visualize the IUD threads, and use an instrument (e.g., ring forceps) to grasp the threads.
6. Guide the IUD threads downward toward the clinician until the IUD emerges through the cervix and vagina. Some women may feel a sharp cramp as the device passes the cervix, but most report no discomfort or little sensation.
7. Most clinicians show the device to the woman to reassure her it has been removed.
8. The removal is now completed. If the woman desires a new device, it can be immediately placed by following the procedure presented earlier in this appendix.

CHAPTER

17

Hormonal Contraception

MARY C. BRUCKER

The editors acknowledge Michelle R. Collins, Sharon L. Holley, Tonia L. Moore-Davis, and Deborah L. Narrigan, who were authors of this chapter in the previous edition.

Introduction

In 1960, the first oral contraceptive was approved by the U.S. Food and Drug Administration (FDA), and thus began the story of modern hormonal contraception in the United States.[1] The "pill," as it came to be known colloquially, enabled women to make choices regarding pregnancy, when and if they desired. Several clinical sites participated in the initial testing of the "pill." One of these clinical sites was the Frontier Nursing Service, where over a 3-year period in the late 1950s, oral contraception was investigated and research demonstrated the advantages of the midwife as the primary provider of contraceptive care.[2]

Hormonal methods of contraception include both combined oral contraceptives (COCs) and progestin-only pills (POPs), and non-oral hormonal formulations, including rings, patches, and subdermal implants. In addition, intrauterine contraceptive devices impregnated with a progestin are marketed; because of the presence of the hormone in these devices, they are discussed in this chapter, rather than in the *Nonhormonal Contraception* chapter. The manufacturers of these agents—which have the brand names Liletta, Mirena, Skyla, and Kyleena—use the terms intrauterine system (IUS) and intrauterine device (IUD) interchangeably in their descriptions. Other sources use the term intrauterine contraceptive device (IUCD). For consistency, IUD is the abbreviation used throughout this chapter for intrauterine devices.

Hormonal contraceptives generally are subclassified as either a short-acting reversible contraceptive (SARC) or a long-acting reversible contraceptive (LARC).[3]

Evolution of Hormonal Contraceptive Methods

For the last several decades, modifications of the types of the hormones and doses in contraceptives have been made in attempts to decrease the adverse effects associated with these agents while maintaining their contraceptive effectiveness. It has been estimated that 1 million pregnancies occur annually among women who say they are taking oral contraceptives, with many of these pregnancies attributable to inconsistent use of the agents. More than 50% of women using COCs miss two or more pills during the second month they use them.[4] Methods that are less dependent upon daily user action are more effective as a contraceptive. Therefore, in recent years, the focus in contraception has shifted away from development of new estrogens or progestins for oral contraceptives and toward development of alternative routes for delivery of hormones. Newer novel approaches include transdermal patches, IUDs, subdermal implants, and injectable products. Contraceptive options other than the oral formulations offer women a wider variety of choices for the hormone delivery method and duration of action with lower maintenance.

Several hormonal methods combine estrogen and a progestin, whereas others contain only progestin (**Table 17-1**). Appreciating which hormones are present in a particular contraceptive method can assist the provider and woman in anticipating both the common side effects and the rare adverse effects associated with that method.

Levonorgestrel IUD (LNG-IUD)		X

Mechanism of Action of Hormonal Contraceptives

Hormonal contraceptives have many biologic effects.[5-8] The primary mechanism of action with regard to contraception is inhibition of ovulation and changes to cervical mucus so that sperm transport is impaired. Fallopian tube motility is also altered, which inhibits sperm motility and the endometrium becomes atrophic. Hormonal methods of contraception contain synthetic steroidal hormones that act centrally, altering the functions of the pituitary gland and hypothalamus. Although it may seem counterintuitive that supplementing natural progesterone and estrogen with synthetic analogues of the same hormones can prevent ovulation and impede sperm transport, this remains the most common mechanism of action for hormonal contraceptives.

Mechanism of Action of Estrogen

A major action of estrogen in hormonal contraception is to stabilize the endometrium, thereby providing cycle control and minimizing breakthrough bleeding.[5] Estrogen also suppresses gonadotropin-releasing hormone (GnRH) and pituitary release of both GnRH and follicle-stimulating hormone (FSH). These actions inhibit development of a dominant follicle and subsequent ovulation. Several pharmacologic formulations of estrogen exist. The major estrogen used in hormonal contraception is ethinyl estradiol. Although popular in years past, mestranol is a less potent type of estrogen that is now found solely in the few remaining 50 microgram COCs.[6]

Estrogen is a lipophilic intracellular hormone that has many physiologic effects. For example, estrogen increases the plasma concentrations of clotting factors, which is why it is associated with an increased risk for venous thromboembolism (VTE).[7] Estrogen also increases insulin resistance, very low-density lipids, high-density lipids and may cause a slight rise in blood pressure. Although these estrogen effects could be potentially dangerous for women who have an a priori risk for VTE or cardiovascular disease, today's COCs have forms of estrogen and low doses that are associated with markedly lowered to negligible risks.

Ethinyl estradiol is metabolized by the cytochrome P450 (CYP450) enzymes, which are highly polymorphic. Many drugs can inhibit or accelerate the function of CYP450 enzymes. More than 150 drugs have been suggested as agents that have drug interactions with ethinyl estradiol. These drug interactions potentiate or inhibit the effects of either estrogen or the effect of the interacting drug. Concomitant use of ethinyl estradiol and any other pharmacologic agent should be individually evaluated. Clinically relevant drug interactions are discussed later in this chapter.

Mechanism of Action of Progestins

Unlike estrogen, in which a single type (ethinyl estradiol) is used almost exclusively for contraception, several progestins are prescribed. Progestins include both synthetic and natural progesterone. Progestins include estranes, gonanes, and pregnanes that are derived from 19-nortestosterone or 19-norprogesterone as well as the first non-testosterone agent drospirenone

(**Figure 17-1**). All synthetic progestins bind to the progesterone receptor. In addition, they have varying affinities for androgen, glucocorticoid, mineralocorticoid, and estrogen receptors. The side effects of different progestins are largely related to their individual affinity for these other receptors. In contraceptive methods, progestins inhibit the release of luteinizing hormone (LH), thereby preventing the LH surge necessary for ovulation. Additional mechanisms of action are theorized to include thickening of the cervical mucus and delayed sperm transport. Progestin-only agents lack the endometrial stabilization from estrogen, which increases irregular vaginal bleeding.

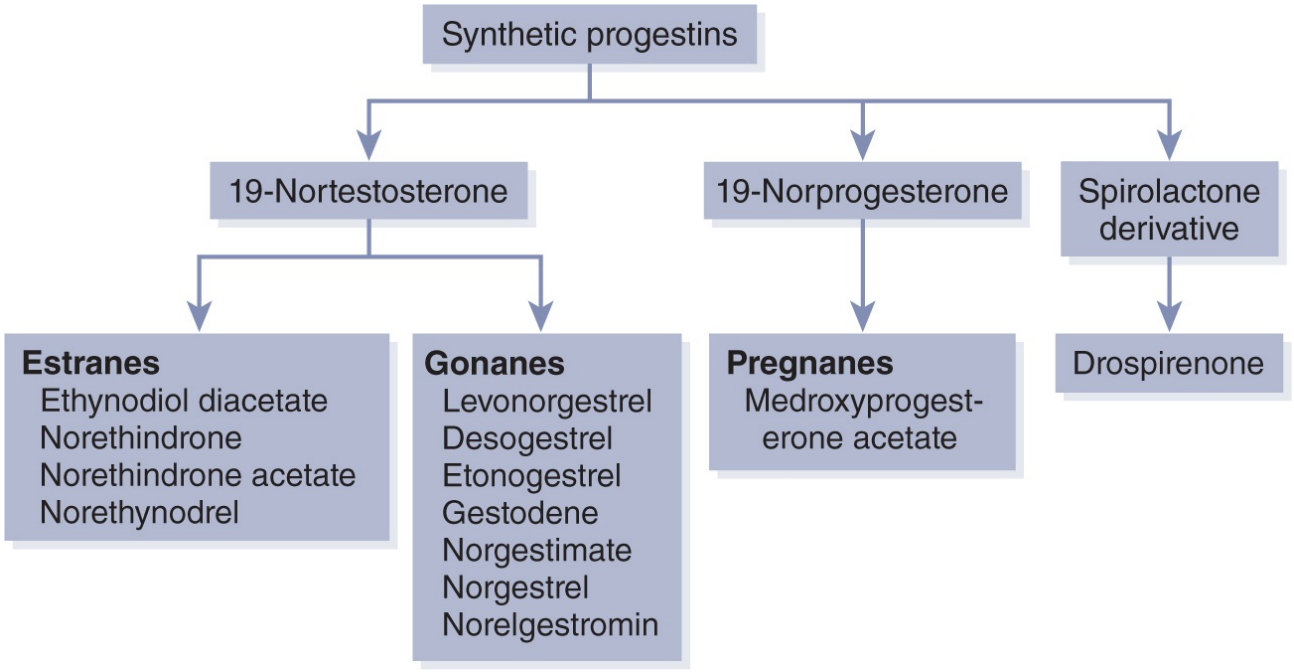

Figure 17-1 Progestins used for contraception.

General Considerations for Hormonal Contraceptives

When providing women with the information they need to make a choice about hormonal contraception, several topics are reviewed including: effectiveness, how long it takes for fertility to return when the agent is discontinued, non-contraceptive benefits, possible drug interactions, danger signs and contraindications.

Effectiveness

Hormonal contraceptives are the most effective method of all reversible contraception products. **Table 17-2** summarizes the effectiveness of the hormonal methods, with the least effective options listed first.[9] Because of their lack of dependency upon user actions, LARCs —unsurprisingly—are more effective than SARCs.

Table 17-2	Effectiveness of Hormonal Contraceptive Methods	
Contraceptive Method	**Type of Method**	**Unintentional Pregnancy (%)[a]**
Oral method (pills containing either combined estrogen/progestin or progestin only)	SARC	9
Transdermal patch	SARC	9
Contraceptive ring	SARC	9
Contraceptive injections	SARC	6
Levonorgestrel IUD	LARC	0.2–0.8[b]
Subdermal implants	LARC	0.05[c]

Abbreviations: IUD, intrauterine device; LARC, long-acting reversible contraceptive; SARC, short-acting reversible contraceptive.

[a] Approximate percentage of women experiencing an unintentional pregnancy during the first year of use.

[b] Based on which IUD is studied.

[c] Based on studies of Implanon. Nexplanon is expected to have similar effectiveness.

Data from Trussell J, Guthrie KA. Choosing a contraceptive: efficacy, safety and personal considerations. In: Hatcher RA, Trussell J, Nelson AL, Cates W, Kowal D, Policar MS, eds. *Contraceptive Technology.* 20th ed. New York, NY: Ardent Media; 2011:45-75.[9]

Return to Fertility

For most hormonal methods, including LARCs, return to fertility is relatively rapid, rarely taking more than a few months.[10] The exception is depot medroxyprogesterone acetate (DMPA), for which an average of 9 months usually passes after the last injection before normal fertility resumes. **Table 17-3** lists the length of time for the average woman to attain fertility after discontinuation of specific hormonal methods.[9,10]

Table 17-3	Average Length of Time for Return to Fertility After Discontinuation of Contraceptive Method
Contraceptive Method	**Average Length of Time for Return to Fertility**
Combined oral contraceptives	1–3 months
Progestin-only pills	1–3 months
Transdermal patch	1–3 months
Contraceptive ring	1 week–1 month
Contraceptive injections	9 months after last injection
Levonorgestrel IUD	Immediately upon removal
Subdermal implants[a]	1–3 weeks after removal[a]

[a] Based on studies of Implanon. Nexplanon is expected to have similar effectiveness.

Based on Trussell J, Guthrie KA. Choosing a contraceptive: efficacy, safety and personal considerations. In: Hatcher RA, Trussell J, Nelson AL, Cates W, Kowal D, Policar MS, eds. *Contraceptive Technology.* 20th ed. New York, NY: Ardent Media; 2011:45-75[9]; Speroff L, Darney P. *A Clinical Guide for Contraception*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2010.[10]

Noncontraceptive Benefits

Discussion of hormonal contraceptives often focuses on side effects and adverse effects associated with their use, rather than on their benefits. Although adverse effects are always reviewed, most of the side effects are minor, and serious adverse effects are rare. However, a number of noncontraceptive benefits also are associated with these agents, as described in **Table 17-4**. Counseling about the noncontraceptive benefits of these products should be balanced with discussion of their untoward effects.[11,12]

Table 17-4	Noncontraceptive Benefits of Hormonal Contraceptives
Reduction of menstrual-associated conditions:	
Dysmenorrhea	
Heavy menstrual flow	
Irregularity	
Menstrual migraines	
Perimenopausal symptoms (e.g., hot flashes)[a]	
Premenstrual syndrome[a]	
Therapeutic use—treatment of women with the following conditions:	
Bleeding associated with fibroids	
Pelvic pain associated with endometriosis	
Acne[a]	
Decreased risk of the following conditions:	
Anemia (from uterine bleeding)	

Colorectal cancer[a]
Endometrial cancer[a]
Hirsutism[a]
Osteoporosis[a]
Ovarian cancer[a]
Lifestyle (drug-induced) amenorrhea[b]

[a] Associated with estrogen and progestin hormonal contraceptives rather than progestin-only contraceptives.

[b] Menstrual suppression may be seen as a benefit to some women, although other women desire a monthly menses as personal assurance that they are not pregnant.

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 110: noncontraceptive uses of hormonal contraceptives. *Obstet Gynecol.* 2010;115:206-218. [Reaffirmed 2016][11]; Hilliard PA. Menstrual suppression: current perspective. *Int J Womens Health*. 2014;6:631-637.[12]

Contraindications to Use of Hormonal Contraceptives

Although most women can use hormonal contraceptives, there are some situations in which these agents are not recommended or are even contraindicated. Contraindications to hormonal contraceptive use are primarily contraindications to estrogen, progestins, or both, and include —most notably—breast cancer and pregnancy. The list of contraindications to estrogen is longer than the list of contraindications to progestins. For example, women with a history of cardiovascular disease or coagulopathy should not use estrogen-containing products. Contraindications defined as Category 3 or 4 in the U.S. Medical Eligibility Criteria for Contraceptive Use are found in **Table 17-5**.[13]

Table 17-5	**Contraindications for Hormonal Contraceptives Based on Category 3 or Category 4 Status in U.S. Medical Eligibility Criteria for Contraceptive Use**
Absolute Contraindications (U.S. MEC for Contraceptive Use Category 4)	**Relative Contraindications (U.S. MEC for Contraceptive Use Category 3)**
Combined Oral Contraceptives (COCs)	
Current breast cancer	Anticonvulsant therapy
Cirrhosis (severe)	Antiviral therapy with ritonavir-boosted protease inhibitor
DVT history of and not on an anticoagulant or acute DVT or PE or DVT/PE and established anticoagulation for at least 3 months but still high risk	Breast cancer history and no evidence of current disease for 5 years
Diabetes mellitus: nephropathy/retinopathy/neuropathy[a] or other vascular disease or diabetes of > 20 years' duration[a]	*Breastfeeding and < 1 month postpartum*
Headache (migraine) with aura	DVT history and low risk for recurrent DVT/PE
History of stroke	Gallbladder disease
Hypertension with systolic ≥ 160 mm Hg or diastolic ≥ 100 mm Hg or vascular disease	*Headaches (migraine) without aura < 35 years[b]*
Ischemic heart disease (current or history)	History of bariatric surgery with malabsorptive procedures
	Hypertension adequately controlled or systolic 140–159 mm Hg or diastolic 90–99 mm Hg
	Inflammatory bowel disease[b]
	Postpartum cardiomyopathy ≥ 6 months

Known thrombogenic mutations Liver tumors: hepatocellular or malignant *Multiple risk factors for atherosclerotic cardiovascular disease*[a] *Peripartum cardiomyopathy (< 6 months) or moderate impaired cardiac function* *Postpartum < 21 days* *Smoking at age ≥ 35 years and ≥ 15 cigarettes a day* [c] Solid organ transplant, complicated Stroke: history of cerebrovascular accident Systemic lupus erythematosus positive or unknown antibodies Valvular disease, complicated *Viral hepatitis acute*[a,b]	Postpartum and breastfeeding with additional risk factors for venous thromboembolism Rifampin or rifabutin therapy *Smoking at age ≥ 35 years and < 15 cigarettes a day* [c]
Contraceptive Implant	
Current breast cancer	Breast cancer history and no evidence of current disease for 5 years Cirrhosis (severe) *Headaches (migraine) without aura < 35 years*[b] History of bariatric surgery with malabsorptive procedures Ischemic heart disease (current or history) Liver tumors: hepatocellular or malignant Solid organ transplant, complicated Systemic lupus erythematosus positive or unknown antibodies Unexplained vaginal bleeding suspicious for serious condition before evaluation
Depot Medroxyprogesterone Acetate (DMPA)[d]	
Current breast cancer *Long-term use of corticosteroid therapy in women with a history or risk of nontraumatic fractures*	Breast cancer history and no evidence of current disease for 5 years Cirrhosis (severe) *Diabetes mellitus: nephropathy/retinopathy/neuropathy or other vascular disease or diabetes of > 20 years' duration*[a]
Depot Medroxyprogesterone Acetate (DMPA)[d]	
	Headaches (migraine) without aura < 35 years[b] *Hypertension with systolic ≥ 160 mm Hg or diastolic ≥ 100 mm Hg or vascular disease* Ischemic heart disease (current or history) Liver tumors: hepatocellular or malignant *Multiple risk factors for atherosclerotic cardiovascular disease*[a] *Rheumatoid arthritis on immunosuppressive therapy*[b] Stroke: history of cerebrovascular accident Systemic lupus erythematosus positive or unknown

	antibodies or severe thrombocytopenia Unexplained vaginal bleeding suspicious for serious condition before evaluation
Levonorgestrel Intrauterine Device	
Current breast cancer Cervical cancer awaiting treatment Gestational trophoblastic disease with persistency elevated beta-hCG levels or malignant disease, with evidence of or suspicion of intrauterine disease *Pelvic inflammatory disease, current*[b] Pregnancy *Sexually transmitted disease with current purulent cervicitis or chlamydial infection or gonococcal infection*[b] *Post septic abortion or birth*[b] *Pelvic tuberculosis*[b] *Unexplained vaginal bleeding*[b]	*Anticonvulsant therapy*[b] *Antiviral therapy with ritonavir-boosted protease inhibitor*[b] Breast cancer history and no evidence of current disease for 5 years Cirrhosis (severe) *Headaches (migraine) without aura < 35 years*[b] *Ischemic heart disease (current or history)*[b] Liver tumors: hepatocellular or malignant *Sexually transmitted infections increased risk*[b] Solid organ transplantation complicated for initiation Stroke: history of cerebrovascular accident Systemic lupus erythematosus positive or unknown antibodies
Progestin-Only Pills (POPs)	
Current breast cancer	Anticonvulsant therapy Antiviral therapy with ritonavir-boosted protease inhibitor Breast cancer history and no evidence of current disease for 5 years *Headaches (migraine) without aura < 35 years*[b] History of bariatric surgery with malabsorptive procedures Ischemic heart disease (current or history) Liver tumors: hepatocellular or malignant Rifampin or rifabutin therapy *Stroke: history of cerebrovascular accident*[b] Systemic lupus erythematosus or unknown antibodies

Abbreviations: DVT, deep vein thrombosis; hCG, human chorionic gonadotropin PE, pulmonary embolus.

[a] Listed as both category 3 and 4.

[b] For initiation of the method, Category 2 or 3 for continuation.

[c] Because smoking is often underreported, the American College of Obstetricians and Gynecologists recommends any woman older than 35 years who smokes should not take COCs.

[d] DMPA is not recommended for women who plan a pregnancy within one year because the return of ovulation after discontinuing this agent can be delayed.

Based on Curtis KM, Tepper NK, Jatlaoui TC, et al. U.S. Medical eligibility criteria for contraceptive use, 2016. *MMWR Recomm Rep.* 2016;65(3):1-103. Available at: https://www.cdc.gov/reproductivehealth/contraception/pdf/summary-chart-us-medical-eligibility-criteria_508tagged.pdf. Accessed August 27, 2017.[13]

Women seeking to use hormonal contraceptives should always be screened for the presence of any contraindications first; if any are present, alternative contraceptive methods should be discussed and recommended. The U.S. Medical Eligibility Criteria (U.S. MEC)

recommendations, which are summarized in the *Family Planning* chapter, include specific contraceptive eligibility guidelines for women who have a variety of disorders and health conditions.[13] The U.S. MEC for Contraceptive Use are also available as an application for smartphones, and on the Centers for Disease Control and Prevention (CDC) website.

Side Effects and Adverse Effects of Hormonal Contraceptives

In general, most randomized controlled trials of drug methods are placebo controlled; that is, these studies explore the risk of use of an agent compared to the risk of not using that agent. One of the challenges in the study of hormonal contraceptives is that ethics precludes such experimentation. Therefore, the majority of studies on the effects of hormonal contraceptives lack the rigor of randomized controlled trials. In addition, contraceptive clinical trials generally focus on healthy women and usually exclude adolescents, women with pre-existing conditions, and even women who are outside the normal parameters for weight. As a result, application of data from studies to everyday clinical practice is challenging. Because the participants in clinical trials are healthy women, some risks may not become apparent until large postmarketing populations adopt the methods. Despite these limitations, hormonal contraceptives have been the subject of extensive research and are considered quite safe for healthy women. The U.S. MEC for Contraceptive Use, as described in the *Family Planning* chapter, provide guidelines for use of the different hormonal methods based on clinical trials as well as national and international studies.[13] In 2016, the CDC published a set of recommendations on some common issues related to use of contraceptives as a companion to the U.S. MEC for Contraceptive Use, as discussed in the *Family Planning* chapter.[13]

Side Effects of Estrogen and Progestins in Contraceptives

Both estrogens and progestins have multiple biologic effects.[5,14] Given the different forms, doses, and routes of administration available, it can be difficult to determine which side effect is related to estrogen and which is related to progestin in a particular product. In general, the most common side effects of estrogen are headaches and nausea. Bloating, leukorrhea, chloasma, and increased cholesterol in bile (which increases the risk of gallstones) are also reported.

All progestin-only methods are safer than the combined products but progestins are associated with bleeding irregularities including amenorrhea. Common side effects of progestins include acne, decreased libido, pruritus, mood changes, premenstrual-type symptoms such as edema, and transient depression, which is usually mild. DMPA is associated with a decrease in bone mass or bone mineral density that is thought to be reversible in women who are not in the perimenopausal period. Studies that have evaluated the effect of progestin on mood changes and depression have conflicting findings, and depression is not a contraindication for use of progestin containing contraceptives. That said, when a woman reports mood changes associated with progestin, an alternate form of contraception should be considered.

Both estrogen and progestin methods may have similar or overlapping side effects,

especially during the first few months of use. Headaches and nausea may be more common with estrogen containing pills, but nausea is often encountered with any oral method. Other problems that women may report with hormonal contraceptives include breast tenderness, acne, and premenstrual symptoms. The latter two are most likely to occur among women using progestin-only methods.

Adverse Effects of Hormonal Contraceptives

Estrogen use increases the risk for some rare, but severe, adverse effects. Notably, estrogen is associated with an increased risk for cardiovascular events such as stroke and myocardial infarction, and thromboembolic events such as deep vein thrombosis (DVT). In addition, estrogen use slightly increases the risk of developing breast cancer. Women who smoke, are older than age 35 years and who use estrogen are at a higher risk for myocardial infarction. The risk of breast cancer is low among reproductive-age women, but evidence indicates that estrogen and progestin contraceptives increase that risk; thus, use of these agents should be carefully considered for women with a personal history of breast cancer. Some progestin-only methods also list breast cancer as a contraindication for use, even though the evidence is not as strong for this proscription. An increased risk of VTE may be associated with use of certain progestins. For example, the risk of venous thrombosis associated with combined oral contraceptives containing the progestins gestodene, desogestrel, and drospirenone plus 30–35 micrograms of ethinyl estradiol is approximately 50% to 80% greater than the risk associated with the same estrogen combined with levonorgestrel.[8] Some studies have suggested that progestins also are associated with an increased risk of breast cancer, although these studies were primarily conducted among perimenopausal/postmenopausal women and the proposed risk is the product of extrapolation. Relationships between progestins and cardiovascular risk and bone health continue to be studied.

Counseling Women About Side Effects and Adverse Effects of Hormonal Contraceptives

The midwife can assist the woman in viewing her individualized risks and benefits. It is important to remember that hormonal contraceptives do not protect a person from acquiring a sexually transmitted infection (STI). Condoms are the only contraceptive method that serves the dual purpose of contraception and STI protection. For example, a woman may decide that the benefits in terms of the reliability and effectiveness of a hormonal method for preventing pregnancy outweigh a relatively minor increase in her risk for a specific condition. Consideration of risk of a condition also should be viewed in light of risk of pregnancy with a less reliable method. For example, the risk of DVT is known to increase with use of estrogen-containing contraceptives. However, for women who do not have a history of coagulopathy or medical disorder that increases her a priori risk for coagulopathy, the risk of DVT associated with estrogen-containing contraceptives is less than the risk of developing DVT during pregnancy. Thus, shared decision making and a careful cost–benefit assessment are essential steps prior to prescribing any hormonal contraception unless an absolute contraindication

exists.

Drug–Drug Interactions

All hormonal contraceptive methods are considered to have potential drug interactions, including implants and IUDs, although their relationships are controversial. The effect of one or both of the agents can be potentiated; one or both can be inhibited; one can be inhibited and the other potentiated; or nothing clinically relevant can occur. Most of these effects occur because the same liver enzymes in the CYP450 family metabolize the two drugs, and one or the other drug alters the function of the enzymes, thereby affecting metabolism of the other agent.

Many drug interactions occur secondary to use of pharmacologic agents that are CYP450 enzyme inducers (i.e., they potentiate the effect of the enzyme, which leads to rapid metabolism of the other drug). Fortunately, healthy women do not commonly use most of the drugs that decrease contraceptive effectiveness. The majority of known drug interactions occur with oral (rather than non-oral hormonal) contraceptives. Nevertheless, the midwife should be particularly alert for potential interactions if a woman is taking medications to treat tuberculosis, a seizure disorder, a clotting disorder, human immunodeficiency virus (HIV), or mild depression.

Among the drugs that have been suggested to decrease the effectiveness of COCs are anti-infectives (specifically rifampin [Rifadin]), anticonvulsants (e.g., carbamazepine [Tegretol], phenytoin [Dilantin], phenobarbital [Luminal]), antifungals (specifically griseofulvin [Fulvicin]), protease inhibitors (e.g., saquinavir [Invirase], ritonavir [Norvir]), and non-nucleoside reverse transcriptase inhibitors (e.g., efavirenz [Sustiva], nevirapine [Viramune]).[13] St. John's wort—a nutritional supplement marketed as a treatment for mild depression—also has been found to decrease the effectiveness of COCs. Simultaneous administration of oral contraceptives with an over-the-counter (OTC) antacid (e.g., Maalox, Mylanta) can result in decreased contraceptive effectiveness due to impaired absorption of the hormones.

Several of these agents also have been suggested to affect the effectiveness of POPs—specifically, rifampin, anticoagulants, antiretrovirals, and St. John's wort. The majority of these drug interactions are associated with breakthrough bleeding and not necessarily pregnancy, but a secondary contraceptive method is recommended for women using any of the aforementioned agents. In addition, anticoagulants may impair steroid metabolism and increase the side effects of oral contraceptives.

Pharmacogenomics also may play a role in drug interactions with contraceptives, and more information is needed in this area. A history of problems with a particular method in the past can direct the choice of a new method. It is always a good practice to obtain a complete history from a woman regarding medications (both prescribed and OTC agents), botanicals, and nutritional supplements and to verify whether any potential drug interaction exists, as information about such interactions is constantly evolving.

Clinical Evaluation for Women Initiating or Changing a Hormonal Contraceptive Method

This section reviews clinical considerations that apply to all hormonal contraceptives. **Table 17-6** summarizes the components of management for any woman initiating or changing a contraceptive method.

Table 17-6 Care of Women Initiating or Changing a Hormonal Contraceptive Method

Assure that no contraindications exist for the chosen method.
If the method is Category 3 according to the U.S. Medical Eligibility Criteria, discuss both risks and benefits with the woman so she can make an informed choice.
Obtain reasonable assurance that the woman is not pregnant.
Verify that the method to be initiated is one that the woman desires and is likely to use correctly. Because hormonal methods influence menstrual flow, it is wise to explore the woman's feelings about decreased flow, irregular bleeding, and amenorrhea.
Verify the woman is not taking any drugs likely to interact with hormonal contraceptives.
For all women using hormonal contraceptives, review the following points:
Signs or symptoms indicating serious complications (danger or warning signs)
Common side effects
Effect on menstrual flow
Noncontraceptive benefits
Average time for return to fertility
Lack of protection from sexually transmitted infections
Date and time for follow-up appointment
Health promotion or screening activities as appropriate, separate from contraceptive needs
For all women using a short-acting reversible contraceptive (e.g., daily pills, weekly patch) that is woman dependent, review the following points:
When and how to initiate the method
Back-up or secondary protection when indicated (and additional supplies for occasional use if needed)
How to use the method correctly and continuously
Common mistakes to avoid
What to do if she fails to use the method correctly (e.g., missed pills)
Safe disposal of used contraceptives and packages
Specific information regarding prescriptions, including when to be renewed and general cost
Provide opportunities for the woman to ask questions.

Special Considerations for Hormonal Contraception

Adolescents and Young Women

In most locales, women younger than 18 years are considered minors and cannot give consent for care. However, legal provisions typically exist that allow these individuals to obtain contraception if desired. All methods of hormonal contraception can be appropriate for

adolescents. The FDA has a black box warning that states adolescents should not use DMPA longer than 2 years given the effects on bone density at a time when bone mineralization is maximal. This recommendation is not supported by all professional associations but should be considered when discussing this option with an adolescent who is considering use of DMPA. Some noncontraceptive benefits, such as decrease in acne, menstrual bleeding, and dysmenorrhea, associated with several options can be of particular value to adolescents.[15] The sections of this chapter that review the different methods contain information that is generally appropriate to persons in this age group. Moreover, there is no evidence that adolescents should be denied implants or IUDs. Some evidence suggests that depot medroxyprogesterone may be associated with reversible bone loss or lack of bone growth, but it does not preclude its use in younger women.[16] Parental consent may be required before prescribing hormonal contraception for treatment of acne.

Lesbian, Gay, Bisexual, Queer, Transgender Men

When offering contraceptive services for a person who identifies as lesbian, queer, gay, bisexual, queer (LGBQ) or transgender or gender nonconforming (TGNC), one should focus on sexual behaviors not identity. Gender identity does not predict sexual orientation. Data on the number of transgendered youth are elusive, but these individuals are almost certainly underserved. A transgender male is biologically female and should be offered contraception and preventive care as indicated. Although gender affirming hormone therapy (testosterone) limits fertility, it is not a reliable contraceptive.[15,16] Therefore transgender men who have not undergone gender-affirming surgery such as hysterectomy and who are sexually active may desire contraception. Contraceptive methods such as IUDs and implants that tend to promote amenorrhea may provide pregnancy protection as well as provide an added benefit of privacy for these individuals.

Women Who Are Postpartum and/or Lactating

Hormonal contraception is not contraindicated for a healthy postpartum woman, although the timing at which such contraception is initiated or resumed is controversial for postpartum women who are lactating. Additional discussion of this subject can be found in the *Postpartum Care* chapter.

In general, women who recently have given birth, regardless of whether they are breastfeeding, should delay use of contraceptive methods containing estrogen until at least 21 days after the birth because of the increased risk for venous thrombosis resulting from the hypercoagulable state during pregnancy and the early postpartum period. Progestin-only methods, including implants, injections, and pills, may be initiated earlier than estrogen-containing methods because the former are not associated with thrombotic activity. Timing of postpartum use of DMPA is controversial, although some sites initiate the injections within 5 days of birth or abortion/miscarriage.

The American College of Obstetricians and Gynecologists suggests that either an implant or an IUD can be inserted within 10 minutes after birth.[17] Although there is evidence of a higher

rate of expulsion of the latter, this risk may be outweighed by the benefit.[18,19] The insertion procedure immediately postpartum is the same as that used with a nonpregnant uterus, although the midwife should use caution because the uterine isthmus is much softer and more prone to perforation at this time. IUDs also may be placed following spontaneous or elective abortion, either immediately or at 4 to 8 weeks post abortion/miscarriage.[20,21] The only contraindication to immediate postpartum insertion of an IUD is for women with postpartum sepsis, who should wait until the infection has resolved.[13,17]

Effect of BMI on Contraceptive Effectiveness

Some evidence has been published suggesting that hormonal contraception—particularly pills, patches, and implants—may be less effective among women who are obese compared to their thinner counterparts. However, study results are conflicting. Body weight may be more important than body mass index (BMI) calculations in determining the effectiveness of hormonal contraception, perhaps indicating a metabolic effect associated with the amount of adiposity, circulating volume of blood, or increased metabolic rate found among women who are obese. Additional research is needed in this area.

Studies of women using oral contraceptives suggest that women weighing more than 70 kg (154 pounds) may be at an increased risk of contraceptive failure, although this is not a current contraindication for use.[22,23] Women who desire to use the patch should be informed that a body weight of 90 kg (198 pounds) or more is considered a concern, because clinical trials found a higher risk of pregnancy in women in this weight group, even if they were not obese according to their BMI.[24] Based on this finding, the FDA has published a precaution for women of this weight or greater who use the patch contraceptive method.

No evidence exists that hormonal contraceptive methods cause consistent weight gain in general.[22,23] Adolescents who are overweight prior to using DMPA may be more likely to gain weight while using the progestin-only DMPA, as are adult women who are either of normal weight or overweight. Conversely, adult women who are obese are less likely to gain weight when using DMPA.[25] Adolescents who experience a weight gain of more than 5% of total body weight after 6 months of DMPA use are at risk for continued excessive weight gain; counseling about food intake and regular exercise should be provided to these young women. For any woman, if the weight gain becomes excessive, she should consider alternative methods of contraception if she is unable to control her weight through diet and exercise.

Based on pharmacokinetic studies of serum concentration of etonogestrel, women who are 130% of their ideal body weight may be at risk for decreased contraceptive effectiveness when using subdermal implants, although studies have not found such a decrease in clinical practice.[26] Even if hormonal methods are less effective for this population of women, implants and IUDs remain the most effective reversible methods of contraception.

Women with HIV or at Risk for HIV

More than 250,000 women in the United States are living with HIV infection, approximately 11% of whom are unaware of their status.[27] For those who are aware of their HIV-positive

status, contraception often is a paramount concern due to the risk of perinatal transmission. All hormonal methods are classified into category 1 or 2 in the U.S. MEC for Contraceptive Use, even for women taking antiviral agents that have potential drug–drug interactions with COCs, because the benefits of contraception outweigh the risks of drug–drug interactions.[13]

For women who are HIV negative, there is no evidence that any specific method of contraception is associated with an increased risk of HIV acquisition.[28,29] However, all women who use a non-barrier method, such as a hormonal method, should be counseled that their form of birth control does not offer protection from acquiring or transferring the infection.

Women with Disabilities

Care of women with cognitive or physical disabilities should be comprehensive, and no contraceptive method is medically contraindicated for women in these populations. The provider's goal, regardless of the woman's age, should be to conduct care in a manner that shows respect for the woman during an assessment of her abilities, acknowledges her autonomy, promotes her comfort, and listens to her desires.

Women with cognitive disabilities cannot be characterized based on a single stereotype. Many women have mental health conditions; others are intellectually limited to varying degrees. These women often are vulnerable to sexual coercion or assault. In years past, some women were sterilized against their will essentially for eugenic reasons. Today, the topics of sexuality, menstruation, and contraception need to be customized based on the individual's desires and ability to understand and share in decision making.[30]

Physical disabilities do not indicate a lack of sexual desire. Some changes may need to be made in facilities to accommodate provision of care to women with special needs. Women with some physical challenges may have difficulty with use of vaginal rings or even patches. Menstrual suppression may be desired by women with special cognitive or physical disabilities, but selection of a method that achieves that goal should be in concert with the wishes of an individual woman.[31,32]

Women in the Military

It was reported that in 2015, approximately 200,000 women—almost 15% of the total U.S. female workforce—are active-duty military personnel.[33] Contraception should be available to all of these individuals based on Department of Defense policies. Some of these women are deployed in areas where the working situation presents unique circumstances related to contraception. For example, combat areas tend not to stock methods that require regular use, such as pills, injections, or rings. Extremely hot climates may interfere with patch adherence. Implants and IUDs may be of particular use to these women, especially since they can be at risk for sexual coercion or assault and desire effective contraception. The side effect of amenorrhea may also be a benefit in an area where hygiene becomes a challenge.

Women Who Are Incarcerated

According to the U.S. Bureau of Justice, the fastest-growing correctional population in the United States is women. More than 100,000 women are currently incarcerated in local jails, and the overwhelming majority are women who have been victims of sexual abuse.[34] In addition, sexual victimization can occur within correctional facilities. Thus, women who are incarcerated are at risk for both STIs and pregnancy. Although hormonal contraceptives cannot provide protection from infections, LARCS in particular are the most effective reversible methods and should be offered as a contraceptive option.[35]

Women in the Perimenopausal Period

Age is not a contraindication for use of hormonal contraceptive methods. The exception is any prescription of estrogen-containing pills for the woman who smokes more than 15 cigarettes per day and is 35 years or older. Such a woman has a risk of myocardial infarction far greater than her nonsmoking counterpart. In contrast, COCs can safely be used by nonsmokers who are perimenopausal.

Healthy women in their 40s continue to be sexually active and fertile, even if their degree of fertility is less than when they were younger. An early perimenopausal symptom is irregular menses, which may give women false assurance that they are not ovulating and, therefore, not at risk of pregnancy. In reality, escape ovulation and a subsequent pregnancy can occur unpredictably. Clearly, these women need effective contraception if pregnancy is not desired.

Some perimenopausal women opt for permanent sterilization, but some forms of hormonal contraception provide additional non-contraceptive benefits. COCs can provide relief from many perimenopausal discomforts such as irregular bleeding, hot flashes, and dyspareunia. The levonorgestrel IUD (LNG-IUD) has an FDA indication as a therapy for women experiencing heavy menses. Other contraceptive methods associated with the side effect of amenorrhea also may be of value for perimenopausal women. Notably, there is some controversy regarding use of DMPA for this population because of the potential for decreased bone mass density immediately prior to entering the postmenopausal period, a time during which bone loss is more likely.

For the woman who is in the perimenopausal period, hormonal methods usually mask menopause because of the changes in bleeding patterns. No evidence exists to guide the midwife in deciding when it is best to discontinue a hormonal method; however, many clinicians discontinue the hormone contraceptive method when a woman is 55 years old.[36] At that time, the vast majority of woman are postmenopausal. If desired, a woman at that time might consider hormone therapy. The hormone therapy used to treat perimenopausal symptoms belongs to the same drug categories as hormonal contraceptives (estrogen and progestin), but is not of sufficient potency to provide effective contraception.

Initiation of Hormonal Contraceptives

For decades, midwives and other providers delayed initiation of a hormonal contraceptive method until after a woman's next menstrual period to reassure both the provider and the woman that the woman was not pregnant. Timing in tandem with a menstrual period also represented an attempt to minimize breakthrough bleeding, although this connection has not been proven. Some providers advocated starting a method on the first day of menses, others within 5 days of a menses, and yet others within a week of menses. For years, many clinicians advised women to start oral contraceptives on the Sunday after a menses started. This method was promoted as a strategy to prevent subsequent menses from beginning on a weekend. Although all these approaches to initiation were based on opinion and not evidence, they continue to be used in some practices today.

Quick Start or Same-Day Start

In 2002, a study was published advocating a new initiation method called *Quick Start*. Quick Start is the term used to describe an initiation method in which the woman begins taking oral contraceptives as soon as she gets them, regardless of where she is in her menstrual cycle. The original Quick Start technique was designed for combined oral contraceptives and had the woman take the first pill in the office when the pills were prescribed.

Quick Start was developed in response to consumer desires. As many as 25% of women who were provided with a prescription for contraceptive pills never had it filled, often using another, less reliable method or no method of contraception at all.[37,38] Women were found to be more satisfied when they were able to obtain the contraceptive method they desired in a timely manner. In addition, waiting for a menses is a questionable practice often deemed unnecessary because of the improved reliability of pregnancy tests. Even in the rare event that a woman is pregnant and is inadvertently exposed to contraceptive hormones, there is no evidence of an increase in the risk of miscarriage or any teratogenic effects from hormonal contraceptives. Quick Start was also initially promoted as a way to ensure longer continuation rates when compared to traditional approaches, although only limited evidence supports this effect.

The Quick Start practice has since expanded from its first use at the time oral contraceptives are dispensed. Studies suggest it can be used for initiation of patches, rings, and injections as well as pills.[38,17] **Figure 17-2** provides an algorithm for Quick Start and various other hormonal methods.[39]

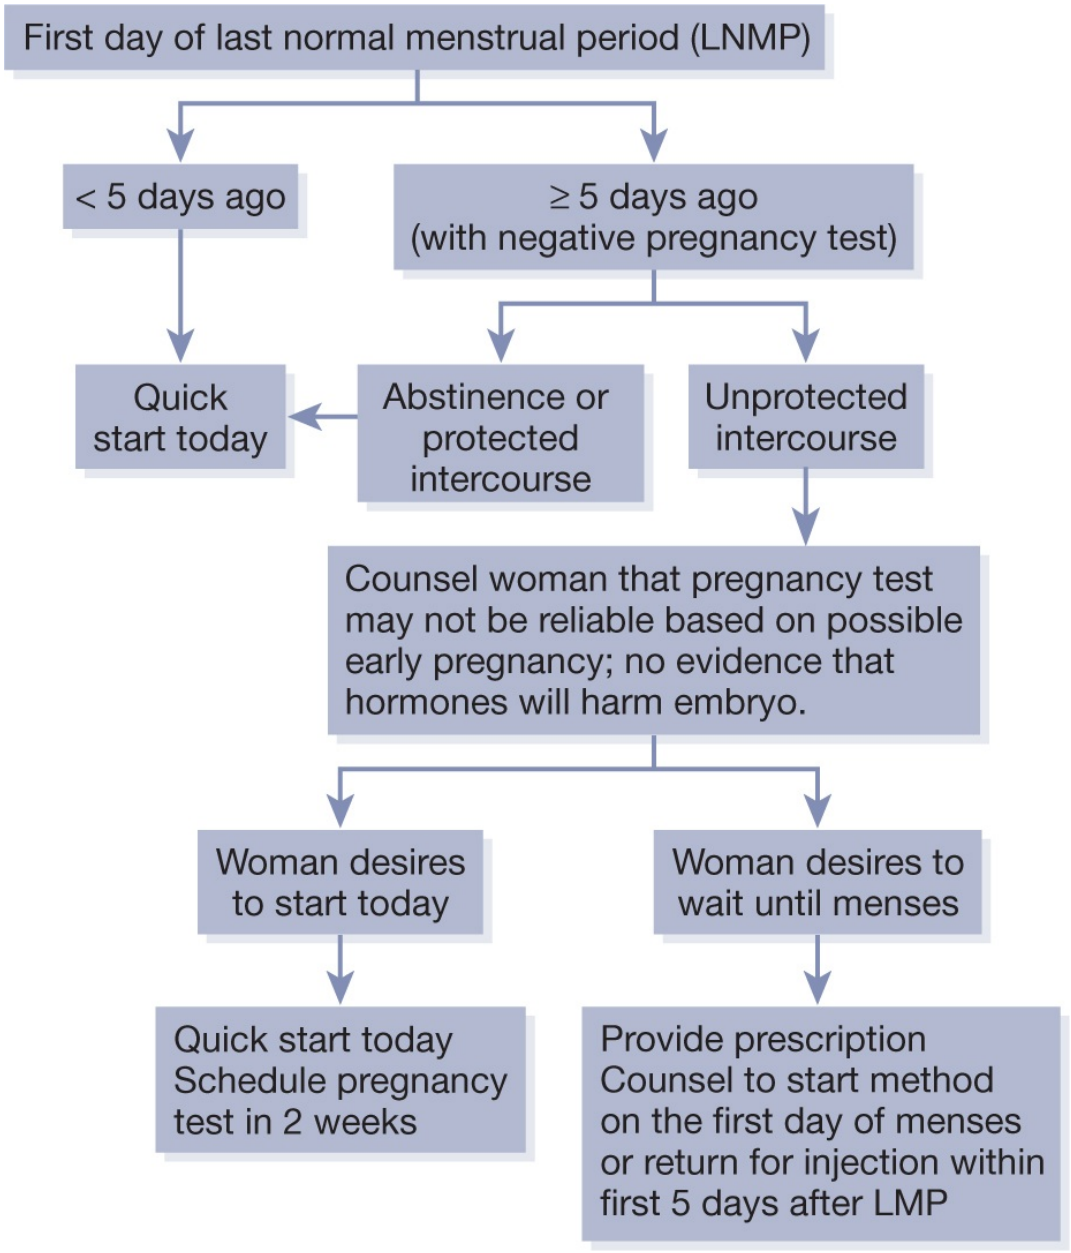

Figure 17-2 Quick Start for pills, patches, rings, and injections.

Modified with permission from The Center for Reproductive Health Education in Family Medicine. Quick Start Algorithm. 2017. www.rhedi.org.[39] Used by permission of RHEDI/Center for Reproductive Health Education in Family Medicine, Montefiore Medical Center, New York City, 2007.

In general, regardless of when a woman begins a hormonal method, there should be some reasonable assurance that she is not pregnant. This assurance can take the form of a normal menses within the last 5 days, a negative pregnancy test, or history indicating that she has not had sexual intercourse since her last menses. Upon initiation of a hormone-based contraceptive method, most women are advised to use a back-up or secondary method until the plasma level of hormone is such that ovulation is suppressed.

Use of Back-up Methods

Evidence regarding the optimal duration of use of back-up contraception is lacking, and most guidelines are empirical at best. Years ago, it was not uncommon to recommend back-up use for a full month after initiation of COCs. Today, a week is more common. Similarly, back-up recommendations for missed pills or patches are not based on scientific studies, but instead represent common clinical practice with extrapolation from some pharmacologic studies.

The suggested back-up method also varies. Some midwives recommend condoms as the back-up, whereas others recommend condoms combined with another spermicidal method such as foam or film. Women who are comfortable with a diaphragm may choose to use that method. As usual, the choice should be based on the considerations outlined in the *Family Planning* chapter and customized to the woman's needs and desires.

Changing from One Hormonal Method to Another

Women may change from one method to another or even discontinue use of contraception for a variety of personal reasons. When a woman desires to switch from one hormonal method to another, her rationale may be based on cost, convenience, desire for increased effectiveness, or a number of other reasons. In this situation, the goal should be to maximize protection from pregnancy. A critical strategy is to avoid any gap between the methods that leaves the woman at risk. Overlapping methods can be a helpful strategy to accomplish this goal. If overlap cannot be arranged, a back-up method can provide temporary contraception. If condoms will be used as the back-up, they offer the added benefit of protection from STIs.

Table 17-7 provides information on how to switch from one hormonal method to another while maintaining maximum protection from pregnancy.[40,41] Women switching from oral contraceptives should follow the guidance in this table and not necessarily finish a package of pills.

Table 17-7 When to Start a New Hormonal Method When Switching from Another Method to Minimize Risk of Pregnancy

Current Method	New Method						
	COC or POP	**Transdermal Patch**	**Vaginal Ring**	**Progestin Injection**	**Implant**	**LNG-IUD**	**Copper IUD**
COC or POP	No gap: take first pill of new pack the day after taking any pill in old pack	1 day before stopping pill	No gap: insert ring the day after taking any pill	7 days before stopping pill	4 days before stopping pill	7 days before stopping pill	Insertion up to 5 days after stopping pills
Transdermal Patch	1 day before stopping patch		No gap: insert ring same day stopping patch	7 days before stopping patch	4 days before stopping patch	7 days before stopping patch	Insertion up to 5 days after stopping patch
Vaginal Ring	1 day before stopping ring	2 days before stopping ring		7 days before stopping ring	4 days before stopping ring	7 days before stopping ring	Insertion up to 5 days after stopping ring
Progestin Injection	Any day up to 15 weeks after injection	Any day up to 15 weeks after injection	Any day up to 15 weeks after injection		Any day up to 15 weeks after injection	Any day up to 15 weeks after injection	Insertion up to 16 weeks after last injection
Implant	7 days before implant removed	7 days before implant removed	7 days before implant removed	7 days before implant removed		Insert 7 days before implant removed	Insertion up to 5 days after implant removed
LNG-IUD	7 days before LNG-IUD removed	7 days before LNG-IUD removed	7 days before LNG-IUD removed	7 days before LNG-IUD removed	4 days before LNG-IUD removed		No gap: insert immediately after LNG-IUD removed
Copper IUD	7 days before IUD removed	7 days before IUD removed	7 days before IUD removed	7 days before IUD removed	4 days before IUD removed	No gap: insert immediately after copper IUD removed and use back-up method for 7 days	

Managing Common Side Effects Associated with Hormonal Contraceptive Methods

Assisting a woman who is experiencing the side effects of any contraceptive is a key role that a midwife can assume to help women optimally use the method. Studies regarding contraceptive use reveal that side effects are the primary reason that the majority of women discontinue their hormonal contraceptive.[9] In addition to counseling women about potential side effects, it is important to include in health education the caveats that not all women will experience these side effects, and that not all discomforts or health concerns experienced while using hormonal contraception will be related to the contraceptive method being used.

Bleeding Irregularities

Changes in menstrual bleeding may be viewed as either an advantage or a disadvantage. Lighter menses generally are well received by most women. Many women are comfortable with amenorrhea, while others are not.[42] The majority of women find unpredictable or breakthrough bleeding to be at least a nuisance. Originally women were counseled that breakthrough bleeding might occur during the first 3 months of use of a hormonal method. However, especially with use of modern low-dose pills, this kind of bleeding may continue for as long as 6 months.

Progestin-only methods are more likely than COCs to be associated with irregular bleeding, including amenorrhea. Strong evidence has not yet emerged regarding how to manage hormone-associated bleeding, although extended and combined regimens have been suggested to suppress menstrual bleeding.[43,44] Many clinicians base their practice in this area on observation or expert opinions. **Figure 17-3** provides a sample algorithm for basic management of a woman with problematic irregular bleeding.[43-45] The pharmacologic treatments included in the algorithm are based on common clinical practices and should not be accepted as evidence based. Most medications provide temporary relief at best.

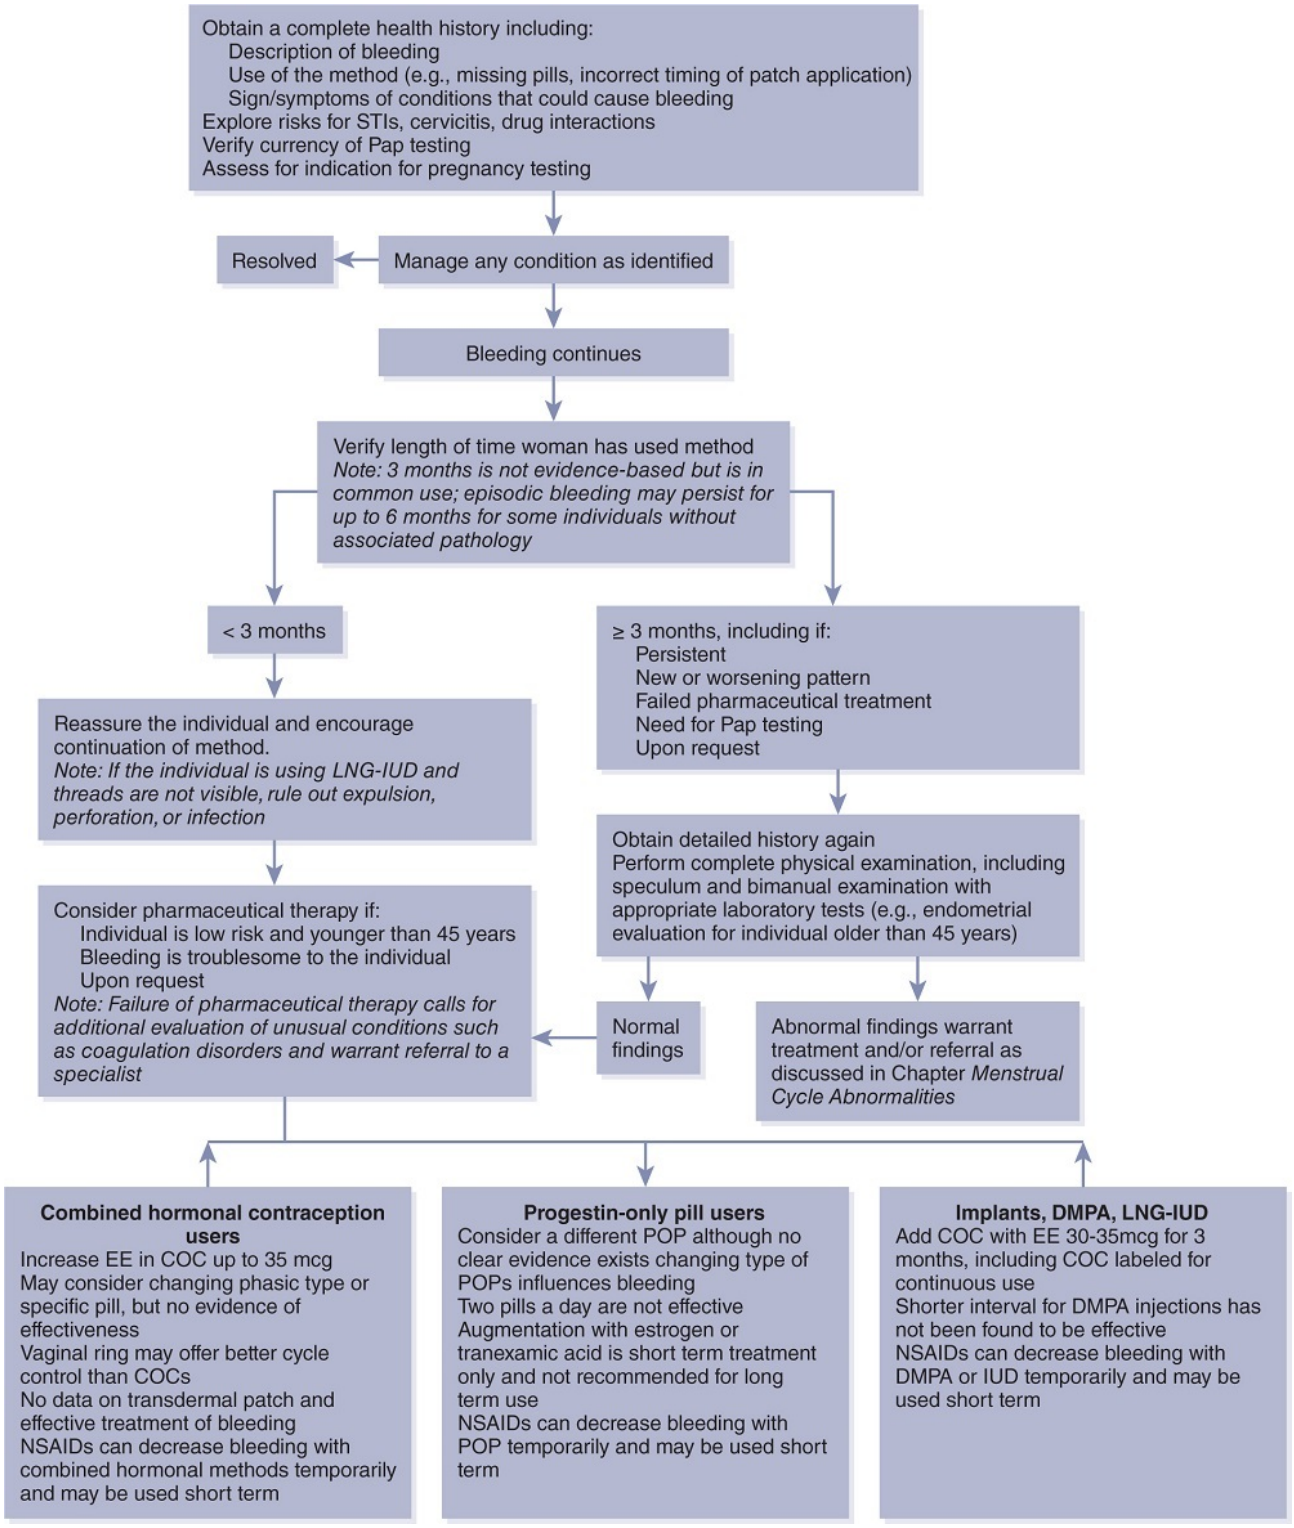

Figure 17-3 Sample algorithm for management of woman using a hormonal contraceptive method and experiencing associated troublesome bleeding.

Abbreviations: COCs, combined oral contraceptives; DMPA, depot medroxyprogesterone acetate; EE, ethinyl estradiol; IUD, intrauterine device; LNG-IUD, levonorgestrel intrauterine device; NSAIDs, nonsteroidal anti-inflammatory drugs; POP, progestin-only contraceptive; STIs, sexually transmitted infections.

[a] Medical therapy is primarily based on expert opinion and common practice. Little strong evidence exists in this area.

Based on Edelman A, Micks E, Gallo MF, Jensen JT, Grimes DA. Continuous or extended cycle vs. cyclic use of combined hormonal contraceptives for contraception. *Cochrane Database Syst Rev.* 2014;7:CD004695. doi:10.1002/14651858.CD004695.pub3[43]; Faculty of Sexual and Reproductive Healthcare Clinical Effectiveness Unit Clinical guidance: problematic bleeding with hormonal contraception–July 2015. Available at: https://www.fsrh.org/standards-and-guidance/documents/ceuguidanceproblematicbleedinghormonalcontraception/. Accessed January 21, 2018;[44] Grossman Barr N. Managing adverse effects of hormonal contraceptives. ***Am Fam Physician.*** 2010; 82(12):1499-1506.[45]

Headaches

Many women have mild occasional headaches, usually associated with tension or allergies. However, for some women, headaches can be disabling and may even herald a severe adverse effect such as a cerebral vascular accident. Some contraceptive methods are associated with increased incidence of headaches, such that the midwife is faced with the perplexing problem of identifying whether the headache is minor or signals a significant healthcare problem. If a woman presents with neurovascular symptoms such as flashing lights, loss of vision, muscle weakness, slurred speech, dizziness, or abnormal cranial nerve changes as well as a headache, these symptoms are an emergency and the woman requires immediate care to rule out a stroke. She also should discontinue the hormonal contraceptive method as quickly as possible and be counseled to use a nonhormonal method until the neurologic condition is resolved. For women who have headaches but no neurologic symptoms, and for whom no abnormalities are found upon examination, the midwife may consider alternative hormonal therapies. For example, women using COCs can have headaches during the withdrawal period (menstrual headaches) and may benefit from an extended-cycle method.[42]

Nausea

Nausea is a common side effect reported by women using any drug, but it is more likely with oral agents and patch contraceptives. There is no simple remedy. No single type of COCs or POPs is superior to another in terms of mitigating nausea. Ultimately, if the nausea and vomiting prove onerous for her, the woman may seek another contraceptive method, especially the contraceptive ring, implant or intrauterine device.[45]

If the nausea is mild but problematic, several suggestions for its management may be made, although evidence is lacking regarding these interventions' effectiveness. Among the most commonly used empirical management strategies for women experiencing nausea with oral contraceptives are taking the pill before sleep and to avoiding ingesting it on an empty stomach. Ginger often is suggested as a food with antinausea effects.

Short-Acting Reversible Contraceptives

Short-acting reversible hormonal contraceptives (SARCs) include pills, injectable agents, transdermal patches, and intravaginal rings that contain either the combination of estrogen and a progestin or only a progestin. Once initiated, the duration of action of these methods can range from a single day to as long as 13 weeks. Advantages of these methods include high rates of effectiveness, relative ease of use, and reduction in dysmenorrhea. Disadvantages of SARCs include the woman's need to take a daily pill or a weekly patch or ring, continued expense, and lack of protection against transmission of STIs.

Combined Oral Contraceptives

COCs produce a pharmacologic—rather than a physiologic—cycle. When the placebo pills are taken, the exogenous estrogen and progestin are "withdrawn" and endometrial wall shedding takes place. This bleeding is sometimes called a "pseudo-menstruation," but the more common term is "withdrawal bleeding," although most women will characterize it as a normal menses or a "period." Typically this bleeding is scant and of shorter duration when compared to a woman's menses associated with normal physiologic events.

The main variations among the formulations of the combined pill relate to the hormonal dose, the relative proportions of estrogen and progestin, and the particular progestin component used. The result is a wide variety of pills, each with a different side-effect profile. Complicating this discussion is the reality that more than 75 brand-name COCs are currently available. In years past, there had been the suggestion that women could be matched to specific pills. Other practices advocated switching certain COCs to others via a complicated process of estimating strength of progestin or dose of estrogen. For most women, however, there is little clinical difference among the formulations.

Regimens for Combined Oral Contraceptives

COCs often are identified according to whether they involve one of three regimens: monophasic, multiphasic, or extended cycle. Different dosing regimens can have various advantages or disadvantages, and one may be preferred over another by a woman.

Monophasic Regimen

The pills in the monophasic regimen come in packs of either 21 or 24 pills that are identical every day in terms of the amount and type of estrogen and progestin. The packs also include either 7 or 4 placebo pills, respectively. Some formulations have replaced the placebo with a folate supplement. One pill is taken each day for a total of 28 days, and then a new pack is begun. Although monophasic COCs have been marketed for decades, the newer regimen of 24 active pills and 4 placebo tablets shortens the duration of withdrawal bleeding and increases effectiveness.

Multiphasic Regimen

The hormone-containing pills in this pack vary in amount of estrogen and/or progestin provided during particular weeks of the cycle of pills and also include either 4 or 7 days of placebo pills. Multiphasic regimens often are referred to as biphasic when two different combinations of estrogen and progestin are provided, or triphasic when the pack has three different combinations or doses. Most multiphasic COCs vary the dose of the progestin, but a few are estrophasic in that they maintain a stable amount of progestin and vary the dose of ethinyl estradiol.

Extended Cycle

For years, women have taken COCs back to back without stopping for a placebo week. The major side effect of this pattern was breakthrough bleeding. Based on women's desire for such convenience, new regimens were introduced. An extended cycle includes hormone and placebo pills, but the hormone pills are taken daily for three consecutive months instead of monthly. For example, in one type of extended-cycle COC, known as Seasonale, the pack includes 84 active hormone pills and 7 placebos. This extended regimen results in menstrual suppression as evidenced by a decreased frequency of withdrawal bleeding and potential amenorrhea. Some of the extended-cycle regimens use pills that contain a reduced dose of ethinyl estradiol instead of placebos, in an attempt to decrease dysmenorrhea and other menstrual-related symptoms.

Special Considerations for Use of Combined Oral Contraceptives

Adolescents can safely use COCs but are more likely than adults to discontinue use if they experience side effects such as nausea; adolescents may also find taking a daily pill more challenging than do older women.[46] Counseling about common side effects, strategies to enhance regular use of the agents such as taking the pill before sleep, and emergency contraception generally are included in health education for all women taking COCs but may be of particular value to young women.

Care of the Woman Requesting Combined Oral Contraceptives

For women requesting to use COCs, the steps in initiating these contraceptives are summarized in **Table 17-6**. Physical examination should include blood pressure and weight, but a pelvic examination is not required. When selecting the specific COC, the lowest dose of estrogen possible should be chosen to minimize risks and side effects. Prescribing four to six cycles for a new user with a return visit to assess the woman's concerns with the method is recommended but may not be needed for all users.

Of all the SARCs, COCs have the largest number of contraindications or Category 3 or 4 considerations in the U.S. MEC for Contraceptive Use.[13] Most of these conditions are significant disorders, especially those associated with cardiovascular events such as hypertension, stroke, headaches with aura, and myocardial infarction. Thrombotic diseases, severe liver disease, breast cancer, lupus, diabetes with neuropathies, and vascular disease also are commonly included in the Category 3 or 4 considerations. The U.S. MEC for Contraceptive Use should be reviewed for any woman who wants to consider COCs as the most efficient way to identify potential contraindications.[13]

Figure 17-4 provides a guide that can be used to counsel women about missed pills. The majority of women, even when using an extended-cycle regimen, will resume normal ovulatory function within 90 days or 3 months of taking the last pill. For years, women have been advised to postpone pregnancy until 3 months after COCs are discontinued to ensure credible dating of a pregnancy. However, there is no evidence that earlier conception is associated with untoward perinatal outcomes.

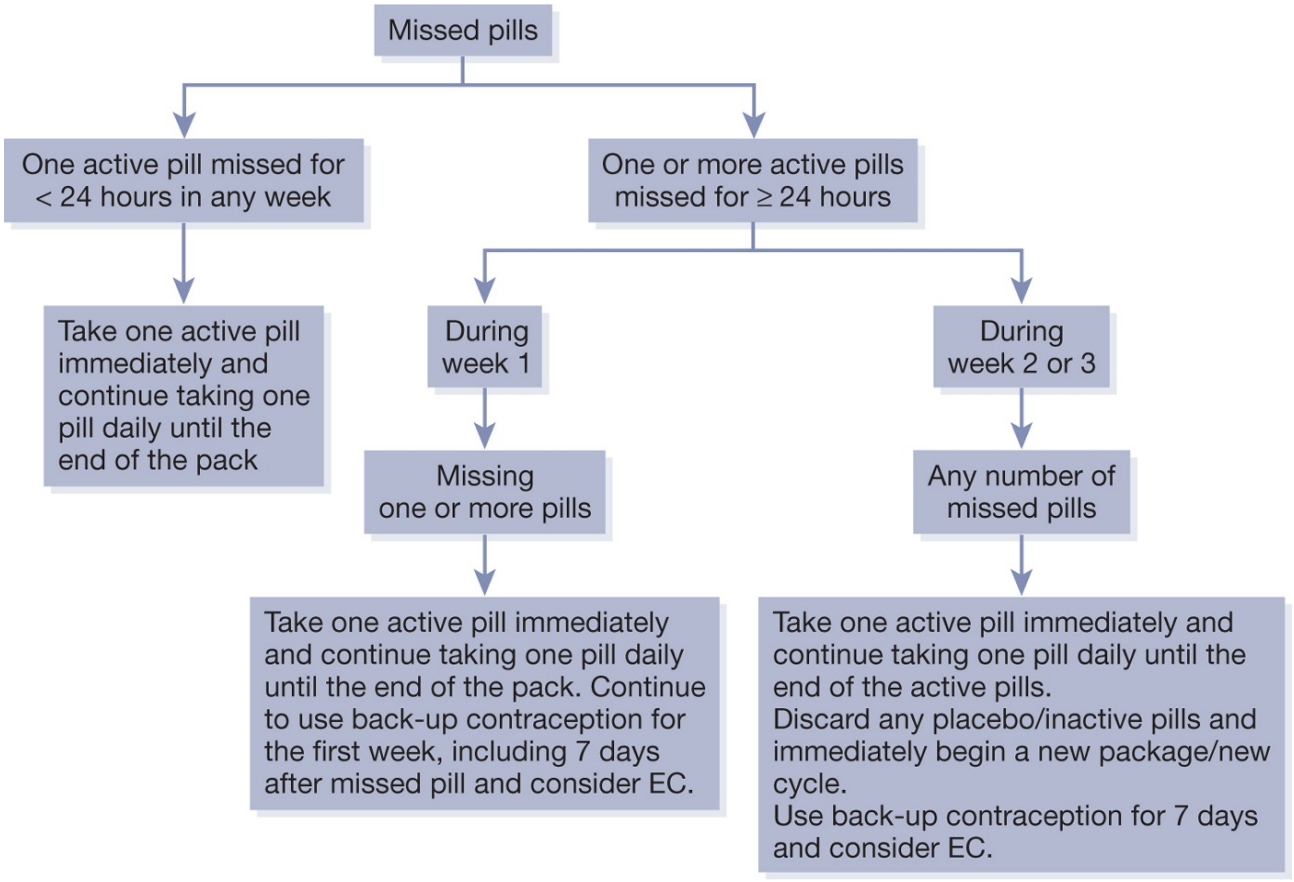

Figure 17-4 Algorithm for counseling women who have missed pills (combined oral contraceptives or progestin-only pills).

Abbreviation: EC, emergency contraception.

Table 17-8 lists content that should be specifically emphasized when counseling women using COCs, in addition to the health education reviewed for any hormonal contraception (Table 17-6).

Table 17-8	**Educational Content to Be Emphasized When Counseling Women Using Combined Oral Contraceptives**[a]
Pills should be taken daily, preferably at approximately the same time. Conditions that should be reported are identified by the mnemonic ACHES: **A**bdominal pain **C**hest pain **H**eadache (severe) **E**ye problems or loss of vision **S**evere leg pain or swelling in a calf or thigh	

[a] In addition to the information in Table 17-6.

Progestin-Only Pills

Progestin-only pills (POPs) contain a low dose of a single progestin and, therefore, can be used by women who want to use contraceptive pills but for whom estrogen is contraindicated. Originally FDA approved in the early 1970s, these agents tend to occupy a niche market for women who are breastfeeding. Although some individuals have called these agents "mini-pills," use of that term can be confusing for women and providers alike because of the number of low-dose COCs available. Therefore, "progestin-only pills" or "POP" is the preferred term. Currently several POPs are available.

Mechanism of Action of Progestin-Only Pills

Because the progestin dose is low, the risk of pregnancy is higher for the average woman using POPs as compared to COCs. To minimize risk of pregnancy, the daily dose must be taken at the same time each day to maintain a steady-state plasma level of the progestin. If more than 24 hours elapses between doses, the plasma level falls and escape ovulation can occur, allowing possible pregnancy if sexual intercourse takes place during that interval.

Special Considerations for Use of Progestin-Only Pills

Although women who are breastfeeding often use POPs, there is conflicting information regarding the amount of progestin transmitted to breast milk. POPs have not been associated with an increased risk of VTE.

Care of the Woman Requesting Progestin-Only Pills

While the management plan for women choosing to initiate progestin-only pills is the same as that for women using COCs, two points should be emphasized. The regularity of the daily dose is unforgiving with POPs; that is, women must take the pills at 24-hour intervals with no more than 3 hours of variation. Second, irregular spotting and bleeding are expected, not simply possible.

Table 17-9 lists topics to be emphasized for the woman regarding progestin-only pill use in addition to the health education required for women using any type of hormonal contraception (Table 17-6). Prescribing 4 months of POPs with a follow-up appointment with the woman in 3 months allows assessment of method satisfaction and review of her experience with side effects, including bleeding irregularities, and her willingness to cope with them. Similar to using COCs, the majority of women using POPs resume ovulatory function within 90 days or 3 months after discontinuing this contraceptive method.

Table 17-9	**Educational Content to Be Emphasized When Counseling Women Using Progestin-Only Contraceptive Pills**[a]
The pill should be taken within 3 hours of the designated time every day.	
If menses continue to be regular and predictable, there should be a suspicion that the woman is ovulating and use of another method or midcycle back-up should be considered.	

Conditions that should be reported are identified by the mnemonic ACHES:

Abdominal pain
Chest pain
Headache (severe)
Eye problems or loss of vision
Severe leg pain or swelling in a calf or thigh

[a] In addition to the information in Table 17-6.

While it is not unusual for women using POPs to have irregular bleeding and amenorrhea, if more than 45 days elapses without any vaginal withdrawal bleeding, the woman should be evaluated for possible pregnancy. Anytime a woman uses POPs and experiences severe abdominal pain, she will need to be evaluated emergently for possible ovarian cyst, ectopic pregnancy, or pelvic inflammatory disease.

Transdermal Contraception (The Patch)

Currently, only one transdermal delivery system for contraception, Xulane, is available in the United States. Ortho Evra was FDA approved in 2002 but withdrawn from U.S. market by the manufacturer in 2015, although it remains available in Canada. Xulane was introduced as a replacement for Ortho Evra; it is the same patch but marketed by a different manufacturer. Xulane is a medicated, adhesive patch with a surface contact area of 14 cm^2. The patch is composed of a thin, lightweight polyester material and constructed in three layers. The outer surface of the patch, called a backing layer, consists of a flexible, beige polyester film and serves as a protective covering. The patch's middle layer contains both the adhesive component and the active drug compounds. A third layer of clear polyethylene film protects the adhesive layer during storage and is removed prior to use.

The contraceptive patch is a combined hormonal method of contraception containing 6 mg norelgestromin and 0.75 mg ethinyl estradiol. Norelgestromin is the primary active metabolite of norgestimate, a progestin commonly used in formulations of some oral contraceptives.

Mechanism of Action of the Contraceptive Patch

The primary mechanism of action for the contraceptive patch is similar to that for the COCs. The transdermal absorption of exogenous estrogen and progestin inhibits ovulation by suppressing release of gonadotropins within the hypothalamic–pituitary–ovarian axis. Alterations in cervical mucus and endometrial lining are secondary mechanisms of contraceptive action. The active drug is absorbed through the skin, thereby avoiding a first-pass effect through the liver. Therefore, this route can decrease the total dose of exogenous hormones delivered when compared to oral contraceptive methods.

The contraceptive patch is self-applied by the woman. Each patch is impregnated with hormones that are adequate for approximately 1 week. To mimic the normal 28-day menstrual cycle, a single contraceptive patch is applied for 7 days and then immediately replaced with a new patch. Three patches are used in a month, resulting in 21 consecutive days of hormone exposure. The fourth week is a patch-free week, and a withdrawal bleed is expected following that interval. The contraceptive cycle is then restarted with the application of a new patch immediately following the 7-day patch-free week. Situations in which the transdermal delivery of the active drugs is disrupted (e.g., partial detachment) can result in decreased effectiveness. However, the adhesive component of the contraceptive patch is not generally affected by heat, humidity, or exercise.

Four application sites have been approved for use with Xulane and have been studied for their therapeutic effectiveness: the buttocks, the upper outer arm, the abdomen, and the upper torso. The area around the breasts is to be excluded, not because of known problems, but because of general concerns about breast tissue being exposed to hormones. Application of the patch to each of these sites has demonstrated therapeutic equivalence by releasing 150 mcg of norelgestromin and 20 mcg of ethinyl estradiol into the bloodstream daily. To avoid problems with adherence/effectiveness, patches should be applied to clean, dry skin and women should be counseled to avoid areas that have been recently exposed to perfumes, gels, lotions,

shampoos, and other topical products unless they clean and dry the skin first.

Special Considerations for Use of the Contraceptive Patch

Contraindications to the use of the contraceptive patch are the same as contraindications for any combined hormonal contraceptive. Side effects include headaches and breast discomfort. There also have been reports of application-site reactions, a non-hormonal-related side effect.

Unlike oral contraceptives, the patch does not require daily maintenance. When dispensed from a pharmacy as a single-month supply, the contraceptive patch is packaged as a set of three individual patches. Even though the patch is marketed for 7 days of use, studies have found that after the second week, a single patch will continue to deliver a sufficient amount of hormones for an additional 2 days, providing some forgiveness at that time should the woman be delayed in making the patch change after week 2 or 3.[14]

The contraceptive patch has received a significant amount of media attention regarding its association with VTE. A Cochrane review estimated that the risk of VTE with patch use is 53 cases per 100,000 women.[47] Other studies have yielded conflicting evidence related to VTE risk in women with contraceptive patch use. The general consensus is that the risk of VTE with the patch is higher than the risk associated with levonorgestrel-containing COCs, but still less than the risk of VTE during pregnancy.

Care of the Woman Requesting Contraceptive Patches

When transdermal patches are requested as the woman's contraceptive method, the midwife should screen the woman for previous skin allergies such as reactions to bandages or other medicated patches. The woman's current weight should also be considered. If her weight exceeds 90 kg (198 pounds), the woman should be advised of the potentially decreased effectiveness of the patch: The package label carries a precaution related to this weight threshold.

It is reasonable to initially prescribe 4 months of contraceptive patches and schedule a follow-up appointment with the woman in 3 months so that if unanticipated problems with detachment occur, the women will have an extra patch. The follow-up visit should include assessment of the woman's satisfaction with the method and experience of any side effects or problems with method use. **Table 17-10** discusses health education specifically related to use of a transdermal contraceptive patch.

Table 17-10	Educational Content to Be Emphasized When Counseling Women Using the Contraceptive Patch[a]
When removing the patch from packaging, the woman should not touch the medicated side. Instead, she should remove only half of the release liner, apply that half to the skin, and then remove the liner for the remaining half, applying with gentle pressure to ensure adhesion.	
Only one patch at a time should be used. Use of multiple patches is more likely to increase side/adverse effects than effectiveness.	
Verify attachment daily. If there is indication that the patch may be detaching, gently press on the patch for approximately 10 seconds. If that effort is unsuccessful, remove the patch and replace it with a new one.	

Patches should not be reused or relocated.

Patches should not be secured by other tape or wrapping.

If the patch becomes nonadherent for < 1 day, remove and apply a new patch. Do not attempt to reapply a patch that has adhered to clothing, as this may decrease effectiveness.

If the patch is off for > 1 day during the 3 weeks, she should apply another patch and start a new 4-week cycle, and use a back-up method for the first week.

Used patches can be discarded in the trash, away from pets and children as they may contain residual hormones. They should never be flushed down a toilet.

[a] In addition to the information in Table 17-6.

The midwife may provide two prescriptions: one for ongoing monthly supply and a second for a single replacement patch in case one is detached. If the woman forgets to apply her second or third patch of the cycle and no more than 1 to 2 days has elapsed since the day she would normally apply the patch (9 days from the application of her current patch), she should apply a new patch as soon as possible (**Figure 17-5**). The original patch change schedule remains unaltered. If more than 9 days has elapsed since the application of the current patch, she should understand that she is not protected from pregnancy and that she should start a new 21-day cycle by applying a new patch and using a back-up contraceptive method for the first week.[14]

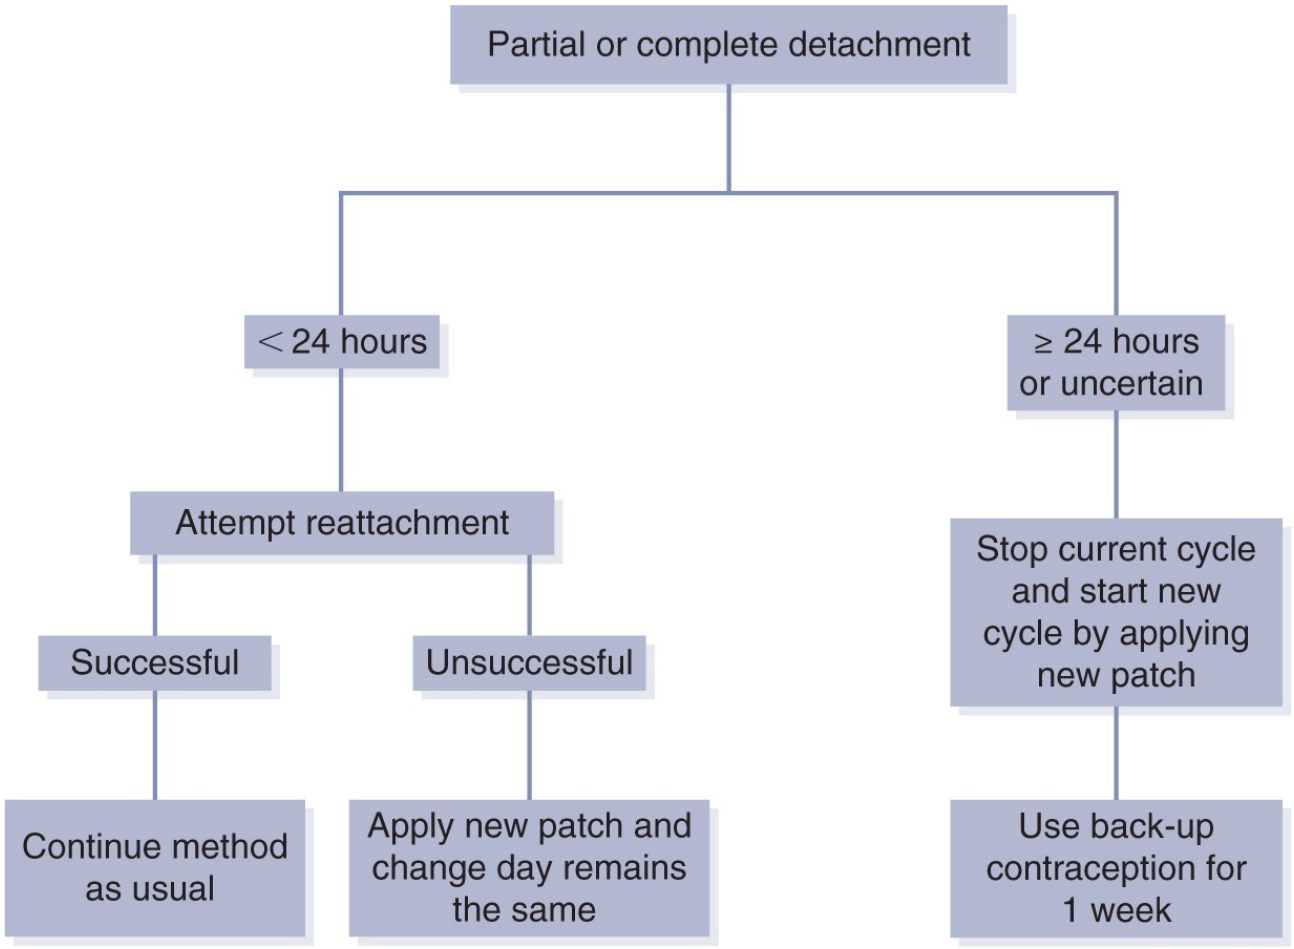

Figure 17-5 Algorithm for management of women with a partial or completely detached transdermal contraceptive patch.

If the woman forgets to take off the patch at the beginning of the patch-free week, she should remove it as soon as she remembers. If more than 9 days has elapsed since placement of the third patch, she should replace the patch according to the original schedule. Depending on how far into the patch-free week she removes the third patch, she may or may not experience a withdrawal bleed, although contraceptive protection is maintained.

If the woman forgets to restart a new patch following the patch-free week, she needs to understand that she is not protected from pregnancy and that she should put on a new patch and use a secondary method for pregnancy prevention for the first week of this new cycle.

Intravaginal Contraceptive Ring

Currently, only one intravaginal delivery system for contraception is available in the United States. NuvaRing, manufactured by Merck Pharmaceuticals, was introduced in the U.S. market in 2001. It is a flexible, vinyl ring measuring approximately 4 mm thick and 54 mm in diameter. The ring is composed of ethylene vinyl acetate, which encases the active components and controls the daily release of the drugs. This combined hormonal method of contraception contains both estrogen and progestin components. The active drugs in the contraceptive ring consist of 11.7 mg etonogestrel and 2.7 mg ethinyl estradiol.

Mechanism of Action of Intravaginal Contraceptive Ring

The primary mechanism of action for the contraceptive ring is similar to that of combined oral contraceptives. The vaginal mucosa absorbs the exogenous estrogen and progestin compounds, inhibiting ovulation via suppression of gonadotropins within the hypothalamic–pituitary–ovarian axis. Alterations in cervical mucus and endometrial lining are secondary mechanisms of contraceptive action. Because the hormones are released directly into the vagina, a lower daily dose of hormones is required in comparison to COCs.

The contraceptive ring is self-administered by the woman, who inserts a ring once per month. Each ring is impregnated with sufficient hormones to last for approximately 21 days. To mimic the normal 28-day menstrual cycle, a single contraceptive ring is inserted and left in place for 21 days. It is then removed for 7 days, thereby inducing a withdrawal bleed. The contraceptive cycle restarts with the insertion of a new ring immediately following the 7-day ring-free week.

The vaginal ring comes in only one size, does not require fitting, and is not position dependent. That is, as long as the ring is in contact with vaginal mucosa, the hormones will be absorbed. The contraceptive ring releases 0.015 mcg of ethinyl estradiol and 0.120 mcg of etonogestrel into the bloodstream daily. The contraceptive ring is intended to be left in the vagina for a continuous period of 21 days; however, if it is out of the vagina for less than 3 hours, contraceptive effectiveness has not been found to be reduced.[10,14]

Special Considerations for Use of the Intravaginal Contraceptive Ring

The most prevalent side effects with the vaginal ring include headache, dysmenorrhea, and breast discomfort. Additionally, a method-specific, nonhormonal side effect is vaginal irritation. When dispensed from a pharmacy, the contraceptive ring comes individually packaged in a resealable foil pouch. NuvaRing is available to be dispensed in boxes of one or three foil pouches. Prior to dispensing, NuvaRing is stored refrigerated, but it can be stored for up to 4 months at room temperature afterward. Temperature extremes should be avoided when storing the contraceptive ring, as there is potential for decreased effectiveness in those situations.

The contraceptive ring is convenient for many women because it does not require daily or weekly maintenance, and its insertion and removal are not difficult. The ring usually is not

perceived by the woman and only occasionally felt by her partner during sexual intercourse. If the woman desires, the contraceptive ring can be removed from the vagina for intercourse; it has been shown to maintain its effectiveness as long as it is replaced within 3 hours. The contraceptive ring should be rinsed only with cool water. Soap, hot water, or other cleansers should not be used on the ring, as they can affect this method's effectiveness.

Contraceptive rings may be of value for adolescents. Not only does this method offer more privacy than oral contraceptives or patches, but it also provides the same benefits as other combined hormonal methods—namely, lighter menses, less dysmenorrhea, no weight gain, and no effect on bone mineral density.

Care of the Woman Requesting an Intravaginal Contraceptive Ring

The management plan for women using the contraceptive ring is similar to that of other combined hormonal contraceptive methods. The midwife should screen for contraindications to combined hormonal contraception.[13] A prescription for emergency contraception should be considered, and women should be encouraged to have spermicide and condoms available in the event that the ring is expelled or an error occurs in removing or starting a new ring on schedule.

It is reasonable for the midwife to initially prescribe 4 months of rings and schedule a follow-up appointment with the woman in 3 months. The follow-up visit is the same as the return visit for any combined hormonal contraceptive and should include assessment of the woman's satisfaction with the method and her experience of any side effects or problems with method use. **Table 17-11** outlines health education points related to the use of the contraceptive ring.

Table 17-11 Educational Content to Be Emphasized When Counseling Women Using the Intravaginal Contraceptive Ring[a]

Remove the ring from its packaging and insert into the vagina by compressing the sides.
The ring must be completely inserted into the vagina.
Insert only one ring at any time. Use of multiple rings is likely to increase side/adverse effects but not effectiveness.
Rings usually are best removed by the woman slipping her index finger under the rim of the ring and guiding it down and out of the vagina.
Because rings should be removed every 21 days, a woman may benefit from using a calendar (hard copy or electronic) as a reminder.
A used ring can be replaced inside its foil pouch and discarded in the trash, away from pets and children. Rings should never be flushed down a toilet.

[a] In addition to the information in Table 17-6.

Spontaneous expulsion occurs in fewer than 3% of women using the contraceptive ring. If the ring is outside of the woman's body for less than 3 hours, then it should simply be rinsed with tepid water and reinserted. If it has been out of her vagina for more than 3 hours, then the woman may not be protected from pregnancy and needs to use a back-up method for 7

consecutive days in addition to reinserting the ring.[14]

If the woman fails to remove the ring and no more than 28 days has passed since she first inserted this ring, she should remove it and insert a new ring. She may or may not experience a withdrawal bleed, but contraceptive protection is maintained. Some women continuously use rings every 21 days, but there is no FDA indication for extended use at this time.

Like the patch, the ring may retain some residual active agent and should be carefully discarded away from children and pets. If more than 28 days has passed since the ring's initial insertion, the woman may not be protected from pregnancy. She should perform a pregnancy test. If the test is negative, she should insert a new ring and use a back-up method for 7 days.

Response to the contraceptive ring has been positive from both women and their partners. Clinical trials are being conducted in other countries for a progestin-only ring, especially to be targeted for lactating women.[48]

Injectable Depot Medroxyprogesterone Acetate Contraceptives

Depot medroxyprogesterone acetate (DMPA) is an injectable hormonal method. Injectable contraception is highly effective, is reversible, does not require partner participation, avoids daily need for intervention, and is not coital dependent.

Mechanism of Action of Depot Medroxyprogesterone Acetate

DMPA is a derivative of progesterone. Its primary mechanism of action is inhibition of ovulation by prevention of follicular maturation. Secondary mechanisms of action include thickening of cervical mucus, which serves as a barrier to sperm, and induction of endometrial atrophy, which reduces the likelihood of implantation. Like other steroidal hormones, DMPA is metabolized by the liver and excreted in the urine.[10]

Two formulations of DMPA are available, both of which require a prescription. The first is DMPA-IM 150 mg/mL (Depot-Provera), which is contained in a 1-mL vial or prefilled syringe and administered every 13 weeks intramuscularly. DMPA is detected in the serum levels within 30 minutes after an injection of 150 mg of this formulation. Serum concentrations vary, but gradually plateau for approximately 3 months, after which the serum concentration gradually declines. The second formulation is DMPA-SC 104 (Depo-subQ Provera 104), an agent administered subcutaneously every 13 weeks that has been found to be equally effective in inhibiting ovulation. The Depo-subQ Provera 104-mg dose and serum levels are approximately 30% lower than those found with the standard DMPA-IM 150-mg dose. This formulation has been shown to have equal, if not improved, tolerability, as side effects of DMPA are dose dependent.

Special Considerations for Use of Depot Medroxyprogesterone Acetate

Allergic reactions are possible but rare, following administration of DMPA-IM 150 and DMPA-SC 104 and a decrease in glucose tolerance has been observed in some women on DMPA. The major and common side effects of DMPA are menstrual changes, irregular bleeding, weight gain, headaches, and delayed return of fertility. The overall incidence of irregular bleeding experienced by women on DMPA can be as high as 70% in the first year of use.[49] Variations usually begin as episodes of unpredictable irregular bleeding and spotting that may last as long as 7 days or more or may be heavy during the first few months. These episodes gradually become less frequent and of shorter duration until the woman has amenorrhea. Approximately 10% to 30% of women experience amenorrhea after one injection, and 40% to 50% do so by the fourth injection. The rates of irregular bleeding and amenorrhea are similar for the subcutaneous and intramuscular formulations.

Weight gain often is noted as a concern among women using DMPA. However, studies of weight gain in users of DMPA have had variable results. The largest systematic review failed to find a consistent association of DMPA with significant increase in weight among users.[50] Nevertheless, it has been reported in some observational trials that women who are obese gain

additional weight, suggesting special attention should be given to counseling for these women.

The use of progestins may cause fluid retention. Certain conditions may, in turn, be exacerbated by this fluid retention, such as headache. Headaches have been reported among DMPA users. Women who develop migraines with aura should stop using DMPA (U.S. MEC for Contraceptive Use Category 3) because aura is a specific risk for stroke. However, studies examining use of natural progesterone or progestin use have found these agents to be associated with a decrease in frequency of migraines.[51] Therefore, a history of headaches is not a contraindication to initiation of DMPA,[13] but women should be counseled to report the development of headaches to their healthcare provider. If a woman develops severe headaches while using DMPA, she should have a thorough evaluation to diagnose the type of headache she experiences.

Long-term DMPA users may develop temporary, but usually reversible, decreased bone density, with declines ranging from 5% to 7% in the hip and spine.[52-55] DMPA suppresses gonadotropin secretion, which in turn suppresses ovarian estradiol production. In this hypoestrogenic state, bone resorption outpaces bone formation, resulting in a decline in bone mineral density. Based on studies of adolescents, bone loss is greatest during the first 2 years of use, but then slows dramatically.[54] Bone density has been shown to return to baseline following discontinuation of DMPA in women of all ages, with this effect being seen as early as 24 weeks after stopping therapy.[55] As the effects of DMPA on bone mineral density are reversible, the lifetime risk of fracture is small.[53] This finding is similar to that with lactational hypoestrogenism, which also has not been associated with an increased risk of fracture. Even so, women with conditions that place them at high risk for osteoporosis and fracture, such as chronic corticosteroid use, disorders of bone metabolism, a strong family history of osteoporosis, or anorexia nervosa, may not be well suited for long-term DMPA use. Likewise, women who have other risk factors that may contribute to lower bone mineral density, such as low calcium intake, alcohol abuse, and lower body mass index, should be evaluated carefully to assess suitability of DMPA use. Inadequate vitamin D levels may also contribute to more substantial bone mineral density loss, particularly among adolescents.[52,54]

Concerns regarding bone loss caused the FDA to mandate a black box warning be placed on the label for DMPA. This warning includes the recommendation that DMPA be limited to a 2-year period of use. However, the labeling also notes that when no other method would be indicated, DMPA can be used. This exception often is employed for adolescents and others for whom other methods would be likely to be less effective.[52,56]

Studies have been inconsistent regarding the effects of DMPA on mood changes. Administration of DMPA in the immediate postpartum period does not appear to predispose women to postpartum depression. If depression occurs or worsens in a woman who is using DMPA as her contraceptive method, her symptoms may persist for the 3-month duration of the drug's effects.

DMPA may cause changes within the vaginal environment and cervical ectopy that can increase susceptibility to STIs, although evidence of such changes is inconclusive. Other potential side effects include nervousness, decreased libido, breast discomfort, dizziness, hair loss, and bloating.[14] Among those women using the subcutaneous formulation, some report an

indentation or induration at the injection site (granuloma or atrophy) or other minor skin reactions.

Return to fertility for women using DMPA tends to take longer than for women using other hormonal methods. Ovulation suppression following DMPA discontinuation is not related to the duration of use, but rather to the weight of the woman. Women with lower body weights may conceive sooner after discontinuation of DMPA than women with higher body weights. If inadvertently used during pregnancy, DMPA is not associated with increased risk of birth defects.

Detectable amounts of the drug have been found in the breast milk of women receiving DMPA; however, no adverse changes in milk composition, quality, or amount have been identified. Likewise, neonates and infants receiving breast milk containing medroxyprogesterone appear to have no adverse developmental and behavioral effects through puberty. Nevertheless, based on theoretical concern for neonatal exposure to exogenous steroids, many providers reserve use of progestin-only contraceptive methods for new mothers until after the first 3–6 weeks postpartum.

Care of the Woman Requesting Depot Medroxyprogesterone Acetate

DMPA can be administered at any time in a menstrual cycle if the woman can be reasonably certain that she is not pregnant. However, if it is given later than the seventh day in the menstrual cycle, the woman should use back-up contraception for 7 days and receive a follow-up pregnancy test several weeks later to confirm the absence of an early pregnancy prior to a second dose of DMPA. If DMPA is initiated within the first 5 to 7 days of the menstrual cycle, a pregnancy test is unnecessary. A pregnancy test is warranted if DMPA is initiated outside of this period. Women can safely continue to use DMPA until menopause.

Fewer absolute (U.S. MEC for Contraceptive Use Category 4) contraindications exist for DMPA compared to COCs, but the relative contraindications (U.S. MEC Criteria for Contraceptive Use Category 3) include several major conditions as well as unexplained vaginal bleeding. The complete list of contraindications is available through the U.S. MEC for Contraceptive Use.[13]

DMPA is injected either subcutaneously or intramuscularly, depending on the formulation. Massaging the injection site can lower the effectiveness of the DMPA. Ovulation does not occur for at least 14 weeks post injection. If the woman is more than 2 weeks late for her subsequent dose, a pregnancy test is recommended prior to administration to assure she is not pregnant. Various methods of appointment reminders are available.

Starting at 13 weeks post injection, a secondary contraceptive method is recommended until the next dose is given. Conversely, subsequent injections may be administered up to 10 weeks after the previous DMPA injection without adverse effects. **Table 17-12** provides important information for women regarding DMPA injections.

Table 17-12 Educational Content to Be Emphasized When Counseling Women Using Depot Medroxyprogesterone Acetate[a,b]

Women should eat a diet high in calcium and vitamin D. If not, a woman should consider taking a daily multivitamin

supplement.

Although such outcomes are rare, a woman should be aware of and report any signs or symptoms of infection at the injection site, such as a fever, or changes at the insertion site, including drainage, redness, and warmth.

Other conditions that should be reported to a healthcare provider:

- Significant headaches
- Menorrhagia
- Depression
- Severe lower abnormal pain or any other signs or symptoms that may suggest pregnancy

[a] In addition to the information in Table 17-6.

[b] Education counseling is primarily based on expert opinion and common practice. Little strong evidence exists in this area.

Long-Acting Reversible Contraceptives

Long-acting reversible contraceptives tend to be more effective than their short-acting counterparts because they are not user dependent. LARCs include implants and IUDs.[10,13] Once inserted, these methods convey contraceptive protection for years. Although these methods tend to have a higher initial expense, their long-term use tends to make them cost-effective.

Subdermal Implants

Implantable contraceptives consist of one or more matchstick-sized rods or tubes containing progestin. These implants are inserted beneath the top layers of skin, on the inner aspect of the upper arm. Depending on the model of implant, subdermal devices can provide contraception for up to 7 years.

The first subdermal implant available in the United States was Norplant. It consisted of six plastic tubes containing levonorgestrel, a progestin. In 2002, the manufacturer removed Norplant from the U.S. market, citing limited availability of product components. Although Norplant is not currently available in the United States, it continues to be used internationally and a woman may have it inserted outside the country and desire to retain it for 7 years.

Although more implants may be available in the future, the only subdermal implant currently available in the United States is an etonogestrel-containing, single-rod device. Nexplanon entered the U.S. market in 2012, replacing its predecessor Implanon. Implanon and Nexplanon are biologically equivalent to each other.

Mechanism of Action of Subdermal Implants

Nexplanon is a polyethylene vinyl rod, 4 cm in length and 2 mm in diameter. The device is impregnated with 68 mg of etonogestrel, a progestin analogue, as well as 12 mg of barium sulfate. This latter substance makes the device detectable by X ray. Nexplanon works by continuously releasing etonogestrel to suppress ovulation. A single Nexplanon implant provides contraception for up to 3 years.

Special Considerations for Use of Subdermal Contraceptive Implants

As with most long-acting contraceptive devices, the initial costs of subdermal implants are significantly higher when compared to the costs of SARCs. However, when averaged over 3 years of use, the total costs of subdermal implants usually make these options less expensive than COCs, POPs, or DMPA. At the time of implant removal, a new device can be reinserted in the same site, thereby providing continuing contraception.

Care of the Woman Requesting a Subdermal Contraceptive Implant

Based on an agreement between the manufacturer of Nexplanon and the FDA, the implants are available for dispensing only to providers who have completed a 3-hour training session focusing on identifying women who are candidates for the implant as well as health counseling, insertion, and removal. Individuals who have taken Implanon training previously can update their training online. Therefore, this chapter will not address specifics on insertion or removal.

A few contraindications exist for contraceptive implants. All contraindications can be found in the U.S. MEC for Contraceptive Use.[13] No specific physical or laboratory assessment is recommended before insertion, with the exception of being reasonably certain that the woman is not pregnant. Monitoring for detrimental side effects, menstrual pattern, blood pressure, and user satisfaction can be done at a follow-up visit approximately 3 months following insertion.

Limited data are available regarding the use of the implants by breastfeeding women, but small amounts of etonogestrel have been observed in breast milk. **Table 17-13** lists health education topics for women using the subdermal implant.

Table 17-13	Educational Content to Be Emphasized When Counseling Women Using Subdermal Contraceptive Implants[a]
Although rare, a woman should be aware of and report the following: Signs or symptoms of infection at the insertion site, such as a fever Changes at the insertion site, including drainage, redness, and warmth	

[a] In addition to the information in Table 17-6.

When a woman wishes to discontinue use of the method, the removal of the implant is usually performed easily during an office visit. Often this is scheduled at the 3-year mark, but some women may desire to continue with the method. In that case, a new implant can be placed into the small incision made for removal.

In spite of adequate education, a midwife may occasionally find it difficult to remove an implant. Removal, however, is never an emergency. The first action should be to verify placement by ultrasound imaging to confirm that the implant is still present as well as to determine its location. On rare occasions, the device may inadvertently be placed very deep (< 2 cm). Should such a situation occur, midwives are encouraged to consult with or refer women to a specialist, especially those at one of the “Family Planning Fellowship” training sites around the country. There the contraceptive specialist will collaborate with interventional radiologists to remove the implant, and other surgeons are available as needed.

Hormonal Intrauterine Devices

Two types of IUDs exist: nonhormonal and hormonal. The chapter *Nonhormonal Contraception* introduces the use of the intrauterine contraceptive device (IUCD). These devices share multiple commonalities and that general information can be found in the aforementioned chapter. For example, most adverse effects, timing for insertion, and removal are the same and found in the Intrauterine Device Insertion and Removal appendix in the Nonhormonal Contraception chapter. This chapter focuses only on specifics of the levonorgestrel IUD, the hormonal device.

Mechanism of Action of Levonorgestrel Intrauterine Device

The levonorgestrel IUD (LNG-IUD) is a T-shaped, flexible polyethylene device widely marketed in the United States. The body of the device includes a reservoir that contains levonorgestrel, a progestin. The LNG-IUD provides for a continuous release of levonorgestrel, which is absorbed locally by the endometrium and results in increased viscosity of cervical mucus, remodeling of the endometrial lining, and impaired tubal motility. As a result of these localized effects, sperm motility is impaired, thereby inhibiting fertilization of the ovum. A possible secondary mechanism of action is suppression of ovulation.

The LNG is a LARC contraceptive method, which is cost-effective when used over a period of years. Women who have an aversion to checking for the device strings after each menstrual period may not desire this method. A few women are intolerant of IUD-associated side effects such as bleeding changes, and others simply do not like the idea of having a foreign object inside their body.

In 2000, the FDA approved the first LNG-IUD, which was marketed with the brand name Mirena. The Mirena IUD releases an average of 20 micrograms of levonorgestrel per day and provides contraception for up to 5 years. This device measures 33 mm by 32 mm wide. Nine years after the initial approval, the FDA approved an additional indication for this device—namely, its use as a therapeutic agent for women with menorrhagia. Subsequent studies have found that the LNG-IUD is more effective than oral therapy and, although not as effective in reducing bleeding as a hysterectomy, more cost-effective than the surgery.[57] When compared to the copper IUD, discussed in the *Nonhormonal Contraception* chapter, an IUD with levonorgestrel is associated with decreased bleeding, decreased dysmenorrhea, and increased incidence amenorrhea. The commonly accepted contraindications for this type of IUD include uterine anomalies, acute pelvic inflammatory disease, pregnancy, breast cancer, and unexplained bleeding.

Today, four different LNG-IUDs are available in the United States (**Table 17-14**). These devices contain different amounts of levonorgestrel and have different FDA-approved indications in terms of years of use. No specific guidelines exist regarding how to match a woman to a particular IUD. Mirena and Liletta, however, are approximately 2–4 mm larger than the others and might be more easily tolerated by a parous woman. These two LNG-IUDs release higher levels of daily levonorgestrel, and may be associated with more amenorrhea, which may or may not be desired.[58] Because of the dosing, they may be indicated for women

with heavy bleeding. Kyleena and Mirena provide the longest duration of action. As with all methods, cost, availability, and personal desires of women must be considered when selecting an LNG-IUD.

Table 17-14 Intrauterine Devices Containing Levonorgestrel

Brand Name	Total Dose of LNG in Device (mg)	Initial Release of LNG (mcg/day)	Size	Years of FDA Approval[a]
Liletta	52	18.6	32 mm horizontal and vertical	4
Kyleena	19.5	17.5	28 mm horizontal and 30 mm vertical	5
Mirena	52	20	32 mm horizontal and vertical	5
Skyla	13.5	14	28 mm horizontal and 30 mm vertical	3

Abbreviations: FDA, U.S. Food and Drug Administration; LNG, levonorgestrel.

[a] FDA approval may change, given that ongoing studies tend to suggest longer-term use is effective.

Special Considerations for Use of Levonorgestrel Intrauterine Device

The IUD insertion and removal procedures carry some risks, even though they are only minimally invasive. Bleeding, infection, perforation of the uterus, and pain can occur, although serious complications are rare. While IUDs do not cause ectopic pregnancy, if fertilization occurs with an IUD in place, there is a greater risk of ectopic implantation. It is important to underscore, however, that the overall risk of ectopic pregnancy for a woman with any IUD is lower than the risk of ectopic pregnancy for a woman not using contraception.

The Intrauterine Device Insertion and Removal appendix in the *Nonhormonal Contraception* chapter provides detailed information about insertion and removal of both nonhormonal (copper) IUDs as well as the four types of LNG-IUDs. Information about pre-insertion medication, STI screening, timing of insertion, and immediate adverse effects also are found in the appendix. Management of a woman with a pregnancy and an IUD in situ, expulsion of the device, and associated ectopic pregnancies are the same for copper and LNG-IUDs and are discussed in detail in the Nonhormonal Contraception chapter.

Care of the Woman Requesting a Levonorgestrel Intrauterine Device

Most women, including adolescents and nulliparas women, are good candidates for intrauterine contraception.[13] Category 3 and 4 contraindications are outlined in the U.S. MEC for Contraceptive Use, and include current pelvic inflammatory disease, breast cancer, endometrial cancer, severe cirrhosis, suspicion of intrauterine disease including chlamydia, gonorrhea, and tuberculosis. Women should not have an IUD inserted immediately postpartum or post abortion if sepsis has occurred.

Table 17-15 lists content to be reviewed when counseling women using an LNG-IUD.

Table 17-15 Educational Content to Be Emphasized When Counseling Women Using an LNG-IUD[a]

Women should verify that the device is in situ by feeling for strings at least monthly.

Use of the mnemonic PAINS can provide a reminder for women regarding conditions that should be reported to the midwife:

Period—late or abnormal bleeding (although this is relatively common for these women)

Abdominal pain or dyspareunia

Infection, especially associated with exposure to STI or an abnormal vaginal discharge

Not feeling well, especially if woman experiences fever, chills, or generalized malaise

Strings missing or inability to feel the plastic thread of the device

[a] In addition to the information in Table 17-6.

Conclusion

Over the last half-century, hormonal contraceptives have expanded from a drug category that included only combined pills to a repertoire of effective methods such as progestin-only pills, transdermal patches, intrauterine devices, vaginal rings, and implants. Hormonal contraception, like nonhormonal methods, is not a “one size fits all” situation: Women should choose the option that represents the best fit for their unique personal circumstances. A woman’s decision should consider her desires, her own eligibility, the conceptive method’s effectiveness, noncontraceptive benefits, and the woman’s ability to use the method correctly and consistently.

CHAPTER

18

Midlife, Menopause, and Beyond

JULIA LANGE KESSLER

The editors acknowledge Anne Z. Cockerham, who was the author of this chapter in the previous edition.

Introduction

Midlife encompasses approximately one-third of a modern woman's life. Most individuals entering midlife are healthy. A person's midlife and older years are characterized by multidimensionality and complexity, including both negative and positive aspects of the normal life-course transition process toward aging.[1] The term *midlife* and its synonym *middle age* lack a standard definition. In general, midlife is characterized as the years from the 40s to late 50s. Midlife encompasses a time of changing hormones, relationships, and roles. The only universal "change" for women is the final cessation of menstruation; other aspects of the midlife and beyond are highly individualized.

The influence of scientific, technological, and healthcare sources for the modern midlife and older individuals, however, can result in women being more vulnerable to messages that "medicalize" aging. Many can benefit from a knowledgeable guide who can assist them *as individuals*, navigating the opportunities and challenges of the menopausal transition and beyond.[2] Partnering with individuals to provide information about the changes surrounding aging, nonpharmacologic and pharmacologic options to manage bothersome symptoms if needed,[3] and lifestyle modifications to optimize health during the many years after menopause are within the scope of midwifery practice today.

Physiology of Midlife, Menopause, and Aging

Menopause is the permanent cessation of menstruation that occurs after the ovaries cease to produce follicles. The median age of menopause in North America is 51 years. During this period of life, numerous physiologic changes occur, including in the ovaries, endocrine milieu, and cardiovascular and skeletal systems, as well as emotional changes. The ovaries and the endocrine system change over the course of a woman's lifetime. During fetal life, the ovaries contain approximately 1 to 2 million follicles—the maximum number of follicles a woman will ever have.[4] The loss of follicles eventually leading to menopause occurs primarily due to atresia, not ovulation, because most women will ovulate fewer than 500 times during their reproductive years.[5]

As a woman ages, the rate of follicular loss increases. In turn, as the number of follicles diminishes, the ovaries become more resistant to the action of follicle-stimulating hormone (FSH).[4] The ovaries also decrease production of estrogen, androgen, and progesterone. Loss of the negative feedback from ovarian estrogen production means that gonadotropin production is no longer inhibited. Subsequently, levels of FSH and luteinizing hormone (LH) rise markedly, to the point that the FSH level exceeds the LH level. Secretion of the ovarian glycoprotein inhibin, which selectively inhibits FSH, also decreases. The decreased release of inhibin eventually results in sustained elevation of FSH. Elevated FSH levels stabilize approximately 24 months after the final menstrual period.[4] Although levels of these hormones generally trend upward over time throughout this process, they can fluctuate. These unexpected, erratic changes provide the rationale for not routinely testing hormone levels as a method to diagnose menopause.

After menopause, the ovary changes considerably both in physical appearance and in function. In spite of the absence of functional follicles, both the remaining corticostromal cells and the hilar cells are steroidogenic; as such, they contribute to androgen production and continue to provide significant amounts of androstenedione and testosterone for several years. These hormones influence a woman's muscle strength and sexual drive.[6]

A postmenopausal woman's ovaries become small and are normally not palpable on bimanual examination. Thus, if a postmenopausal woman's ovary is palpated, an ovarian neoplasm must be ruled out.[4]

During the postmenopausal period, the cervix gradually decreases in size and produces less mucus; this change can contribute to vaginal dryness and dyspareunia. Progressive atrophy of the cervical epithelium creates an increasingly sparse capillary bed and makes the surface of the cervix appear smooth, shiny, and pale.[4]

After ovarian follicular activity ceases, hormonal stimulation of the endometrium and myometrium also dissipates. Endometrial tissue, regardless of its location, becomes atrophic and inactive in postmenopausal women. Thus, not only does the uterine lining become atrophic, but small to moderate-size fibroids, which are highly sensitive to estrogen stimulation, usually shrink after menopause, as do the cyst-like invasions of the myometrium characteristic of adenomyosis.[7]

The three main human estrogens are estrone (E_1), estradiol (E_2), and estriol (E_3).

Postmenopausally, estrone accounts for the majority of circulating estrogen; it is derived principally from the metabolism of estradiol and from the conversion of androstenedione in adipose tissue. Conversely, estradiol—the most potent of the three estrogens—accounts for 95% of the circulatory estrogen in premenopausal women. The dominant follicle and the corpus luteum both excrete large amounts of estradiol in reproductive-age women.[4] Estriol, a weak estrogen, is secreted from the placenta but can also be metabolized in small amounts from estrone.[6] Postmenopausal women have serum estradiol levels lower than 37 pg/mL (picograms/milliliter) and mean estrone levels between 6 and 63 pg/mL. In contrast, premenopausal women have estradiol levels in the range of 10–100 pg/mL in the early follicular phase, 200–800 pg/mL at midcycle, and 200–340 pg/mL during the luteal phase, as well as premenopausal estrone levels in the range of 30–180 pg/mL. Although 95% of postmenopausal androstenedione production occurs in the adrenal gland and 5% occurs in the ovaries, the ovarian stroma continues to produce androstenedione and testosterone under the influence of LH. These hormones, along with the androstenedione produced by the adrenal glands, are converted to estrone in peripheral adipose tissue. Thus, increased conversion to estrone is associated with a higher body mass index (BMI) or increasing weight in postmenopausal women.[4] Some estradiol continues to be produced, but the amount is significantly less than that produced in reproductive-age women.

Menopause

Although menopause is a universal experience for women as they age, menopause may be influenced by diet, environment, cultural beliefs, and genetics. Women may have few, if any, bothersome symptoms when menopause occurs naturally. By comparison, when menopause is induced by surgery, chemotherapy, or radiation therapy, symptoms are more likely to be troublesome.[4]

The experience of menopausal symptoms is culturally determined to a great degree. Generalizing from the experiences of one group of women to other groups can lead to misunderstandings and suboptimal care.[8] In many cultures, menopause is a welcome change that heralds a period of wisdom, renewal, and energy. Midwives can provide women with balanced information about menopause in modern society that can help foster positive attitudes toward this period of life.[9]

Terms and Definitions for Menopause

As noted in **Table 18-1**, the definition of menopause is based on a retrospective diagnosis that is accurate only 12 months after a woman's last menstrual cycle. **Table 18-1** includes other terms frequently used to describe aspects during this period of a woman's life.[4,6,10-14] A number of the terms that relate to menopause are imprecise, but continue to be used colloquially.

Table 18-1 Definitions Related to Menopause

Term	Definition
Climacteric	Process of age-related change from a reproductive state to a nonreproductive state. Sometimes used interchangeably with *perimenopause*. In some regions, this term is considered too vague for use and has fallen out of favor.
Early menopause	Natural or induced menopause that occurs long before the average age of spontaneous menopause. This imprecise umbrella term encompasses premature menopause. The most frequently used cut-off age for early menopause is 40 years, but this is not standardized.
Estrogen therapy (ET)	Treatment of women for menopausal symptoms such as vasomotor conditions or vulvovaginal atrophy.
Estrogen plus progestin therapy (EPT)	Similar to *estrogen therapy* but with added progestin to decrease the risk of endometrial hyperplasia or cancer.
Final menstrual period (FMP)	The last menstrual period of a woman's life; it is recognized after 12 months of amenorrhea has passed. The average age at FMP in the Western world is 51 years (range: 40–58 years).
Hormone therapy (HT)	Primarily use of estrogen with or without an added progestin. Also known as *menopausal hormone therapy (MHT).* The older terms "hormone replacement therapy" (HRT) and "estrogen replacement therapy" (ERT) have fallen out of favor because "replacement" implies that the pharmacologic agent provides premenopausal hormonal levels. In reality, HT provides only a small fraction of the hormone levels produced by premenopausal ovaries. Moreover, "replacement" connotes an unnatural deficiency state when the changed endogenous hormone levels that a menopausal woman experiences are actually natural and expected.
Induced menopause	Cessation of menstruation due to surgical removal of a woman's ovaries or ablation of ovarian function from chemotherapy or pelvic radiation therapy. Also known as *surgical menopause*.
Menopause	A one-time event that marks permanent cessation of ovulation and menstruation. It is diagnosed when a woman has had 12 months of amenorrhea with no other identified cause such as pregnancy.
Menopause transition	A time of menstrual and endocrine changes, beginning with variation in cycle length and ending with the FMP. Average age at onset is 46 years (range: 39–51 years). Average duration of transition is 5 years (range: 2–8 years).
Perimenopause	Symptomatic years of menopausal transition, encompassing the time from early menopausal transition to 12 months after the FMP. Experts disagree about whether this term should be reserved for use with the public or if it is suitable for use in scientific literature. It is similar to the time of menopause transition. This term is often used synonymously with *climacteric.*
Postmenopause	The period of time after a woman's final menstrual period.
Premature menopause	Any menopause that occurs in women younger than 2 standard deviations below the mean estimated age for the reference population. The age frequently used as a benchmark is 40 years.
Primary ovarian insufficiency	Ovarian failure leading to amenorrhea in women younger than 40 years. Sometimes used synonymously with *premature ovarian failure*. Some authorities prefer premature ovarian

	insufficiency rather than premature ovarian *failure*, because cessation of ovarian function is not always permanent.
Progesterone	A steroid hormone secreted by the corpus luteum and by the placenta. This term is most commonly used to describe women's naturally occurring hormone.
Progestin	A natural or synthetic substance that mimics the actions of progesterone. This term is most commonly used to describe the therapies women use for contraception and menopausal hormone therapy.

Stages of Reproductive Aging

Because chronological age is not an accurate predictor of a woman's path to menopause, leading menopause researchers developed an alternative system for assessing women's stages of life at the Stages of Reproductive Aging Workshop (STRAW). Investigators published the initial system in 2001, research continued during the next 10 years, and the updated STRAW + 10 system was published in 2012. This system has become the gold standard for describing reproductive aging through menopause.[11] **Figure 18-1** provides a graphic representation of the STRAW + 10 stages. Use of this staging system can aid clinicians and women in understanding the expected physiologic changes that occur during the menopausal transition. The stages progress from a woman's reproductive years toward her final menstrual period and then beyond.

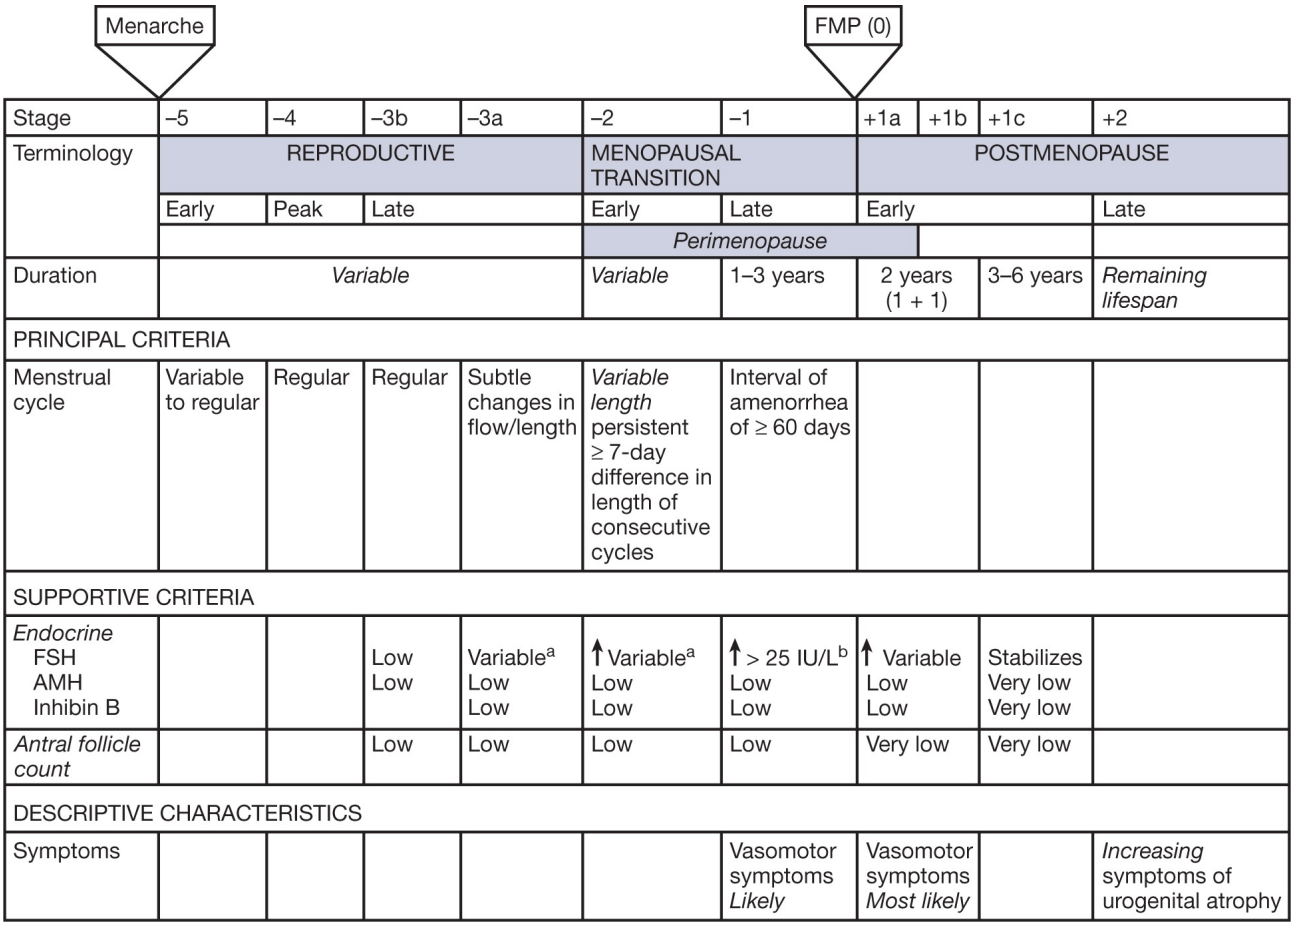

Figure 18-1 The Stages of Reproductive Aging Workshop + 10 staging system.

Abbreviations: ↑ , elevated; AMH, anti-Müllerian hormone; FMP, final menstrual period; FSH, follicle stimulating hormone.

Late Reproductive Stage (Stage –3b)

During the late reproductive stage, women begin to notice changes in the amount of menstrual flow and in cycle length, and they often have shorter cycles. FSH levels usually increase, but can vary from one cycle to the next. Importantly, even irregular or long cycles can still be ovulatory. In as many as 25% of these cycles, women may ovulate[7]; thus, women may conceive a pregnancy during this phase.

Early Menopausal Transition (Stage –2)

As women move closer to their final menstrual period, menstrual cycle length becomes even more variable. In this stage, there is often a difference of 7 days or more in the length of consecutive cycles, and these variations persist for at least 10 cycles after the first variable-length cycle. The FSH level remains elevated but, once again, varies. Estradiol levels remain in the normal range but may even be slightly elevated until approximately 1 year before the cessation of follicular development. This finding is contrary to earlier research that indicated estradiol levels gradually waned in the years before menopause.[6]

Late Menopausal Transition (Stage –1)

During the late menopausal transition stage, women generally are amenorrheic for spans of 60 days or longer, have wide deviations in cycle length, exhibit marked fluctuations in hormone levels, and are increasingly anovulatory. In this stage, which usually lasts 1 to 3 years, women frequently experience vasomotor symptoms. The conclusion of the late menopausal transition phase is the final menstrual period (FMP).

Early Postmenopause (Stages +1a, +1b, and +1c)

The FSH level continues to increase and estradiol levels continue to decrease until approximately 2 years after the FMP. Early postmenopause is subdivided into three distinct stages:

- *Stage +1a* usually lasts 1 year, and its end marks the 12-month period required to make the retrospective diagnosis of spontaneous menopause.
- *Stage +1b* lasts approximately 1 year and is characterized by rapid changes in FSH and estradiol levels. Symptoms such as hot flashes are most likely to occur in this stage.
- *Stage +1c* lasts approximately 3 to 6 years, during which women experience a period of stabilization with high FSH and low estradiol levels.

Late Postmenopause (Stage +2)

The late postmenopause stage encompasses a woman's remaining lifespan; with today's life expectancy, this time period may account for one-third of her life or more. Hormone levels stabilize during this stage, and symptoms associated with low estrogen levels, such as vulvovaginal atrophy, can become increasingly apparent.

Smoking, lower body weight, nulliparity, never-use of oral contraceptives, and lower socioeconomic status are factors that have been found to be associated with spontaneous menopause occurring earlier than the average age of 51 years.[15] Some experts consider higher body weight to be associated with later age at menopause,[16] but others argue that this association is not clear.[17] Family history can also affect a woman's age at her final menstrual period.[15]

Diagnosing Menopause

No single laboratory test can predict or confirm menopause. Instead, the diagnosis of menopause is based on a woman's menstrual and medical history and on her reported symptoms.[4] Thus, a diagnosis of menopause is generally assured if a woman has been amenorrheic for 12 months and if there is no reason to suspect an underlying alternative cause of the symptoms.

Hormone testing to predict menopause or help manage symptoms is not usually of clinical value. **Table 18-2** lists potential indications for obtaining hormone levels and problems associated with hormone testing.[4,6] As with any test, hormone testing should be ordered only if the results can affect treatment options offered to the woman.

Table 18-2 Hormone Testing During Perimenopause and Menopause

Hormone	Possible Reasons to Obtain Test	Problems Associated with Test
Estrogen levels	To assess absorption of estrogen in women with persistent vasomotor symptoms in spite of hormone therapy	Estradiol and estrone levels are erratic; isolated levels are unlikely to give meaningful information
Progesterone	To document ovulation in perimenopausal women who are trying to conceive	Levels likely to be low in anovulatory cycles; isolated levels are unlikely to give meaningful information
Follicle-stimulating hormone (FSH)	Multiple FSH levels demonstrating sustained elevation > 30 mIU/mL, or months of amenorrhea and FSH > 40 mIU/mL, can provide a reasonably sound diagnosis of menopause; sometimes useful for a woman with an unclear or unusual clinical presentation	Highly variable during perimenopause: even elevated FSH levels (> 30 mIU/mL) can return to the premenopausal range days, weeks, or months later
Luteinizing hormone (LH)	If a woman taking hormonal contraceptives needs laboratory confirmation of menopause, a serum FSH:LH ratio greater than 1 on the seventh pill-free day can provide a reasonably sound diagnosis of menopause	LH elevation occurs late in perimenopause—much later than FSH elevation; minimal or no utility in confirming perimenopause or menopause
Prolactin	To rule out a pituitary cause for oligomenorrhea or amenorrhea, particularly in the presence of galactorrhea	Prolactin levels do not vary with aging or menopause
Thyroid-stimulating hormone (TSH)	To rule out thyroid dysfunction as a cause for symptoms otherwise attributed to perimenopause and menopause (e.g., abnormal uterine bleeding, hot flashes, sleep difficulties, fatigue, weight gain)	Thyroid levels do not vary with aging or menopause
Testosterone	To rule out testosterone excess state from testosterone treatment or endogenous excess	Levels change little from 4 years before to 2 years after menopause; little value in diagnosing testosterone insufficiency because testosterone levels are only one part of total androgen status

Based on North American Menopause Society. *Menopause Practice: A Clinician's Guide*. 5th ed. Mayfield Heights, OH: North American Menopause Society; 2017[4]; Fritz MA, Speroff L. Menopause and perimenopausal transition. In: *Clinical Gynecologic Endocrinology and Infertility.* 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2011:673-748.[6]

Hallmark Symptoms of the Perimenopausal/Menopausal Period

The severity of symptoms during the perimenopausal and menopausal periods varies dramatically from woman to woman. As such, the management of these symptoms is individualized based on symptom severity and the woman's choice of treatment options.

Bleeding Pattern Changes

Approximately 90% of women experience 4 to 8 years of menstrual changes before their final menstrual period.[4] Exactly what those changes entail for an individual woman is unpredictable and can differ from menses to menses. The most common pattern is a gradual decrease in both the amount and duration of the menstrual flow, leading to vaginal spotting and then to cessation of bleeding. However, some women experience more frequent or heavier periods during the perimenopause period and occasionally the heavy bleeding is troublesome and occasionally pathologic. This type of abnormal uterine bleeding (AUB) is discussed in detail in the *Menstrual Cycle Abnormalities* chapter. **Table 18-3** compares normal and potentially abnormal bleeding patterns during the perimenopausal period.[4]

Table 18-3 Normal Versus Potentially Abnormal Bleeding Patterns During Perimenopause

Common Perimenopausal Menstrual Changes	Potentially Abnormal Perimenopausal Bleeding Patterns[a]
Shorter intervals between periods (but at least 21 days)	Very heavy bleeding, especially with clots
Longer intervals between periods	Long bleeding duration (> 7 days or ≥ 2 days longer than usual)
Lighter bleeding	Very short cycles (< 21 days from beginning of one period to beginning of next period)
Heavier bleeding than normal (difficult to quantify; consider evaluation if significant change)	Irregular bleeding: spotting or bleeding between periods
Shorter duration of bleeding	Bleeding after sex
Longer duration of bleeding (up to 1–2 days longer than usual)	
Skipped periods	
No changes	

[a] Any bleeding that occurs after menopause (i.e., after 12 months of amenorrhea) should merit investigation of a pathologic cause.

Based on North American Menopause Society. *Menopause Practice: A Clinician's Guide.* 5th ed. Mayfield Heights, OH: North American Menopause Society; 2017.[4]

Genitourinary Syndrome

At least half of postmenopausal women experience some external genital, urinary, and sexual changes reflective of the hypoestrogenic state that occurs during menopause (**Table 18-4**).[17,18] The term genitorurinary syndrome of menopause replaces older terms used such as

vulvovaginal atrophic changes and atrophic vaginitis.[17,18] The vagina, vestibule, and bladder trigone have a high concentrations of estrogen receptors. When estrogen levels diminish, physiologic and anatomic changes occur in these organs.[17,18] The vaginal and cervical epithelium gradually becomes thin, dry, and pale in a diminished-estrogen environment. This tissue sometimes becomes inflamed, and a visible capillary bed may appear as a diffusely red appearance or small petechial hemorrhages. During the perimenopausal/postmenopausal period, the vagina transitions from the acidic environment dominated by lactobacilli to an alkaline environment with more diverse flora that can include pathogenic organisms.[4] In addition, rugae disappear and the vaginal secretions diminish.[4]

Table 18-4 Signs and Symptoms Associated with Genitourinary Syndrome of Menopause

	External genitalia	Sexual	Urologic
Physiologic Changes	General: thinning and graying of pubic hair Labia: atrophy and labia minor absorbed, loss of hymeneal remnants, introitus retracts Vagina: reduced secretions, decreased elasticity in vagina, loss of rugae, pallor, petechiae or erythema, friability	Decreased arousal, orgasm, desire lubrication	Urethral eversion Prominence of urethral meatus
Signs and Symptoms	Alkaline pH Genital dryness Postcoital bleeding Vaginal burning or itching	Bleeding or spotting with intercourse Pain with penetration	Dysuria, frequency or urgency Nocturia Postvoid dribbling
Associated Conditions	Pelvic organ prolapse Vaginal or introital stenosis	Dyspareunia Dysorgasmia	Meatal stenosis Recurrent urinary tract infections Stress or urinary incontinence Urethral polyp Urethral prolapse

Based on Portman D. Genitourinary syndrome of menopause: new terminology for vulvovaginal atrophy from the International Society for the Study of Women's Sexual Health and the North American Menopause Society. *Menopause*. 2014;21(10):1063 -1068[18]; Gandhi J, Chen A, Dagur G, et al. Genitourinary syndrome of menopause: an overview of clinical manifestations, pathophysiology, etiology, evaluation, and management. *Am J Obstet Gynecol*. 2016;215(6):704-711.[19]

Arousal time slows with aging for both women and men, allowing more time for foreplay during sexual activity is advisable. Sexual activity itself improves blood supply to the pelvis and the vaginal tissues. Consequently, sexually active older women often have less atrophy than older women who are not sexually active.[4] Women troubled by genitourinary syndrome symptoms occasionally report dryness or itching of the vulva and vagina and pain upon vaginal penetration. In such women, the midwife may find micro-abrasions and few or absent vaginal

rugae when a pelvic examination is performed. Urinary changes include prominence of urethral meatus, frequency, dysuria, nocturia, and possibly incontinence.

Vasomotor Symptoms

Vasomotor symptoms are extremely common in the perimenopausal period, although the exact prevalence is difficult to determine. Studies have provided different statistics on this phenomenon, with estimates of the percentage of women reporting hot flashes ranging from 8% to 80%.[20] Regardless of the precise rate of occurrence, hot flashes—like changes in the pattern of bleeding—are so common that they are considered a hallmark of perimenopause. Ethnicity, diet, climate, lifestyle factors, and women's attitudes about aging may all influence an individual's experience of vasomotor changes. In North America, African American women report hot flashes more frequently than Hispanic, white, or Asian women.[21] Women who have undergone surgically induced menopause have a higher incidence and more severe hot flashes, at least for the first year, compared to women having naturally occurring menopause.[4] Women who are younger at the time of menopause tend to have more frequent vasomotor symptoms.[11]

The physiology of vasomotor symptoms remains poorly understood,[6] and the terms *vasomotor symptoms*, *hot flashes*, *hot flushes*, and *night sweats* all refer to the same experience. This phenomenon is characterized by recurrent, transient periods of flushing, sweating, and a sensation of heat, often accompanied by palpitations and a feeling of anxiety, and sometimes followed by chills.[4] These flashes can occur during a woman's sleep, causing her to wake and describe the event as a night sweat.

A single hot flash usually lasts 1 to 5 minutes, during which time a woman experiences a sudden wave of heat that soon spreads over her body and particularly over her face and upper torso. Elevations in skin temperature, heart rate, skin blood flow, and metabolic rate follow quickly. As the hot flash ends, skin temperature begins to gradually return to normal and the woman sometimes feels chilled, often due to heat loss from sweating and continued peripheral vasodilation.[21]

Although a woman's precise risk of experiencing vasomotor symptoms cannot be predicted, some general risk factors have been identified. Numerous studies have associated cigarette smoking with increased risk of hot flashes. Women who have discontinued smoking for 5 years or more report less severity and frequency of hot flashes, compared to current smokers.[22] Previous research indicated that women with a low BMI and minimal adipose tissue experience more hot flashes, which may be due to a decrease in endogenous estrogen production. More recent evidence indicates that adipose tissue can act as an insulator, which promotes a higher core body temperature (supportive of hot flashes), although more research is needed in this area.[4]

The highest prevalence of vasomotor symptoms occurs within the first 1 to 2 years postmenopause, yet many women report experiencing hot flashes shortly before the final menstrual period. Approximately 50% of women have hot flashes for 4 to 5 years after their final menstrual period, 25% have hot flashes for more than 5 years, and 10% for as long as 15 years.[6] A small number of women report having hot flashes for decades after menopause. Some

women have relatively few hot flashes, whereas other women have very frequent hot flashes. Moreover, some women interpret these symptoms as easily managed, whereas other women report that flashes are disrupting their lives.

Women who have mild hot flashes often find relief with common sense and relatively easily instituted lifestyle changes. Women may implement the lifestyle changes listed in **Table 18-5**; if they find that these interventions are adequate, women may not require medications.[21,22,24,25]

Table 18-5	Lifestyle Interventions Used to Treat Vasomotor Symptoms
Intervention	**Comments**
Avoidance of hot flash triggers	A symptom diary to identify triggers, and thereby help the woman avoid them, and to increase personal feelings of control may be of value.
Discontinue smoking	Women who smoke tend to have more hot flashes than women who do not; in addition, the more a woman smokes, the greater her risk for more severe vasomotor symptoms.
Maintain healthy weight and fitness level	Although evidence is mixed regarding whether poor exercise habits and obesity have a causal relationship with vasomotor symptoms, these strategies may be of value and have positive effects on health in general.
Promote a cool environment	Anecdotal reports of cooler temperatures and dressing in layers of breathable clothing such as cotton suggest these interventions may help some women cope with hot flashes.
Relaxation techniques such as yoga, meditation, deep breathing, guided imagery, mindful stretching, massage, mindfulness, aromatherapy, and prayer	Methodological challenges limit the ability to evaluate the effect of these strategies, but there is little likelihood of harm and most of these techniques have little cost. These interventions may decrease anxiety.

Based on Fisher TE, Chervenak JL. Lifestyle alterations for the amelioration of hot flashes. *Maturitas.* 2012;71:217-220[21]; Smith R, Flaws JA, Gallicchio L. Does quitting smoking decrease the risk of midlife hot flashes? A longitudinal analysis. *Maturitas.* 2015;82(1): 123-127[22]; Daley A, Stokes-Lampard H, Thomas A, MacArthur C. Exercise for vasomotor menopausal symptoms. *Cochrane Database Syst Rev.* 2014;11:CD006108. doi: 10.1002/14651858.CD006108.pub4[24]; Saensak S, Vutyavanich T, Somboonporn W, Srisurapanont M. Relaxation for perimenopausal and postmenopausal symptoms. *Cochrane Database Syst Rev.* 2014;7:CD008582. doi: 10.1002/14651858.CD008582.pub2.[25]

Mood Symptoms

Experts disagree about whether changes in hormone levels during the perimenopausal/postmenopausal period actually *cause* mood symptoms. The interactions between hormones and mood are complex, as are the interactions between the "symptom clusters," including pain, vasomotor symptoms, and sleep disruption, that women may experience during the perimenopause period.[23] Moreover, many women experience coexisting stressors, and some of these stressors during this time may be caused or exacerbated by a newly empty nest, or the "sandwich generation" phenomenon of caring for both children and elderly family members.[4] In spite of the controversies surrounding this topic, several risk factors for mood disorders are well known: Women with a history of depression or

premenstrual syndrome seem to be more vulnerable to depression around the time of menopause.[11]

Lifestyle Strategies for Treatment of Perimenopausal or Menopausal Symptoms

Some symptoms experienced during menopause may be indicative of underlying pathology separate from menopause and warrant investigation. An array of healthy lifestyle strategies can be offered to women who request relief from menopausal symptoms such as hot flashes, sleep difficulties, sexual concerns, and vulvovaginal discomfort (***Table 18-5***).[21,22,24,25]. Some of these strategies, such as maintenance of a healthy weight, smoking cessation, and increased exercise, have additional benefits for cardiovascular and bone health.

Hormone Therapy for Treatment of Menopausal Symptoms

The most effective treatment for vasomotor symptoms and vaginal atrophy related to menopause is hormone therapy (HT) with estrogen or estrogen and progestin. In 2002, reports emerged from the large Women's Health Initiative (WHI) study that initiated a rapid sea change in the recommendations for women during the perimenopausal/menopausal period. The WHI was a national study supported by the U.S. National Institutes of Health (NIH), designed to address major health problems associated with morbidity and mortality among postmenopausal women. More than 160,000 women age 50 to 79 years participated in the study. One of the three major randomized controlled trials (RCTs) examined menopausal hormonal therapy (HT), specifically estrogen therapy (ET) or estrogen plus progestin therapy (EPT). The expectation, based on observational studies and case reports, was that study findings would reveal these drugs provide relief of several menopausal symptoms and decrease the risk of cardiovascular events, especially coronary heart disease.[26]

Risks and Benefits of Hormone Therapy

The risks and benefits associated with HT are complex and may be related to the age at which therapy is initiated. The findings from the WHI provide the basis for most of the projected risks and benefits from the use of HT. **Table 18-6** summarizes these risks and benefits and can be used as a resource when discussing HT with women. Although the full longitudinal study was intended to continue for 9 years, the RCT examining the effects of EPT was discontinued early because the interim analysis found an increased—not decreased—risk of coronary heart disease among women in the EPT cohort. In addition, participants in this group had statistically significant increased risks of breast cancer, stroke, and pulmonary embolism. It was determined that these risks outweighed the benefits of decreased risks of colorectal cancer and bone fracture.[27] The findings were disseminated widely, including in consumer publications. Although the absolute number of adverse events were low, both consumers and healthcare providers were concerned enough that prescriptions for menopausal hormone therapies rapidly decreased.

Table 18-6 Risks and Benefits of Hormone Therapy Based on Randomized Controlled Trials Reported by the Woman's Health Initiative

Condition	EPT	ET
Risks[a]		
Coronary heart disease	Increased	NS
Stroke	Increased	Increased
Pulmonary embolism	Increased	Increased
Venous	Increased	Increased

thromboembolism		
Breast cancer	Increased	NS
Gallbladder disease	Increased	Increased
Stress incontinence	Increased	Increased
Urge incontinence	NS	Increased
Probable dementia	Increased	NS
Benefits		
Endometrial cancer	Decreased	NA
Hip fractures	Decreased	Decreased
Total fractures	Decreased	Decreased

Abbreviations: EPT, estrogen plus progestin therapy; ET, estrogen therapy only; NA, not applicable; NS, not statistically significant.

[a] Risk based on hazard risk with statistical significant finding, although the degree of risk varies among conditions and the absolute number may be small.

Data from Rossouw JE, Anderson GL, Prentice RL, et al. Risks and benefits of estrogen plus progestin in healthy postmenopausal women: principal results from the Women's Health Initiative randomized controlled trial. *JAMA*. 2002;288(3):321-333[27]; Anderson GL, Limacher M, Assaf AR, et al. Effects of conjugated equine estrogen in postmenopausal women with hysterectomy: the Women's Health Initiative randomized controlled trial. *JAMA*. 2004;291(14):1701-1712.[28]

Two years later, the portion of the RCT that evaluated ET in women with previous hysterectomies was also terminated early.[28] Estrogen alone did not decrease the risk of cardiovascular disease in this group, and there were indications of an increased risk of stroke. However, a decreased risk of bone fractures was found, and, unlike the EPT group outcomes, no statistically significant increased risk of breast cancer was detected.

The WHI has been criticized because the average age of participants in the EPT group was more than a decade older than the average age of a woman experiencing her final menses, or menopause. This problem may affect the risk of cardiovascular disease associated with HT. Subsequent studies have found a trend toward lower rates of cardiovascular mortality in women age 50 to 59 years who start ET within the first 10 years of experiencing menopause. Therefore, some experts suggest early adoption of HT in the perimenopausal period may have some cardiovascular benefits and this is an area of ongoing research. Nevertheless, today's guidelines continue to reflect the original WHI findings and recommend that HT be limited to short-term treatment of healthy women with moderate to severe symptoms.[4] HT is not recommended for prevention of cardiovascular disease.

Another limitation of the WHI is that a single specific progesterone (medroxyprogesterone acetate [Provera]) and a single specific estrogen (conjugated equine estrogen) were used. Subsequent studies with different estrogens and progestins have yielded slightly different statistical findings, although the majority of reports are congruent with the original WHI reports.[4,29,30]

Contraindications for Hormone Therapy

Contraindications for ET/EPT include undiagnosed abnormal vaginal bleeding; known, suspected, or history of breast cancer; known or suspected estrogen-dependent cancer; current or history of deep vein thrombosis or pulmonary embolism; current or recent (within the last year) stroke or myocardial infarction; liver disease; known or suspected pregnancy; and known hypersensitivity to ET/EPT. Smoking is not a contraindication to ET/EPT, although it is a contraindication for combined hormonal contraceptive use by women older than 35 years.

Hormone Therapy Options

HT is available in several different formulations that allow for oral, transdermal, or topical application. HT is considered a safe option for healthy women who are within 10 years of menopause, younger than 60 years, and lack any contraindications. Some professional associations recommend calculating a woman's baseline risk for cardiovascular disease and breast cancer before considering HT. Online calculators are listed in the Resources section at the end of this chapter. Counseling about HT includes a discussion about the risks, benefits, side effects, contraindications, and alternatives tailored for the individual.[31] This section reviews the information that is included in this discussion.

Estrogen Therapy Versus Estrogen and Progesterone Therapy

ET is available in oral, transdermal, topical, and vaginal formulations; EPT is available in oral and transdermal formulations. For women with a uterus who are using systemic estrogen, a progestin also is needed to protect from the endometrium-building effects of estrogen and predisposition to endometrial hyperplasia.[32] Conversely, women who have undergone a hysterectomy do not usually need a progestin. Most menopause experts agree that women with a uterus who use estrogen in *nonsystemic* doses (i.e., local vaginal therapy) do not need a progestin, although some experts advocate endometrial surveillance with an ultrasonographic measurement of endometrial thickness when women use a local vaginal therapy for more than 7 to 12 months.[14]

Choosing a Hormone Therapy and Regimen

Rarely does the specific estrogen or progestin is rarely an important aspect of choice. Most of the drugs are proprietary fixed drug compositions and are usually prescribed by brand name. Some estrogens are chemically manipulated to be conjugated or esterified so that they become more water soluble; those drugs are then administered orally or vaginally. Patches, gels, rings, spray, and some creams generally contain 17ß-estradiol. Synthetic estrogens are available in some products. Progestins also vary, with some products containing either drospirenone, levonorgestrel, norethindrone acetate, or norgestimate. These products are also available in a range of doses.

Medroxyprogesterone acetate (Provera) is one of the few progestins used separately from estrogen. It is not commonly used, however, because most women using EPT rely on a single

fixed drug combination. For women who experience problematic side effects of medroxyprogesterone acetate, some novel approaches have been suggested, such as use of a levonorgestrel-containing intrauterine device (IUD) or regular endometrial biopsies or transvaginal monitoring.

None of the specific agents seems to be more effective than the others for most women. For some individuals, there are additional considerations regarding the proprietary drug Premarin and its combinations such as Premphase and Prempro. Premarin, often termed conjugated equine estrogens (CEEs), actually is a complex blend of a number of steroids, including estrogens that are derived from pregnant mares' urine and other estrogenic compounds and androgens. Some women may be uncomfortable receiving hormones from horses, especially those who are concerned about the animals' well-being. For these women, use of other estrogens can be recommended.

Recently a new fixed drug combination has become available that includes conjugated estrogens and bazedoxifene (Duavee), an estrogen antagonist/agonist (EAA) originally marketed for prevention of osteoporosis. This formulation is indicated for treatment of women with mild to severe hot flashes and to prevent osteoporosis. The package insert states that women who only require protection from osteoporosis should seek another formulation without estrogen, perhaps to reduce estrogen-related risks.[33]

Outside the United States, various other synthetic agents may be used to treat vasomotor symptoms. Tibolone, a 19-nortestosterone derivative, is used especially in Europe, but is not available in the United States.[34] Dehydroepiandrosterone (DHEA) also has been used for this indication, but studies have failed to demonstrate its effectiveness and androgenic side effects limit its use.[35]

When considering the optimal route of administration, an important first consideration is whether the woman needs *systemic* or *local* vaginal therapy. If a woman needs relief from systemic symptoms (e.g., hot flashes), she needs systemic-level dosing, which can be obtained with oral and transdermal formulations. For women with localized concerns such as vulvovaginal atrophy, topical therapy or one of the vaginal rings (e.g., Femring) is appropriate.[36]

The topical products do not result in systemic levels of hormone. Vaginal rings are to be replaced every 90 days. A vaginal tablet is available and generally is used twice a week; vaginal creams are used daily. The decision to choose oral administration versus another route can be guided by individual preference, ability to use the method, and other factors such as avoidance of the first-pass effect with transdermal products.

Clinicians should be aware that systemic HT has been associated with worsening of preexisting stress and urge urinary incontinence and with increased incidence of new urinary incontinence.[37] In contrast, local vaginal estrogen topical therapy may improve continence.[38]

A variety of dosing regimens are available for estrogen plus progestin therapy. One of the oldest EPT regimens is *cyclic EPT*, in which a woman takes estrogen for the first 25 days of each month. Progestin is added to the estrogen for the last 10 to 14 days, and no hormones are taken for the final 3 to 6 days of the month. This regimen is seldom used now because women tend to experience withdrawal bleeding and hot flashes on the hormone-free days.

With *continuous-cyclic (sequential) EPT*, women take estrogen every day and add progestin

for 10 to 14 days each month. This regimen provides predictable withdrawal bleeding but no hot flash–inducing estrogen-free days. Premphase is one brand-name product that uses this formulation; it is sometimes prescribed for women in the menopausal transition during which HT-induced endometrial growth is likely. Premphase creates a predictable pattern of bleeding during this transitional period.

Continuous-combined EPT, in which women take estrogen and progestin every day, is currently the most commonly used formulation of HT. Within this category, several brand-name drugs are available. Within a few months of using this dosing option, a woman's endometrium becomes thin and most women are amenorrheic.

Intermittent-combined EPT (also called *pulsed progestin* or *continuous-pulsed EPT*) is also available. In this regimen, women take estrogen every day; they take progestin intermittently for 3 days on, 3 days off, repeated without interruption. Only one product, Prefest, uses this regimen.

Some women prefer a non-oral systemic formulation. Available formulations in this category include skin patches that are replaced once or twice weekly and gels or spray that may be used daily.

Most HT products are also available in a variety of doses. The effective dose for symptom relief varies from woman to woman, so a certain amount of trial and error is often needed to determine the appropriate dose. Clinicians should prescribe the lowest dose of HT that effectively manages symptoms and encourage women to use this therapy for the shortest time possible. Optimally, EPT should be taken for no longer than 5 years, but the decision to discontinue therapy should be individualized. For ET, a longer duration may be safer. These guidelines are congruent with the results of a longitudinal study conducted as part of the WHI, in which women using EPT for a median of 5.6 years and women using ET only for a median of 7.2 years were found to have no increase in all-cause, cardiovascular, or cancer mortality during 18 years of follow-up.[39] The guiding principle should be to start with a low dose and titrate upward, eventually selecting the lowest dose that accomplishes the HT goal.[4] Charts listing all the potential HT products are available from several Internet sites.[40] The most important aspect is identifying a drug and regimen that provides a woman relief of her symptoms.

Pregnancy Prevention

Pregnancy is possible until 12 months after a woman experiences her final menstrual period. Women in the perimenopausal period who want to avoid pregnancy should use contraception and not rely on HT to prevent pregnancy. Although both HT and combined hormonal contraceptives contain estrogen and progestin, the dose and formulation of HT will not prevent pregnancy. Moreover, a woman whose ovaries are still functioning in a reproductive capacity is not likely to benefit from the doses of hormones found in HT because they are low in comparison to a reproductive-age woman's hormone levels. Therefore, women generally do not begin taking HT until they have reached menopause. For healthy women who experience perimenopausal symptom relief with hormonal contraception use, many clinicians recommend making the transition to HT, if needed, when the woman has reached age 55 years—the age at

which 90% of women will have reached menopause.[4]

Discontinuation of Hormone Therapy

When women discontinue HT, intuition would indicate that gradual tapering would result in a less unpleasant experience than abrupt discontinuation. In reality, evidence does not support this theory: Women's experiences seem to be no better with gradual tapering of HT than with sudden discontinuation.[4,11]

Bioidentical Hormone Therapy and Custom-Compounded Formulations

Bioidentical hormones are plant-derived hormones that are chemically identical to the endogenous hormones (e.g., estrogen, progesterone) a woman's ovaries produce during her reproductive years.[4] Many bioidentical hormone therapies are available in Food and Drug Administration (FDA)-approved, well-tested formulations. Although the list is long, a few examples include 17ß-estradiol products such as Estrace, Climara, Divigel, Evamist, and Estring; estradiol acetate products such as Femring; and oral micronized progesterone (Prometrium).[4]

Unfortunately, some consumers, healthcare providers, and pharmacists use the term "bioidentical hormone" to describe formulations that are more accurately described as "custom-compounded." Custom-compounded products were initially intended for use by women for whom standard FDA-approved products were ineffective, but post-WHI safety concerns caused an increasing number of women and clinicians to explore options other than the commercial products used in the WHI.[4] Custom-compounding of HT involves individual mixing of preparations, usually by a compounding pharmacist. Such products may include one or more hormones, sometimes delivered via nonstandard dosing routes such as subdermal implants, sublingual tablets, rectal suppositories, or nasal sprays, in an attempt to individualize therapy for a particular woman.

A number of concerns have arisen regarding custom-compounded HT. Clinicians who prescribe custom-compounded hormones often base the dosing on salivary hormone testing, even though there is no scientific evidence to support the claim that such testing can accurately dictate HT doses.[4] Moreover, no evidence supports the contention that custom-compounded hormones are safer than traditional HT, and their effectiveness is an open question given the limited research conducted on these formulations.[41] Safety concerns stem from the lack of batch-to-batch testing for consistency, purity, or dose.[42] The FDA does not regulate compounded products. Instead, individual state agencies regulate compounding pharmacies, and this regulation process varies widely from state to state.

Topical progesterone, which is typically found in the custom-compounded HT gels, creams, and lotions, does not adequately raise serum levels to protect the endometrium against estrogen's stimulatory effects, which may ultimately lead to endometrial hyperplasia and endometrial cancer in some women.[4] Custom-compounded hormones also may be substantially more expensive because they may not be covered by insurance.[41]

Several organizations—including the North American Menopause Society (NAMS), the

FDA, the American Congress of Obstetricians and Gynecologists (ACOG), the Endocrine Society, the American Medical Association, and the American Cancer Society—agree that custom-compounded therapy is no safer than traditional, commercially prepared and FDA-approved therapies and that compounding may impart additional risks.[2]

Nonhormonal Prescription Options for Treatment of Menopausal Symptoms

Lifestyle changes are not always effective and some women do not want to use or cannot use hormonal therapies. For these individual's, nonhormonal strategies are available.

Nonhormonal Treatments for Genitourinary Symptoms

The best anticipatory guidance regarding the vulvovaginal changes is to advise women to maintain adequate moisture throughout the body, as well as in the reproductive system. In contrast, moisturizers are longer-lasting products that can maintain moisture and beneficially lower the vaginal pH.[4] Water-based lubricants can be used to increase comfort during sexual activity. Oil-based products coat the vaginal lining, thereby preventing the release of natural secretions and should be avoided. These products also cause condom breakage. If possible, it is best to avoid use of antihistamines and other over-the-counter drugs that have drying effects, including douches, sprays, and colored or perfumed toilet paper and soaps.

Nonhormonal Treatments for Vasomotor Symptoms

Although some nonhormonal drugs have evidence to support their effectiveness, none is as effective as systemic HT in treating hot flashes, and all of these medications have varying side-effect profiles. Certain selective serotonin reuptake inhibitors (SSRIs)/serotonin-norepinephrine reuptake inhibitors (SNRIs) (e.g., fluoxetine [Prozac, Sarafem], paroxetine [Paxil]) have moderate effectiveness in providing relief from hot flashes and are especially useful for women with coexisting mood disorders. Women may respond rapidly to these agents, but tapering is required to discontinue them. SSRIs and SNRIs may also result in decreased libido in women.

The anticonvulsant gabapentin (Neurontin) has been found to be moderately effective for treatment of hot flashes, but its common side effect of somnolence may be problematic. Pregabalin (Lyrica), a drug used for treatment of fibromyalgia or neurologic conditions, is being investigated for potential use for vasomotor symptoms but is not recommended at this time. Methyldopa (Aldomet) has limited effectiveness and a significant negative side-effect profile; it should not be used for this indication.[4,14]

An estrogen antagonist/agonist, previously known as a selective estrogen receptor modular, is available as a treatment for women with postmenopausal dyspareunia. Ospemifene (Osphena) is a daily oral tablet that results in thickening of vaginal tissue. A potential risk with use of this medication is stimulation of the endometrium leading to increased risk of endometrial hyperplasia or cancer. Localized estrogen treatments such as creams and rings can be prescribed as an adjunctive treatment.

Complementary and Alternative Therapies

Complementary and alternative medicine (CAM) encompasses a variety of healthcare practices and products. Complementary therapies are used *in addition to* and alternative therapies are used *instead of* conventional approaches.

Despite extensive use of CAM, few of these therapies have solid evidence to support their safety and effectiveness.[43] A valuable resource for clinicians and the public about the safety and effectiveness of CAM is the National Center for Complementary and Integrative Health, which is part of the National Institutes of Health.[44]

Phytoestrogens

A large number of botanically derived phytoestrogen supplements and foods are purported to ease menopausal symptoms.[45] In addition to conflicting research findings about these substances, there is a great deal of confusion about the terminology associated with them. *Phytoestrogen* is a broad term for plant-derived compounds that have estrogenic and antiestrogenic effects. The three major classes of phytoestrogens are isoflavones, lignans, and coumestans.[46]

Isoflavones are plant-derived compounds with estrogen-like activity and a chemical structure similar to that of estradiol. Soy and red clover are the two most commonly used isoflavones for the relief of menopausal symptoms.

Soy, usually derived from whole soybeans, is the most widely consumed isoflavone-containing food. The amount of isoflavones in soy-containing foods varies widely. Moreover, the manufacturing process used for each food can have negative effects on the amount of isoflavones found in the final product. Although the research evidence about the effects of soy is conflicting and some studies have failed to find effectiveness,[45] it is possible that soy has modest benefits for the short-term (e.g., 3 months) treatment of hot flashes but not for longer periods. Moreover, a trial of 3 months is sufficient to evaluate whether a woman is likely to respond to therapy. Soy does not appear to have harmful effects on the endometrium or on the breast, even in women at increased risk for breast cancer and breast cancer survivors.[4]

Red clover contains different types of isoflavones and has different affinities for various steroid receptors when compared to soy. Evidence is mixed about effectiveness, with a few studies demonstrating small beneficial effects on hot flash reduction but most research has not found red clover to be effective.[4]

Lignans, found in flaxseed oil and whole grains, and *coumestans*, found in alfalfa sprouts and certain beans and peas, are thought to have a much lower hormonal affinity than isoflavones. These phytoestrogens are not very useful in decreasing menopausal symptoms.[4]

Herbal Therapies

Despite widespread consumer interest in herbal therapies, a lack of standardization of doses and the sparse number of high-quality, large studies that have evaluated the safety and effectiveness of herbs make determination of effectiveness challenging. In addition, herbal

therapies can cause adverse events and are associated with herb–drug interactions, although the extent of each is difficult to determine.[4]

The herbal remedies that women most often use to relieve menopausal symptoms are black cohosh, chaste tree berry, dong quai, evening primrose oil, gingko, ginseng, kava, licorice root, St. John's wort, valerian, and wild yam. **Table 18-7** lists each of these herbs' proposed effects on menopausal symptoms, dosages, and summary of safety and effectiveness.[4,46-52]

Table 18-7 Herbal Remedies Used Most Often for Relief of Perimenopausal and Menopausal Symptoms

Herb	Proposed Effects	Dose	Comments
Black cohosh (*Cimicifuga racemosa*)	Diminishes hot flashes	20 mg twice/day of proprietary standardized extract; recommended dose of Remifemin supplement is 40–80 mg/day	Possible evidence of benefit for hot flash relief. Most widely studied herb for menopausal symptoms, but recent studies have many methodological limitations. Much variation in brands and preparations.
Chaste tree berry (*Vitex agnus castus*)	Diminishes PMS symptoms; regulates menses	250 mg of crude herb or 20 mg/day of 12:1 ratio of standardized extract	Evidence of benefit for PMS symptoms. Possible benefits for regulating irregular perimenopausal bleeding. Popular in Europe and approved therapy in Germany for PMS, mastalgia, and menopause symptoms.
Ginseng (*Panax ginseng*)	Improves mood, minimizes fatigue	100–600 mg/day of standardized extract in divided doses	No data indicating effectiveness for hot flashes. Possible effectiveness for overall feelings of well-being. Significant problems with purity of preparations.
Kava (*Piper methysticum*)	Minimizes irritability, promotes sleep	150–300 mg of root extract per day in divided doses	Effective for treating anxiety but effect is small. Possible hepatotoxicity; some experts recommend avoiding completely.
St. John's wort (*Hypericum perforatum*)	Diminishes hot flashes, decreases irritability, treats depression	300 mg of standardized extract taken 3 times per day	Evidence of benefit for mood stabilization and mixed evidence for hot flash relief. Sometimes used in conjunction with black cohosh. Multiple drug-herb interactions.
Valerian (*Valeriana officinalis*)	Promotes sleep; decreases anxiety	**Insomnia:** 300–600 mg aqueous extract 30–60 min before bed; **Anxiety:** 150–300 mg aqueous extract each morning and 300–400 mg each evening	Evidence of benefit for insomnia and anxiety. Few side effects at recommended dosages and with relatively short-term use.

Abbreviation: PMS, premenstrual syndrome.

Is there anything special about valerian? *Menopause.* 2011;18:937-939[50]; Taavoni S, Ekbatani N, Kashaniayn M, Haghani H. Effect of valerian on sleep quality in postmenopausal women: a randomized, placebo-controlled clinical trial. *Menopause.* 2011;18: 951-955[51]; Leach MJ, Moore V. Black cohosh (*Cimicifuga* spp.) for menopausal symptoms. *Cochrane Database Syst Rev.* 2012;9: CD007244. doi: 10.1002/14651858.CD007244.pub2.[52]

There is no evidence of effectiveness for evening primrose oil (*Oenothera biennis*). Not only is there a lack of evidence for the use of dong quai (*Angelica sinensis*) or gingko (*Gingko biloba*) for symptom relief, but both of these products are also associated with heavy uterine bleeding and even potential subdural hematomas. Licorice root (*Glycyrrhiza glabra*) has not been found to be effective, and high doses or long-term use can cause hypertension and kidney, liver, or cardiac dysfunction. Some women use wild yam (*Dioscorea villosa*) as a cream based on the perception that it provides progestational effects, but this herb is not converted to

progesterone in the body.[4]

Acupuncture

Practitioners of acupuncture stimulate precise points of the body, usually by inserting fine needles into the skin. Studies show inconsistent results for the effectiveness of acupuncture for relieving menopausal symptoms. Methodological limitations, such as challenges in creating double-blind study designs, limit researchers' ability to more definitively answer questions about effectiveness. In summary, many experts agree that acupuncture is a promising therapy but requires more study to determine its effectiveness.[4,53]

Homeopathy

Homeopathy is based on the principle of "like cures like," in which practitioners use highly diluted preparations of plant extracts and minerals to promote an individual's innate healing processes. As yet, the precise mechanisms of action of homeopathy are poorly understood. A homeopathic remedy is theorized to act as a catalyst, stimulating the body to heal itself. The homeopathic remedies that menopausal women use most often to relieve symptoms are Lachesis, Pulsatilla, and Sepia. Although some trials show promising results with such therapies,[54] most homeopathy research has failed to provide robust results supporting their effectiveness in improving menopausal symptoms. Further study using high-quality study designs is needed. Nevertheless, although its effectiveness studies are ongoing, homeopathy is thought to be quite safe.[4]

Hypnosis

Among the other therapies that have been advocated for treatment of women with vasomotor symptoms is clinical hypnosis. A multiyear, NIH-funded project exploring this therapy included small RCTs that demonstrated women undergoing clinical hypnosis had a decreased number of hot flashes compared to a placebo group.[55] Additional research is needed in this area, although these results are promising.

Common Conditions Experienced by Women During Midlife and Beyond

The Study of Women's Health Across the Nation (SWAN) is an ongoing, multisite, longitudinal, epidemiologic study supported by the National Institutes of Health, which is designed to examine the health of women during their middle and older years.[56] SWAN is examining the physical, biologic, psychologic, and social changes occurring in this cohort and is providing a rich repository of information about these women. As a result of SWAN and other research studies, it has become clear that many conditions exist that are linked to aging, yet separate from menopause. As women age, a variety of chronic diseases, such as hypertension, diabetes mellitus, and cancers, are more likely to develop.[4,57]

Urinary Tract Infections

When urinary symptoms appear to be related to atrophic changes, vaginal estrogens can provide some relief of urgency, frequency, nocturia, incontinence, and recurrent urinary tract infections.[58] Systemic HT is not recommended for treatment of women with incontinence and may be deleterious.[58]

Urinary tract infections should be promptly treated because they are a common cause of sepsis among older women. Incontinence and overactive bladder are not an inevitable part of aging, and clinicians should not regard them as expected outcomes among older women.[4,59] Incontinence is discussed in more detail in the *Gynecologic Disorders* chapter.

Sexuality

The majority of women who are in midlife or older remain sexually active, and menopause is generally not related to sexual satisfaction.[60] As women age, they may place more emphasis on aspects of sex other than vaginal penetration, and the ability to recalibrate expectations allows for sexual satisfaction even if sexual activity differs from that pursued during the younger years.[60] Unfortunately, many myths about sex and aging continue to exist, including the myth that midlife and older women are uninterested in sex. According to findings of the National Social Life, Health, and Aging Project, many women are sexually active at midlife and beyond: 62% of women age 57 to 64 years reported partnered sexual activity in the previous year, as did 39% of women age 65 to 74 years, and 17% of women age 75 to 85 years.[61] More than 50% of sexually active women in all age groups reported having sexual activity 2 or 3 times per month. Health promotion for women of all ages who are in new or nonmonogamous relationships, should include discussions about the prevention of sexually transmitted infections.

Some midlife women report difficulties with sexual function. Although each woman's experience is different, the three primary sexual health concerns that midlife women report are decreased sexual desire, decreased vaginal lubrication, and inability to have an orgasm. Information regarding sexual history taking can be found in the *Introduction to the Care of*

Women chapter. Certain situations for the midlife or older woman might require even more time to evaluate in depth. These include changes in body image following a hysterectomy or mastectomy; arousal phase disorders, which can be exacerbated by anxiety or depression; and an unwelcome loss of sexual partners due to divorce or death.

Decreases in levels of ovarian hormone levels, which can vary from woman to woman, may contribute to sexual function changes. Decreased blood flow to the clitoris and loss of vaginal elasticity can contribute to discomfort during sexual activity. As testosterone levels gradually decline, many women notice a decrease in libido. Midwives should consider referring women of any age for sex therapy if they report concerns related to sexual function, especially when there is long-standing sexual dysfunction, current or past abuse, or an acute psychological event. Additional information about sexual disorders can be found in the *Gynecologic Disorders* chapter.

Among women who experience natural menopause, researchers have found differences in decline of sexual arousal related to race/ethnicity: Women of Japanese descent appear to experience a greater decline when compared with white women, whereas African American women experience a smaller decline. Women with induced menopause have reported a decline that lasted for as long as five years.[4]

Androgen Therapy

Some clinicians argue that it is beneficial for midlife women to receive androgen therapy because even a slight and gradual decrease in a postmenopausal woman's total testosterone level may be associated with decreased libido and other negative changes that can be managed with androgen therapy.[4,11] Others argue that women often require supraphysiologic dosing to appreciate any improvement in sexuality. Women's serum androgen levels do not accurately predict sexual function, and exogenous androgen use is not associated with an actual increase in sexual behavior.[4,14]

Currently there are no androgen-containing HT products for women approved by the FDA, although some clinicians prescribe custom-compounded micronized testosterone or various other androgen-containing products on an off-label basis. Side effects associated with androgen therapy include acne, growth of facial and body hair, clitoral enlargement, permanent voice deepening, emotional volatility, and deleterious effects on lipids and liver function.[4] Effects on cardiovascular disease or breast cancer, as well as long-term consequences of androgen therapy, are poorly understood. In addition, androgens do not protect the endometrium from estrogen's hyperplasia effects, and women with an intact uterus who receive estrogen–androgen therapy should also use a progestin.[14]

Endometrial Hyperplasia or Cancer

Bleeding after menopause may be an indication of endometrial or uterine malignancy or a condition of premalignancy such as atypical endometrial hyperplasia. Women who experience postmenopausal bleeding should be referred to a specialist for further evaluation. Endometrial biopsy and sonographic scanning are usually included in the initial assessment.[4] **Table 18-8**

identifies some of the critical elements to be included in a consultation or transfer note for a women with postmenopausal bleeding. In addition to the biopsy and ultrasound, other management interventions may include a dilatation and curettage and potentially a hysterectomy if a malignancy is discovered.

Table 18-8	Sample Critical Elements for a Consultation or Transfer Note for a Woman with Postmenopausal Bleeding
Date or year of final menstrual period	
Risk factors for endometrial cancer, including genetics, family history, personal past history, nulliparity, and obesity	
Current and past use of hormone therapy, including hormonal contraception and specific hormonal therapy	
Current medications, including tamoxifen	
Last Pap test and results

Sleep Disturbances

Midlife women frequently report problematic sleep patterns, defined as an inadequate number of hours of sleep, sleep of poor quality, or an inability to function in an alert state during desired waking hours. Women might experience insomnia as a prolonged time needed to fall asleep, as inability to stay asleep all night, or as early awakening without being able to get back to sleep. Estimates of sleep difficulties vary widely, but as many as 48% of women in the United States age 40 to 64 years report sleep difficulties, including fewer hours of sleep than desired, more frequent insomnia, and more frequent use of prescription sleep aids when compared to premenopausal women.[4]

Sleep difficulties can have adverse effects on quality of life. Primary sleep disorders such as restless legs syndrome are common in midlife women. Night sweats secondary to hot flashes can be managed with other treatments for vasomotor conditions. However, night sweats are not the only etiology of sleep disorders.

Women who report problems sleeping in addition to diminished capacity to enjoy life, energy loss, appetite disturbance, or increased somatic complaints, or who have poorly diagnosable physical problems, may be experiencing major depression. Thyroid dysfunction, autoimmune disorders, infections such as HIV and tuberculosis, illnesses causing chronic pain, and medication effects are all worthy of consideration when providing care to women reporting sleep difficulties.[4] Likewise, chronic illnesses such as cardiac and mood disorders and anxiety from stressful life events can be related to sleep difficulties.

Women with mild sleep disturbances or women who are motivated to avoid medication therapy are often successful at improving the quality and quantity of their sleep with lifestyle

changes. Avoiding caffeine in the evening may improve sleep patterns; women should be aware that caffeine can be found in energy drinks, some nonprescription pain relievers, premenstrual syndrome symptom-relief remedies, weight-control products, alertness aids, cold medications, and diuretics. Moreover, caffeine has a long half-life and it can take several hours before the stimulant effects wane.[4] Alcohol can initially assist a person in falling asleep, but it can also cause fragmented sleep and early awakening. Nicotine also disrupts sleep, as do drugs such as marijuana, heroin, and prescription opioids.

A light snack with protein and complex carbohydrates, or a source of tryptophan such as milk or chamomile tea, may improve the ability to fall asleep. Engaging in vigorous exercise or stressful activities close to bedtime can cause difficulties in relaxing and falling asleep, but regular, moderate exercise earlier in the day can promote healthy sleep habits. Erratic sleep hours, as well as naps, can negatively affect sleep quality. A regular schedule capitalizes on the light/dark cycle. A warm bath or other pleasant ritual, as well as reserving the bedroom for only sleep and sex, can condition better sleep patterns.[4]

Weight Changes

Midlife women frequently report weight gain, with the average weight gain during the menopause transition being approximately 5 pounds. However, evidence does not support a causal relationship: Neither menopause nor HT appear to *cause* weight gain.[4] Instead, aging and lifestyle factors are more likely to cause an increase in weight. Lean muscle mass decreases with age, lowering a woman's metabolic rate. This reduced metabolic rate, combined with a more sedentary lifestyle, causes women to burn fewer calories and gain weight if they do not reduce their caloric intake.[62]

Regardless of cause, it is clear that many women in the United States are overweight or obese. These women are at an increased risk for adverse health consequences, including cardiovascular disease, hypertension, type 2 diabetes, certain cancers, and premature death. Thus, diagnosis and management of obesity and overweight, including counseling about lifestyle management strategies, are vitally important.

Hair and Skin Changes

Sun damage, redistributed or decreased subcutaneous fat, skin laxity from weight changes, and decreased underlying muscle tissue cause most of the skin changes that women notice during midlife years. Other potential midlife skin changes include dryness, acne, hair loss, brittle and slow-growing nails, and decreased wound healing, all of which may contribute to psychological distress or altered body image.[4]

The midwife is likely to find a variety of benign skin lesions when examining the skin of women in their midlife years. Some examples are skin tags (fibroepitheliomas) or benign, soft, brown, pedunculated polyps usually found on eyelids and the neck. Seborrheic keratosis or sharply defined, flat, light or dark brown papules are usually found on the trunk. Campbell de Morgan spots (cherry angiomas) are red dome-shaped papules also found primarily on the trunk. Acne rosacea, an inflammatory condition of the sebaceous glands, likewise has an

increased incidence with age.

Although the great majority of skin lesions are benign, the clinician should always consider the possibility of a dermatologic malignancy and consult with or refer the woman to a dermatologist as indicated. This vigilance is particularly important when a woman has a lesion that has asymmetry, border irregularities, color variations, a diameter greater than 6 mm, or a sudden increase in size.[4] If any vulvar lesions have an atypical appearance, vulvar cancer should be considered and vulvar biopsy and/or referral to a specialist arranged.

Thyroid Function Changes

The incidence of thyroid dysfunction increases as women age, and screening for thyroid dysfunction is more cost-effective in perimenopausal and postmenopausal women than it is in younger women.[4] Relying on classic symptoms of thyroid disease to prompt screening is problematic in this age group because other common perimenopausal symptoms such as changes in menstrual bleeding characteristics, sleep difficulties, fatigue, mood changes, heat intolerance, and palpitations overlap with symptoms of thyroid dysfunction. Thus, a higher index of suspicion is needed to diagnose and treat thyroid disease early in the older woman compared to her younger counterpart.[4]

Oral Health

The oral mucosa contains estrogen receptors, so variations in hormone levels can have a direct effect on the oral cavity.[63] Postmenopausal women experience periodontal disease more frequently and more severely. Saliva naturally decreases during menopause and may lead to oral problems such as xerostomia, burning mouth syndrome, an increase in dental caries, dysesthesia, taste alterations, gingivitis, periodontitis, and osteoporotic jaw. A thorough oral health history, clinical examination of the oral cavity during a physical examination, and regular dental care provided by a dentist are indicated.

Bone loss in postmenopausal women is directly correlated to tooth loss. The loss of 1% of the body's total bone mineral density quadruples the risk for tooth loss.[4] Prevention of osteopenia and osteoporosis as well as treatment of women with osteoporosis will facilitate maintaining bone and dental health. Adequate vitamin D levels help to prevent and treat osteoporosis-associated periodontal disease. Regular and frequent periodontal/dental examinations as well as meticulous care at home should be stressed.[4]

Bone Health, Osteopenia, and Osteoporosis

In addition to oral health, bone health has major ramifications for the older woman. Osteoporosis is a deceptively silent disease. In this disorder, bone mass and strength are lost and bone quality deteriorates—changes that increase the risk that the bone will fracture.[64] **Table 18-9** defines key terms related to osteoporosis.[64-66] Most women do not have any symptoms and may not realize they have osteoporosis until a fracture occurs. Approximately 2 million osteoporosis-related fractures occur annually in the United States, which leads to significant morbidity among women.[65] Hip fracture is the most costly and dramatic type of fracture. Thus, preventing fracture—particularly hip fracture—is a women's health priority.

Table 18-9 **Osteoporosis Definitions**

Term	Definition
Bone mineral density (BMD)	Surrogate marker for bone strength and resistance to fracture
	Measured by dual-energy X-ray absorptiometry
	Usually measured and reported for the hip, femoral neck, and spine
	Results reported as standard deviations from the mean of a reference population
Dual-energy X-ray absorptiometry (DEXA or DXA)	Gold-standard diagnostic technology for measuring BMD
FRAX	Online fracture risk assessment tool to assist in clinical decision making for screening and treatment decisions
	Calculates absolute fracture risk/estimate of risk for fracture in the next 10 years
	Calculations include age, bone density, and risk factors
Osteoblasts	Bone-building cells (*"**B**lasts **b**uild"*)
Osteoclasts	Bone-breakdown cells (*"**C**lasts **c**ut down" or "**C**lasts **c**arve out"*)
Osteopenia	Low bone mass
	T-score between –1.0 and –2.5
Osteoporosis	Skeletal disease of low bone mass and deterioration of bone micro-architecture
	Resulting bone fragility increases the risk that bone will fracture
	BMD T-score < –2.5 constitutes osteoporosis
T-score	Comparison with mean peak BMD of a normal, young, same-sex population
	Number of standard deviations that a person's BMD differs from the mean peak BMD of a normal young adult of the same sex
	Most commonly used measurement when making clinical decisions about midlife and older women
Z-score	Comparison with a reference population of the same age, gender, and ethnicity
	Not commonly used when evaluating midlife and older women; can be misleading because bone density is often low in older adults
	Used primarily for children, teens, and young adults

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 129: osteoporosis. *Obstet Gynecol.* 2012;120:718-734[64]; Tufts G. New treatment approach for osteopenia. *J Midwifery Womens Health.* 2011;56:61-67[65]; North American Menopause Society. Management of osteoporosis in postmenopausal women: 2012 position statement of the North American Menopause Society. *Menopause.* 2012;17:25-54.[66]

Humans build bone throughout childhood, adolescence, and young adulthood, with bone mass peaking by age 18 to 25 years. Genetic factors, and to a lesser extent nutrition, physical activity, and general health, determine the amount and quality of bone that a woman has at when bone is maximal. Throughout the bone formation process, osteoclasts help to remove old bone and osteoblasts help to build new bone. With increasing age and as women become postmenopausal, more bone is removed than is built; the result can be weakened bone structure and decreased bone mass. In turn, bone becomes more fragile and is more prone to fracture even without significant trauma.[64] Certain risk factors predispose individuals to experience an even greater extent of bone loss and/or an even higher risk of fracture. **Table 18-10** summarizes risk factors for osteoporosis and osteoporosis-related fractures.

Table 18-10 Risk Factors for Osteoporosis and Osteoporotic Fractures in Women

Nonmodifiable Risk Factors	Potentially Modifiable Risk Factors
Age ≥ 65 years	Smoking
Personal history as an adult with fracture without substantial trauma	Body mass index < 20 or weight < 127 pounds
Family history of osteoporosis	Eating disorder or excessive exercise-induced amenorrhea
Hip, spine, or wrist fracture without substantial trauma in a first-degree relative	Chronic glucocorticoid use (e.g., prednisone > 5 mg/day for > 3–6 months)
Race: white and Asian women are at greatest risk, followed by Hispanic and African American women	Multiple risk factors for falling (e.g., decreased leg or arm muscle strength, diminished vision, environmental hazards, impaired cognition)
Sex: female	Chronic illnesses: rheumatoid arthritis, hyperparathyroidism, impaired absorption syndromes
Late menarche (> 15 years) or early menopause (< 45 years)	Heavy alcohol use (≥ 3 drinks/day)

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 129: osteoporosis. *Obstet Gynecol.* 2012;120:718-734[64]; Tufts G. New treatment approach for osteopenia. *J Midwifery Womens Health.* 2011;56:61-67[65]; North American Menopause Society. Management of osteoporosis in postmenopausal women: 2012 position statement of the North American Menopause Society. *Menopause.* 2012;17:25-54.[66]

Clinicians usually diagnose and manage women with low bone mass by measuring bone mineral density (BMD) with dual-energy X-ray absorptiometry (DXA), an enhanced type of X ray. Examples of indications for BMD are listed in **Table 18-11**. Although BMD is not a perfect surrogate for fracture risk, a person's BMD is more predictive of fracture than cholesterol level is predictive of myocardial infarction.[67]

Table 18-11 Considerations for Ordering Bone Mineral Density Testing

At menopause: women with a history of fracture or with a parent who had a hip fracture or multiple vertebral or nonvertebral fragility fractures
Before menopause or during menopausal transition: women with specific risk factors for increased fracture risk such as anorexia, long-term glucocorticoid use, metabolic bone disease, hyperthyroidism, low body weight, prior low-trauma fracture, or high-risk medication
For treatment decisions: to monitor effects of osteoporosis therapy, if being considered for medications, or if evidence of bone loss would lead to treatment

As indicated by FRAX: clinicians can use FRAX to determine which women younger than 65 years should have BMD testing; if FRAX indicates that a woman has a 9.3% or higher 10-year risk of major osteoporotic fracture, it is reasonable for that woman to have a DXA
To monitor effects of DMPA on bone density

Abbreviations: BMD, bone mineral density; DMPA, depot medroxyprogesterone acetate; DXA, dual-energy X-ray absorptiometry; FRAX, World Health Organization's Fracture Risk Assessment Tool.

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 129: osteoporosis. *Obstet Gynecol.* 2012;120:718-734[64]; Tufts G. New treatment approach for osteopenia. *J Midwifery Womens Health.* 2011;56:61-67[65]; North American Menopause Society. Management of osteoporosis in postmenopausal women: 2012 position statement of the North American Menopause Society. *Menopause.* 2012;17:25-54.[66]

If bone mass is placed on a continuum in which normal bone mass is 1 standard deviation (SD) above and below 0, *osteopenia* represents the next finding on the continuum. Osteopenia is defined as decreased bone mass ranging from 1 SD below 0 to 2.5 SD below 0. This condition is three times more prevalent than osteoporosis. Moving even farther away from normal bone mass on the continuum, *osteoporosis* represents even more significantly decreased bone mass, 2.5 SD below 0 and lower (**Figure 18-2**). A T-score is the most commonly used reporting method for the results of the DXA measurements.[64] Generally, DXA measurements are taken at the femoral neck, at the posterior–anterior lumbar spine, and as a total hip measurement; the lowest of the three values determines the diagnostic category to which the individual is assigned.[64]

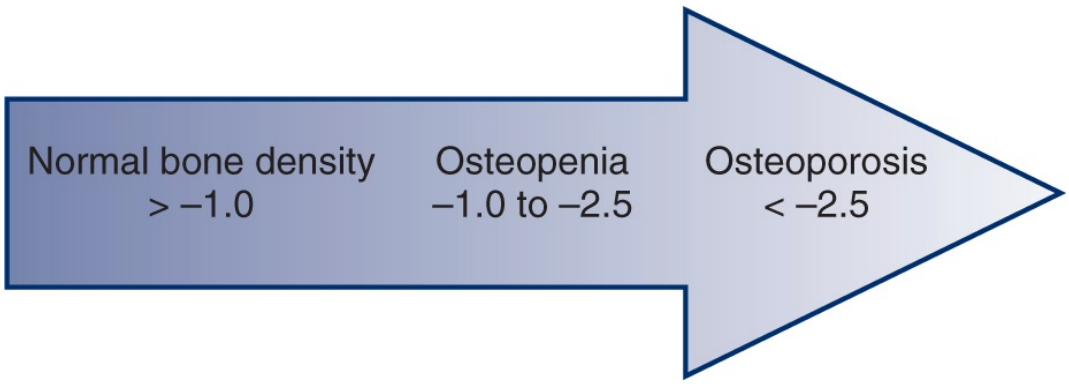

Figure 18-2 Bone mineral density continuum.

Data from National Osteoporosis Foundation. *Clinician's Guide to Prevention and Treatment of Osteoporosis.* Washington, DC: National Osteoporosis Foundation; 2010.[68]

FRAX: The Fracture Risk Assessment Tool

Clinically, the important goal related to bone health is *fracture prevention*, rather than simply promoting a specific BMD score. BMD is just one aspect of a woman's bone health, as other factors also influence fracture risk. The World Health Organization's Fracture Risk Assessment Tool, also known as FRAX, was developed to assist clinicians in estimating the likelihood of a major (e.g., hip, spine, forearm) fracture in the next 10 years.[64] Economic modeling for cost-effectiveness determines the cut-offs for treatment recommendations. For the U.S. population, the National Osteoporosis Foundation recommends treatment for persons with a 3% or higher

chance of breaking a hip in the next 10 years or a 20% or greater chance of breaking any major bone in the next 10 years.[68]

Risk factors in the FRAX algorithm include age, gender, smoking, consumption of three or more alcoholic drinks per day, rheumatoid arthritis, low BMI, prolonged corticosteroid use, secondary osteoporosis, parent with a hip fracture, and lower BMD.[65] The algorithm does not take into account certain aspects of these risk factors, such as the amount of tobacco use or corticosteroid use, and it does not consider some risk factors at all (e.g., activity level; risk for falling; and intake of caffeine).[69]

The National Osteoporosis Foundation provides several clinical caveats to consider when using FRAX. When caring for women in the United States, for example, clinicians should consider that FRAX is intended for postmenopausal women and not for younger adults or children. For women currently or previously taking osteoporosis medications, the midwife should exercise caution in interpreting FRAX scores because FRAX has not been validated in this population. Moreover, while the intent of FRAX is to make clinical decisions more straightforward, all treatment decisions require careful clinical judgment of characteristics of the individuals. FRAX does not capture all risk factors; conversely, its recommendations do not mandate treatment.[69]

Lifestyle and Nonpharmacologic Strategies to Promote Bone Health

Robust scientific evidence supports several lifestyle changes and nonpharmacologic strategies to promote bone health for all women. These strategies are generally inexpensive, have minimal inherent risks, and can confer benefits for other aspects of a person's health. They include consuming a healthy diet with an adequate amount of certain nutrients, participating in regular weight-bearing exercise, maintaining a healthy weight, and avoiding tobacco use and excessive alcohol intake.

Of the various dietary nutrients, calcium and vitamin D are the most vital for bone health, and consumption of a diet rich in these nutrients and/or supplement intake of them lowers fracture risk.[65] Major organizations such as the National Osteoporosis Foundation, the National Academy of Sciences, and the Institute of Medicine recommend that women older than age 50 years consume 1200 mg of calcium per day and 800–1000 IU of vitamin D per day.[68] The best sources of vitamin D and calcium are in foods. Vitamin D and calcium supplements for the purpose of improving bone health have not been shown to be effective and are not recommended for healthy adults.[70] Recommendations regarding the use of Vitamin D for falls prevention in women 65 years and older are described in the *Health Promotion Across the Lifespan* chapter.

Muscle-strengthening and weight-bearing exercise has multiple benefits for the bone health (and overall well-being) of midlife and older women. Improved strength, balance, agility, and posture can reduce the risk of falling; falling has the potential to bring significant negative sequelae, such as fractures, pain, disability, and death. Exercise also has a modest effect on bone density; that is, bone mass increases in response to activities that place stress on bones.[65]

Body weight less than 127 pounds and a BMI less than 20 kg/mm^2 are risk factors for low

bone mass and increased fracture risk. The benefits of gaining weight should be discussed with very thin women, with recommendations made for approaches that can be used to achieve a healthy weight.[65,68]

In addition to their many other deleterious health effects, smoking and excessive alcohol intake have significantly negative effects on women's bones. Women smokers have lower bone mass, lose bone more quickly, and have significantly higher fracture risk than nonsmokers.[68] While moderate alcohol intake does not have any recognized detrimental effects on bones, consuming three or more alcoholic drinks per day increases the risk of osteoporotic fracture and falling.[65,68]

Pharmacologic Therapies for Osteoporosis Management

A focus on lifestyle strategies may be all that is necessary to promote bone health and minimize fracture risk for midlife and older women at low risk for fracture. However, midwives should consider pharmacologic therapy for women with any of the following: osteoporosis (T-score of –2.5 or lower), history of a low-trauma hip or vertebral fracture, or osteopenia (T-score between –1 and –2.5) *if* FRAX indicates a 10-year probability of 3% or greater of a hip fracture or a 10-year probability of 20% or greater of a major osteoporosis-related fracture.[65,68,69]

Estrogen in the form of ET or EPT has long been an FDA-approved agent for preventing osteoporosis, however, it is not approved as a treatment for this condition. Aside from estrogen, a variety of FDA-approved medications are available to prevent and/or treat osteoporosis, including bisphosphonates, raloxifene (Evista), calcitonin (Fortical), and teriparatide (Forteo). **Table 18-12** summarizes the medications in each category, dose, and basic prescribing issues. Adherence to pharmacologic osteoporosis treatment is often poor, with adherence rates in 6- to 12-month studies ranging from less than 25% to as high as 81%.[68] Thus, if the midwife and the woman decide that medication is indicated, it is important that the woman be educated about her fracture risk and the purpose of therapy, and then identify and eliminate barriers to appropriate use of that agent.[69] Dosing frequency seems to affect adherence, such that weekly dosing enhances adherence for many women when compared to daily dosing.[65,68]

Table 18-12 Medications for Treatment of Women with Osteoporosis

Medication Generic (Brand)	Dose	Comments
Bisphosphonates		
Alendronate (Fosamax)	Prevention: 5 mg daily or 35 mg weekly tablet or oral solution Treatment: 10 mg daily or 70 mg weekly tablet or oral solution	Bisphosphonates are considered by many experts to be first-line therapy for osteoporosis
Ibandronate (Boniva)	Prevention: 2.5 mg daily or 150 mg monthly tablet Treatment: 2.5 mg daily or 150 mg monthly tablet or 3 mg every	Choice of bisphosphonate is often

	3 months IV	made based on the desired dosing regimen
Risedronate (Actonel)	Prevention and treatment: 5 mg daily; 35 mg weekly; 35 mg weekly packaged with 6 tablets of 500 mg calcium carbonate; 75 mg on two consecutive days every month; and 150 mg monthly tablet	Take 30–60 min before eating in the morning, with 8 ounces water; sit/stand upright for 30–60 min
Zoledronic acid (Reclast)	Prevention: 5 mg IV every 2 years Treatment: 5 mg IV annually	Side effects for all oral bisphosphonates: difficulty swallowing, esophageal inflammation, gastric ulcers
Calcitonin		
Salmon calcitonin (Miacalcin; Fortical)	Treatment (> 5 years postmenopause): 200 IU daily nasal spray	FDA approved for treatment of women with vertebral osteoporosis but not osteoporosis at nonvertebral sites (e.g., hip) Other agents are more reliable at both vertebral and nonvertebral sites; calcitonin is not a first-tier therapy
Estrogen Agonist/Antagonists (EAAs) [previously known as selective estrogen receptor modulators (SERMs)]		
Raloxifene (Evista)	Prevention and treatment: 60 mg daily	Not only inhibits bone resorption, but also decreases risk of breast and uterine cancers Effective at reducing the risk of vertebral fractures but not hip or other nonvertebral fractures Can cause hot flashes Contraindicated in women with venous thromboembolism history
Parathyroid Hormone		
Teriparatide (Forteo)	Treatment (postmenopausal women at very high fracture risk): 20 mcg daily SQ	Indicated for women with established osteoporosis at very high risk of primary fracture Indicated for women with continued fractures despite use of other antiresorptive therapies

Abbreviations: FDA, U.S. Food and Drug Administration; IV, intravenous; SQ, subcutaneous.

Based on North American Menopause Society. Management of osteoporosis in postmenopausal women: 2012 position statement of the North American Menopause Society. *Menopause.* 2012;17:25-54[66]; National Osteoporosis Foundation. *Clinician's Guide to Prevention and Treatment of Osteoporosis.* Washington, DC: National Osteoporosis Foundation; 2010.[68]

Conclusion

Menopause is a healthy, natural life process. Similar to pregnancy, menopause is a time when women often present to the healthcare system. Midwives are well situated to care for women at midlife. Midwifery care during this phase of life includes development of an individualized plan for health promotion and disease prevention, as well as health screening and early identification and management of disease. As primary care providers, midwives have an opportunity to provide leadership in the delivery of holistic, woman-centered health care to women as they age without imposing negative biases.

PART IV

Antepartum

JOYCE E. ROBERTS

It is generally accepted that prenatal care is essential for achieving the best outcomes of pregnancy. However, the quality of prenatal care, when it is initiated, the number of "visits," the qualifications and expertise of the caregiver, the context of the care (e.g., birth center, clinic, hospital based, private or public), as well as the accessibility of secondary, consultative or medical care are all important to achieve positive health outcomes. Ideally, prenatal care will occur within a collaborative, multidisciplinary context wherein various health professionals are available to contribute to timely and accurate diagnosis of problems and offer appropriate interventions. Ultrasound, genetic diagnosis, and prenatal educational resources are especially important.

The chapters in this section address a wide range of healthcare services, including genetics, pregnancy, and medical complications that affect women during pregnancy. Prenatal care includes the consideration of guidelines, such as those developed by the U.S. Preventive Services Task Force, the assessment of pregnancy status, interpretation of screening tests, consideration of diagnostic strategies, and decisions about when to seek consultation and how to engage in collaborative care when the woman's needs merit medical care and management of complications.

The general health and reproductive history of a pregnant woman are critical antecedents to the healthy progression of a pregnancy and positive birth outcomes. It would be ideal if prenatal care was always preceded by preconception care, but often this is not the case. Lack of preconception care makes prenatal care especially important for achievement of optimal pregnancy outcomes, as well as an occasion to influence the future health of the woman—indeed, the health of her children and family and, ultimately, society—through timely recognition of health problems and the promotion of positive health practices. This type of care is especially critical as a means to identify chronic diseases and health behaviors that might be modified or addressed during the course of prenatal care. Key behaviors to be considered

include nutritional practices, substance use, and exercise.

The chapters in this section provide specific information regarding genetics; anatomic and physiological changes during pregnancy; the interpretation of pregnancy status, including the assessment of key physical parameters; and guidance regarding the recognition of health problems and complications unique to pregnancy.

A key initial consideration is the gestational age of the pregnancy—that is, the age of the fetus. Assessment and determination of gestational age is used to organize the topics addressed in this section and incorporated in the accompanying figures and tables that summarize key information. Gestational age is an essential "lens" through which the midwife should "hear" and "view" the information acquired in conversation with the woman and in clinical observation. It is a key parameter that helps the midwife achieve the purposes of prenatal care—namely, accurately assessing the status of pregnancy during a prenatal visit, recognizing problems through the interpretation of the woman's symptoms and the results of diagnostic tests, and offering timely interventions to achieve healthy pregnancy outcomes and a satisfying pregnancy and birth experience for the expectant mother.

Two basic dimensions of pregnancy are considered in providing prenatal care. The first is the physical health of the pregnant woman, the status of her pregnancy, and the growth and well-being of her fetus, including various screen modalities, laboratory tests, and genetic screening. The second is the experiential aspects of pregnancy and the woman's responses to her pregnancy. The chapters in this section provide essential content about the scope and content of prenatal care with consideration of the woman's emotional status, as well as the physical dimensions of pregnancy and fetal growth. This content includes the assessment of pregnancy status, the genetic basis of the fetal condition, the critical features of diagnostic tests, and the screening, recognition, and management of health problems and complications of pregnancy within a care setting that allows for consultation and multidisciplinary care. This information is presented in a systematic fashion that will enable the reader to interpret the objective data related to prenatal assessment and care and to use it in a way that reflects the best-practice principles used in providing prenatal care. Detailed tables and charts summarizing screening criteria, specific tests, and the range of results, along with listings of additional resources related to prenatal care, are included.

Given the limited accuracy of diagnostic testing and the uncertainty of the outcomes of interventions, it is essential that the midwife deliberately engage the woman in her own assessment of her situation and shared decision making. The midwife should ensure that the woman understands the information and alternatives available to her, and that the woman considers interventions in accordance with her beliefs and values.

These chapters will enable midwives to address the challenges of providing prenatal care—specifically, obtaining and interpreting information about the ongoing pregnancy, knowledgably recognizing health problems and complications of pregnancy, and using a deliberative approach within the interactive context of ongoing prenatal visits with pregnant women and their support persons. In addition, midwives are encouraged to maintain an orientation geared toward facilitating women's "readiness" for labor and ability to deal with the challenges of early parenting, including breastfeeding.

Introduction

Pregnancy is a time of profound anatomic and physiologic change. In addition to the reproductive organs, all maternal physiologic systems make adaptions needed to support the developing fetus and, at the same time, maintain maternal homeostasis. A thorough understanding of these changes is an essential foundation for all healthcare providers—including midwives—who care for women during pregnancy. This chapter provides an overview of changes in the reproductive organs, the effect of the major hormones of pregnancy, fetal development, maternal adaptations that take place during pregnancy.

The Reproductive Organs During Pregnancy

Pregnancy lasts approximately 266 days or 38 weeks from ovulation (postconceptional weeks). This translates into 10 lunar months or 9 calendar months (because some months have 5 weeks). If dating occurs from the last normal menstrual period, some sources note the duration of human pregnancy is 280 days or 40 completed weeks' gestation. When counting gestation in weeks, it is important to remember that the number changes after the week is completed. Therefore 23 5/7 weeks' gestation is 23 completed weeks since the last menstrual period and an additional 5 days. This translates to 21 completed weeks and 5 days since conception.

Over the course of pregnancy, a woman's breasts grow and prepare for lactation. The uterus increases to approximately 5 times its normal size; at 38 gestational weeks, the uterus measures approximately 32 centimeters long, 22 centimeters across, and 24 centimeters wide. The cervix must first act as a barrier maintaining the uterine contents. However, at the end of pregnancy, the cervix becomes soft and short, opening to allow passage of the fetus during birth. These remarkable changes are the result of a complex interplay of hormonal stimulation that has important clinical implications for all women, but especially those who have congenital uterine anomalies, as well as those who experience miscarriage, preterm labor, preeclampsia, and other pregnancy complications.

The Breast

Under the direction of several different pregnancy hormones, the breast undergoes two distinct developmental changes to prepare for lactation during pregnancy. Both stages—mammogenesis and lactogenesis I—include hyperplasia and hypertrophy.[1] Hyperplasia refers to an increase in the number of cells, or cellular proliferation. Hypertrophy refers to enlargement of the cells; that is, cells grow in size.

Mammogenesis begins early in pregnancy. Breasts enlarge via cellular hyperplasia, and the breast lobules increase in size. The nipples become erectile, the areola becomes proportionately larger and darker, and superficial veins can become visible. During this process, an individual may feel her breasts are tender or even painful. Alveoli expand and proliferate at the end of breast lobules; the lobules proliferate as well.

Toward the middle of pregnancy, the alveoli epithelial cells change into secretory epithelium, which is the first stage of lactogenesis. Toward the end of pregnancy, the alveoli secrete colostrum but are primarily quiescent secondary to inhibition by progesterone, one of the primary pregnancy hormones. After birth, the influence of progesterone abruptly ceases and lactogenesis II—that is, the onset of milk production—begins. A more detailed description of lactogenesis II is presented in the *Breastfeeding and the Mother–Newborn Dyad* chapter.

The Uterus

The three layers of the uterus (endometrium, myometrium, and perimetrium) become clearly defined over the course of pregnancy. The uterus grows at a steady, predictable rate during pregnancy, with its expansion first becoming detectable at approximately 5 weeks' gestation. The initial uterine growth occurs in the anteroposterior diameter, while the isthmus or lower segment of the uterus can become very soft. This softening results in marked compressibility in the lower uterine segment that is present for a short period of time at approximately 4 to 6 weeks after the first day of the woman's last menstrual period started, and approximately 2 weeks after conception. This unusual compressibility, called *Hegar's sign*, is a probable sign of pregnancy. As seen in **Figure 19-1**, during a bimanual examination, the lower segment of the uterus is so soft that it can be easily compressed between the fingers of the examiner's two hands (one on the abdomen and the other gloved hand in the posterior fornix of the vagina).

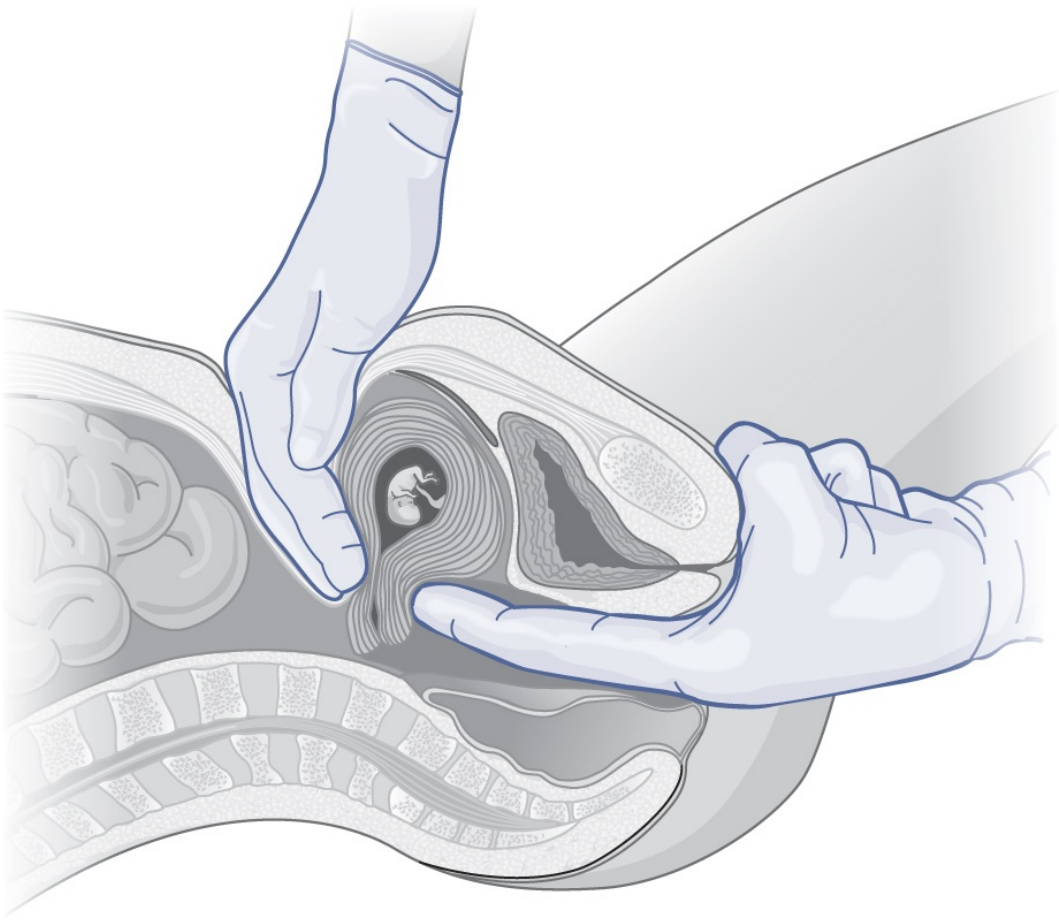

Figure 19-1 Hegar's sign.

The uterine shape changes from the nonpregnant pear shape to a ball or sphere in the first trimester, and then expands to an elongated cylinder. The anatomic location of the uterus in relation to maternal anatomy is illustrated in **Figure 19-2**.

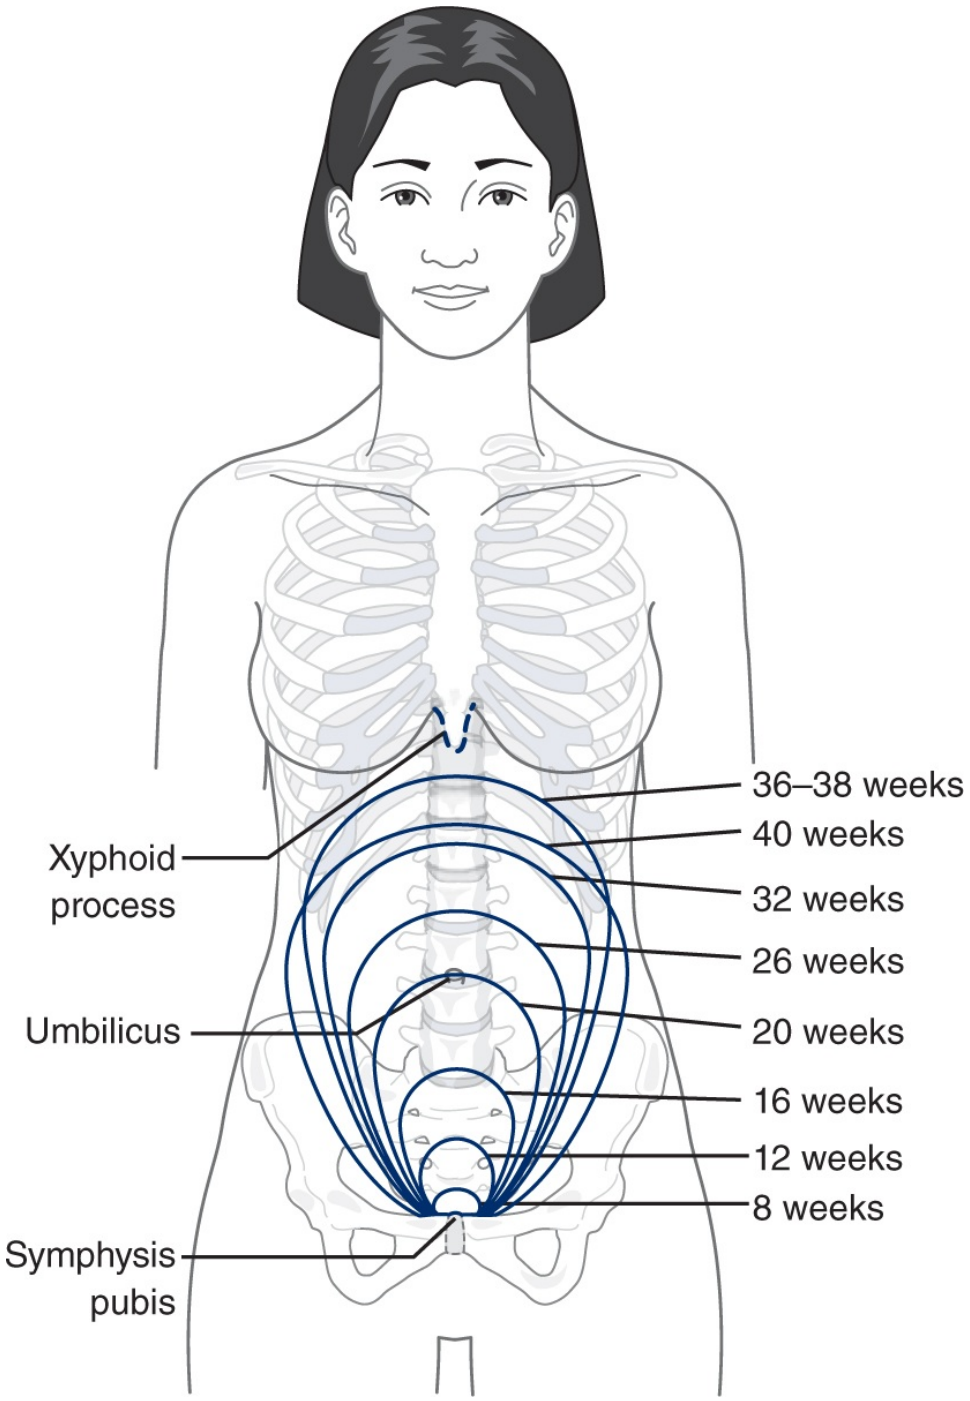

Figure 19-2 Approximate normal fundal heights during pregnancy.

The uterine round ligaments attach on either side of the uterus just below and in front of the insertion of the fallopian tubes; they then cross the broad ligament in a fold of peritoneum, pass through the inguinal canal, and insert in the anterior (upper) portion of the labia majora on either side of the perineum. The ligaments are composed largely of smooth muscle that is continuous with the smooth muscle of the uterus. The round ligaments hypertrophy during pregnancy and stretch as the uterus enlarges. During periods of rapid uterine growth, women may feel stretching or sharp pain in the inguinal area when moving or turning, which is secondary to additional torsion or stretching of the round ligament.

Growth of the uterus is due to two processes: (1) estrogen- and progesterone-induced

hyperplasia of uterine smooth muscle cells within the myometrium during early pregnancy and (2) hypertrophy of the uterine muscles later in pregnancy. The muscles increase their content of actin, myosin, sarcoplasmic reticulum, and mitochondria, which collectively serve as the machinery used to contract the muscles during labor and birth, as described in the *Anatomy and Physiology During Labor and Birth* chapter. The myometrium thus has both properties of contractility and elasticity. Contractility allows for lengthening and shortening, whereas elasticity refers to the ability to stretch.

Transformation of the Endometrium into the Decidua

The secretory endometrium contains columnar epithelium, epithelial cells, and nonresident or migratory immune cells and spiral arteries. The radial arteries that supply the myometrium branch into basal arteries, which become the spiral arteries that supply part of the myometrium and the endometrium.[2]

The endometrial changes that allow and facilitate implantation are collectively termed the *decidual reaction*. The name "decidua" was chosen for this process because, like the leaves on deciduous trees, the transformed tissue is shed after birth.[3] The decidual reaction occurs in response to estrogen, progesterone, and a complex dance or "cross-talk" of locally produced chemicals generated by the blastocyst and maternal endometrium.

Approximately 8 days after ovulation, the secretory endometrium provides a 4- to 5-day "window of opportunity" for blastocyst implantation.[4] During this short span of time, immune cells congregate, the endometrial glands become more secretory, and the epithelial surface develops small protrusions called pinopods and cell-adhesion molecules.[5] The pinopods absorb fluid from the uterine cavity and likely play key roles in attracting the blastocyst. Once the blastocyst is in contact with the endometrium, the pinopods and trophoblastic protrusions interact to facilitate implantation (**Figure 19-3**).[6] It is thought that physiologic variations in the development of the endometrial "window of opportunity" could result in failure of implantation; this hypothesis is currently the subject of infertility research.

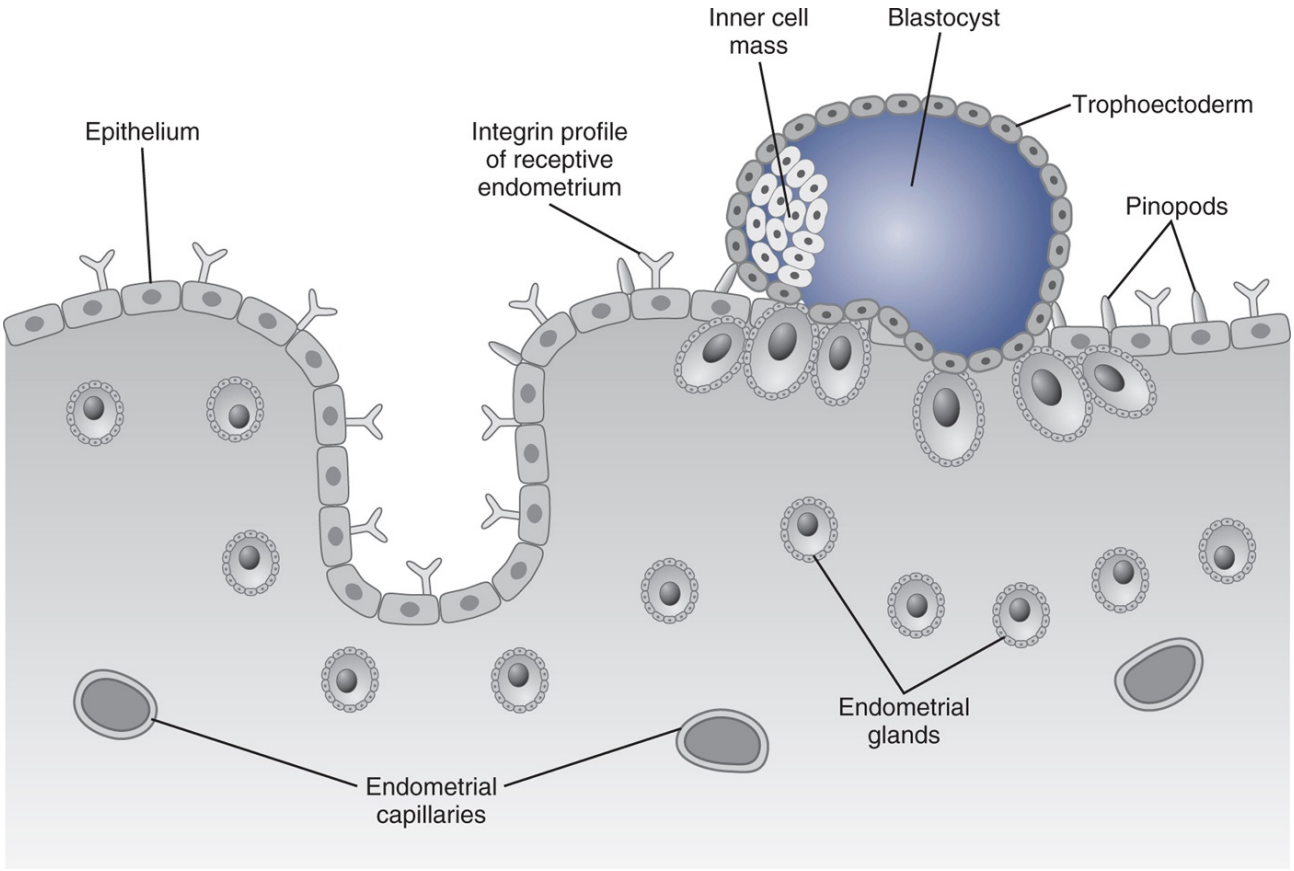

Figure 19-3 Implantation of the blastocyst.

The decidual reaction starts once the blastocyst is present at the endometrial site of implantation. The endometrial stromal cells become larger, round, decidual cells that have a membrane to which the trophoblast can anchor itself, and another surge of chemical "cross-talk" occurs.[7]

The decidua fulfills multiple roles, including a key role in directing trophoblastic invasion and provision of nutrition to the embryo in the early stages of embryology. The entire maternal decidua is divided into three regions: the *decidua basalis*, the *decidua capsularis*, and the *decidua parietalis*. These three regions are named for their positional relationship to the conceptus. The decidua basalis is the site where implantation occurs and is the future site of the maternal potion of the placenta. It is subdivided into a *zona compacta* and a *zona spongiosa*, the latter of which is the site of detachment of the placenta in the third stage of labor. The decidua capsularis lies like a capsule around the chorion, whereas the decidua parietalis is found on the opposite uterus wall. At approximately the fourth month of gestation, the decidua capsularis comes into contact with the decidua parietalis. The merging of these two causes the uterine cavity to become obliterated.

Uterine Innervation

Changes in uterine innervation are among the most interesting physiologic effects of pregnancy. The uterus is primarily innervated by the sympathetic nervous system, with some fibers coming from the parasympathetic nervous system and cerebrospinal tract. Innervation is not consistent

throughout the uterus; for example, more nerve fibers are found near the cervix as compared to the fundus. Sympathetic nerve fibers in the uterine fundus virtually disappear during pregnancy, whereas those in the cervix remain.[8,9] Although the reasons for these changes are not clear, it is postulated that the lack of sympathetic innervation protects the uterus from sympathetic stimulation via catecholamines and resultant contraction activity. Uterine contractions during pregnancy and labor occur secondary to endocrine stimulation rather than via muscle fiber nerve stimulation.

Cervical Remodeling During Pregnancy

In nonpregnant women, the cervix is an average of 3 centimeters long.[10-12] In essence, it is a tubular structure, made up of two major structures: the *ectocervix* and the *endocervix*. The ectocervix, which is visible from the vagina, comprises an external layer of columnar epithelial cells and a layer of squamous epithelial cells. The endocervix is the internal, canal-like portion of the cervix, which opens into the uterus. It is covered with a single layer of columnar epithelial cells. The cervical openings are referred to as the *internal os* and *external os*, as described in the *Anatomy and Physiology of the Female Reproductive System* chapter. In nulliparous women, the opening of the endocervix at the external os is pinpoint and circular in size; in contrast, in multiparous women, the external os has a slit-like appearance.

Glandular tissue in the cervix produces thick, tenacious mucus, which forms the mucus plug sealing the endocervical canal. This mucus plug helps prevent ascending bacteria or pathogens from entering the uterine cavity during pregnancy.

During pregnancy, the cervix is composed primarily of connective tissue covered by a thin layer of smooth muscle, which itself is covered by the columnar epithelial cells. The extracellular connective tissue within the cervix contains protein (in the form of collagen and elastin) and proteoglycans (primarily hyaluronic acid and decorin); it is referred to as the *extracellular matrix*. Approximately 80% of the cervix comprises extracellular matrix and 15% is smooth muscle, but the distribution is quite heterogeneous.[10-14] The area closest to the internal os has more smooth muscle, whereas the area closer to the external os has more extracellular matrix. The strength of the collagen tissue depends on the type and number of crosslinks between the collagen microfibrils.

Over the course of pregnancy, labor, birth, and the postpartum period, the cervix normally undergoes four distinct phases: (1) softening, which is also called *remodeling*; (2) accelerated softening at the end of pregnancy, referred to as *ripening*; (3) dilation; and (4) repair.[13] Under the influence of estrogen in pregnancy, the cervix first begins to soften approximately 4 weeks after the first day of a woman's last menstrual period. This cervical softening, called *Goodell's sign*, is one sign of pregnancy.[11] As vascularization increases, a cyanosis or bluish-purple discoloration called *Chadwick's sign* develops. Chadwick's sign is usually first evident at 6 to 8 weeks' gestation.

Following the initial relatively rapid softening, the cervix continues to soften throughout the pregnancy, albeit at a slower rate. The collagen becomes more soluble and compliant, but does not lose structural integrity. Several factors can adversely influence cervical architecture during pregnancy, including infection, genetic factors, and previous surgical procedures that involved the cervix. Usually the cervix remains between 30 and 40 millimeters in length throughout gestation. Women whose cervix shortens to less than 20 millimeters are at increased risk for preterm labor.

Cervical Ripening Prior to Labor

"Cervical ripening" is the term used to describe the process of accelerated remodeling and softening that begins weeks prior to the onset of labor. Cervical remodeling and activation of

uterine contractions are the two primary physiologic events that are associated with the initiation of parturition or labor. Cervical ripening results from a series of interactions between hormonal and mechanical factors that have not been fully elucidated. As progesterone levels fall and estrogen levels rise, the water content and vascularization of the cervix increase and the collagen cells become disorganized, which results in a marked reduction in the mechanical strength of the collagen bundles.

The local paracrine activity of prostaglandins PGE2 and PGF2a also influence the cervical ripening and the onset of labor. Fetal production of corticotropin-releasing hormone and cortisol causes an upregulation of prostaglandin receptors in the cervix and uterus. PGE2 facilitates cervical vasodilation. Finally, production of pro-inflammatory cytokines leads to infiltration of the cervix by leukocytes and macrophages. These cells release enzymes that facilitate alterations in extracellular matrix proteins, loosening of collagen fibers, and a reduction in collagen content.

Cervical Effacement and Dilatation

Toward the end of gestation and extending into early labor, the cervix shortens or thins so that there is no discernable length between the external os and the internal os. This process, which occurs in response to uterine contractions, is referred to as *effacement*. The cervix also begins to *dilate* as the process continues. Effacement and dilatation generally occur during early labor in nulliparous women but may occur prior to progressive labor in multiparous women. However, the onset of labor is not often discrete. There is significant variability between individuals with regard to the degree of effacement and dilatation that has occurred when labor begins.

Many women notice an increase in vaginal secretions during pregnancy called *leukorrhea*. This phenomenon likely occurs because, in addition to normal vaginal secretions produced by the epithelial cells, the cervical glands secrete an increased amount of mucus at this time in order to form the cervical mucus plug. These cervical and vaginal secretions likely form the basis of the physiological discharge of leukorrhea.

Hormones of Pregnancy

The placenta is the primary physiologic interface between the maternal and fetal compartments and is a central mediator for chemical messages between the fetus and the pregnant woman. The primary hormones of pregnancy produced by the placenta are estrogen, progesterone, human chorionic gonadotropin (hCG), and human placental lactogen (hPL). Each of these hormones has a major role in supporting pregnancy (**Table 19-1**). In addition, the placenta and the fetus synthesize other chemical mediators that act both locally and systemically to support growth and development of the fetus and placenta itself; many of these mediators are still being discovered.

Table 19-1 **Major Hormones and Functions During Pregnancy**

Hormone	Source	Selected Functions During Pregnancy
Human chorionic gonadotropin (hCG)	Syncytiotrophoblast	Stimulates production of progesterone from the corpus luteum
	Placenta	Prevents degeneration of the corpus luteum, thereby ensuring ongoing estrogen and progesterone production
		Promotes formation of syncytiotrophoblast during trophoblastic invasion
		Aids spiral artery remodeling during the process of trophoblastic invasion
		Promotes angiogenesis in uterine vasculature
		Stimulates thyroid production of thyroxine in the first trimester
		Suppresses myometrial contractions
Human placental lactogen (hPL)	Placenta	Increases insulin resistance
		Stimulates production of growth hormones
Progesterone	Corpus luteum	Promotes systemic vasodilation
	Placenta	Has anti-inflammatory actions to protect trophoblast from being rejected
		Supports decidualization within the endometrium
		Prevents myometrial contractility
		Inhibits uterine production of prostaglandins
		Supports mammary growth for lactation
		Withdrawal at term leads to uterine contractions
Estrogen	Ovaries	Softens collagen fibers in cervix and ligaments
	Corpus luteum	Increases uterine blood flow
	Placenta	Promotes growth of the uterus and breast glandular tissue
	Fetus	Increases production of insulin-like growth factors
		Enhances myometrial contractility
		Increases myometrial sensitivity to oxytocin, may upregulate oxytocin receptors

Human Chorionic Gonadotropin

Human chorionic gonadotropin is a glycoprotein with both alpha and beta subunits. The alpha subunit is structurally the same as luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). The beta unit can have various forms depending on the tissue that produces it and is the basis of modern qualitative pregnancy tests.[15-17] Serial plasma levels of beta-hCG can be used to provide quantitative levels used to diagnose and monitor development of the early conceptus.

Human chorionic gonadotropin is secreted by the syncytiotrophoblast tissue within the blastocyst before implantation occurs, and then later by the placenta. The first role of hCG is to sustain estrogen and progesterone production in early pregnancy by preventing degeneration of the corpus luteum. The level of the free beta unit of hCG (beta-hCG) rises in early pregnancy and is first detectable approximately 8 to 10 days after ovulation, or shortly before the first missed menses. This timing coincides with implantation of the fertilized ovum.[18] This level doubles approximately every 48 to 72 hours in 85% of women with normal pregnancies, maintaining this rate of increase until it reaches a peak of approximately 100,000 mIU/mL at 8 to 11 gestational weeks. At this point, the plasma level of beta-hCG slowly decreases to a stable level of approximately 20,000 mIU/mL (**Figure 19-4**).[18]

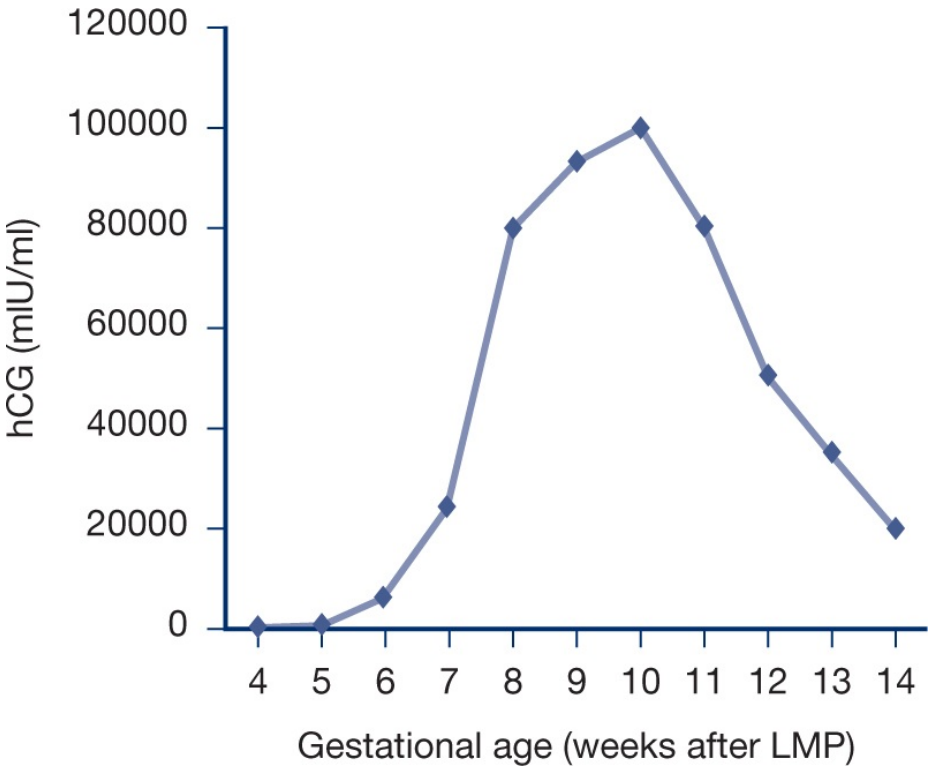

Figure 19-4 Human chorionic gonadotropin values in the first trimester of pregnancy.

Abbreviations: hCG, human chorionic gonadotropin; LMP, last menstrual period.

The characteristic doubling time of hCG has been used in serial measurements of blood values to assess the viability of pregnancy. Because there is wide individual variability in hCG levels, however, some patterns of serial hCG levels (e.g., slower than expected increases) can be difficult to interpret. Moreover, although an hCG level may be obtained every 2 days if clinically indicated, assessing these values every 48 hours can sometimes be too soon to see a

full doubling of the hCG plasma level.[19] Serial quantitative measures of the beta subunit are used to determine the viability of a pregnancy, as described in the *Prenatal Care* and *Medical Complications in Pregnancy* chapters. Plasma levels of the beta subunit are also used as a marker for tumors that have an embryologic origin, such as choriocarcinoma and hydatidiform mole.

The natural rise and fall of hCG levels also corresponds to the natural history of nausea and vomiting in the first trimester. Although the direct etiology of nausea and vomiting in pregnancy is not known, it has been postulated that hCG may play a role. Nevertheless, studies that have linked hCG levels to nausea symptoms have not shown a direct correlation between the two. Women who have severe nausea and vomiting or hyperemesis may also have subclinical hyperthyroidism; in such women, the alpha subunit of hCG is able to stimulate the thyroid gland as though it were TSH.[20]

Human Placental Lactogen

Human placental lactogen, which is structurally similar to growth hormone, ensures adequate fetal nutrition by altering maternal glucose metabolism so that glucose is available for fetal uptake. This transformation is achieved primarily by mobilizing fatty acids from lipids to provide an alternative fuel for the pregnant woman while sparing glucose for the fetus. hPL also increases maternal insulin resistance, thereby assuring consistent blood levels of glucose for fetal use. Glucose is transported across the placenta via facilitated diffusion.

The fetus relies primarily on glucose for nutritional needs; fetal production of glucose either does not occur or is undetectable.[21] It appears that the fetal liver does not develop the mechanism necessary for gluconeogenesis until just before birth.

The hPL-induced insulin resistance results in an increase in maternal insulin levels. This, in turn, stimulates amino acid production, thereby ensuring that amino acids are also available for fetal growth and development.

hPL is secreted by the placental syncytiotrophoblast. This agent is detectable in maternal circulation at 6 to 8 gestational weeks, with levels increasing in direct proportion to placental growth.

Progesterone

Progesterone and estrogen—both steroid hormones—act as intracellular chemical messengers by binding to intracellular receptors. These hormones influence many aspects of DNA transcription and cellular activities.

Progesterone is essential for maintenance of pregnancy in all mammals, and its name is derived from this function: “pro-gestational steroidal ketone.” This hormone maintains the uterus in a quiescent state and helps suppress the maternal immune response to fetal antigens so that the fetal tissue is not rejected. Progesterone is produced by the corpus luteum in early pregnancy. The placenta then assumes the progesterone production at some point during gestational weeks 7 to 9, an event called the “luteal-placental shift.” Additional functions of progesterone during pregnancy are listed in **Table 19-1**.

Low levels of progesterone in pregnancy are associated with an increased risk of spontaneous abortion. Women with luteal-phase defects can have progesterone levels that drop in early pregnancy, leading to spontaneous abortions. Progesterone supplementation has been shown to be effective for treating threatened miscarriage.[22,23] Progesterone is also used to prevent preterm birth in women who had a previous preterm birth.[24] Alternatively, administration of mifepristone, a progesterone receptor antagonist, will cause miscarriage.

Estrogen

Three types of naturally occurring estrogen have been identified: estrone, estradiol, and estriol. Estriol (E_3) is the primary estrogen of pregnancy. Estrogen production during pregnancy entails a three-part interplay between the woman, fetus, and placenta; each of these three separate but interrelated factors completes part of estrogen synthesis but not all of it. Estrogen is initially synthesized in the corpus luteum until the eighth or ninth week of gestation. At that point, the fetal adrenal glands are mature enough to produce the necessary estrogen precursors, and the placenta is able to produce and excrete the active forms of estrogen. Placental estrogen production depends on input from both the fetal and maternal adrenal cortex because the placenta cannot produce the androgenic C19 steroid dehydroepiandrosterone (DHEA), and its sulfoconjuate, DHEA-S, which are essential substrates of estriol.

Selected effects of estrogen during pregnancy are listed in **Table 19-1**. Estrogen encourages growth of breast tissue, stimulates uterine contractility, and increases uterine receptiveness to oxytocin. For most of pregnancy, however, the uterus remains refractory to the effects of estrogen—a consequence of the influence of progesterone, which ensures that the uterine myometrium has very few estrogen receptors.

Fertilization and Implantation

The processes that make it possible for the single cell that results from the fusion of the ovum and the sperm to develop and mature within the course of months are the subject of many fields of study, including genetics, embryology, and fetology. It is beyond the scope of this chapter and this text to cover these topics in detail. Instead, this chapter presents an overview of the knowledge needed by a practicing midwife with regard to the milestones of embryologic and fetal development and the intricate and vulnerable steps that create organs and organ systems. This understanding will help the midwife discuss embryonic and fetal development with the woman and her family and also provides general knowledge regarding the causes of congenital malformations.

Fertilization

Fertilization is the process of fusion of two haploid (containing 23 chromosomes) cells—a sperm and an ovum—to form a diploid (containing 46 chromosomes) cell or zygote. Once a sperm cell binds to receptors on the oocyte membrane, its nucleus is pulled into the cytoplasm of the oocyte and the oocyte membrane depolarizes, causing destruction of other sperm cells. This prevents the binding of other sperm cells and, therefore, polyspermy. Once the sperm enters the ovum, the oocyte, which was arrested in the metaphase of the second meiotic division, completes metaphase. As the nuclei of the ovum and the sperm swell, fertilization occurs, the nuclear membranes disappear, and pairing of the chromosomes occurs to create the diploid zygote (**Figure 19-5**).

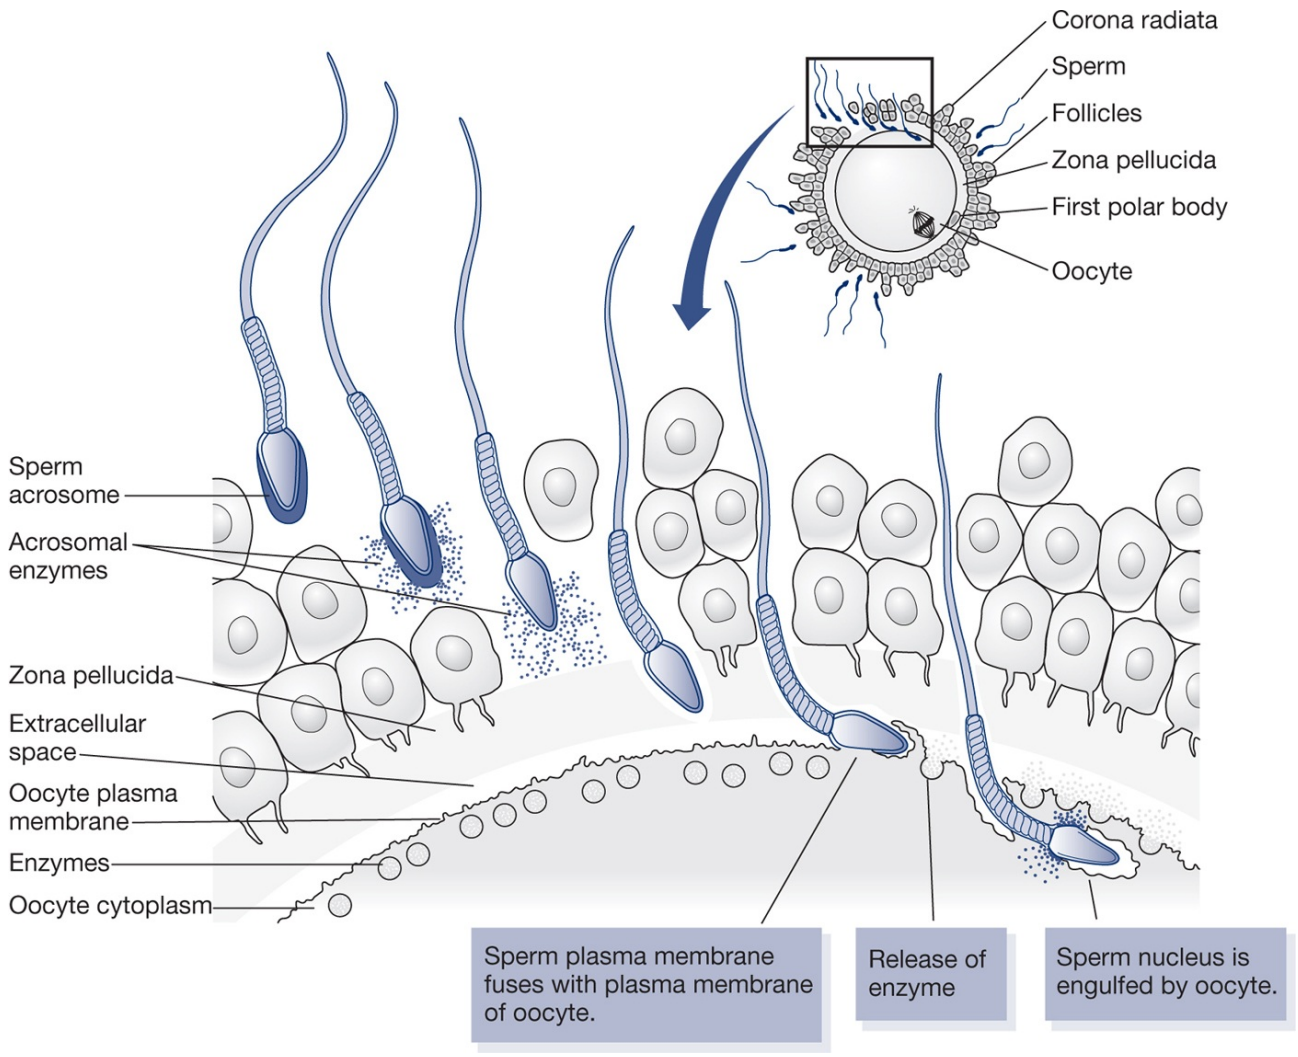

Figure 19-5 The process of fertilization.

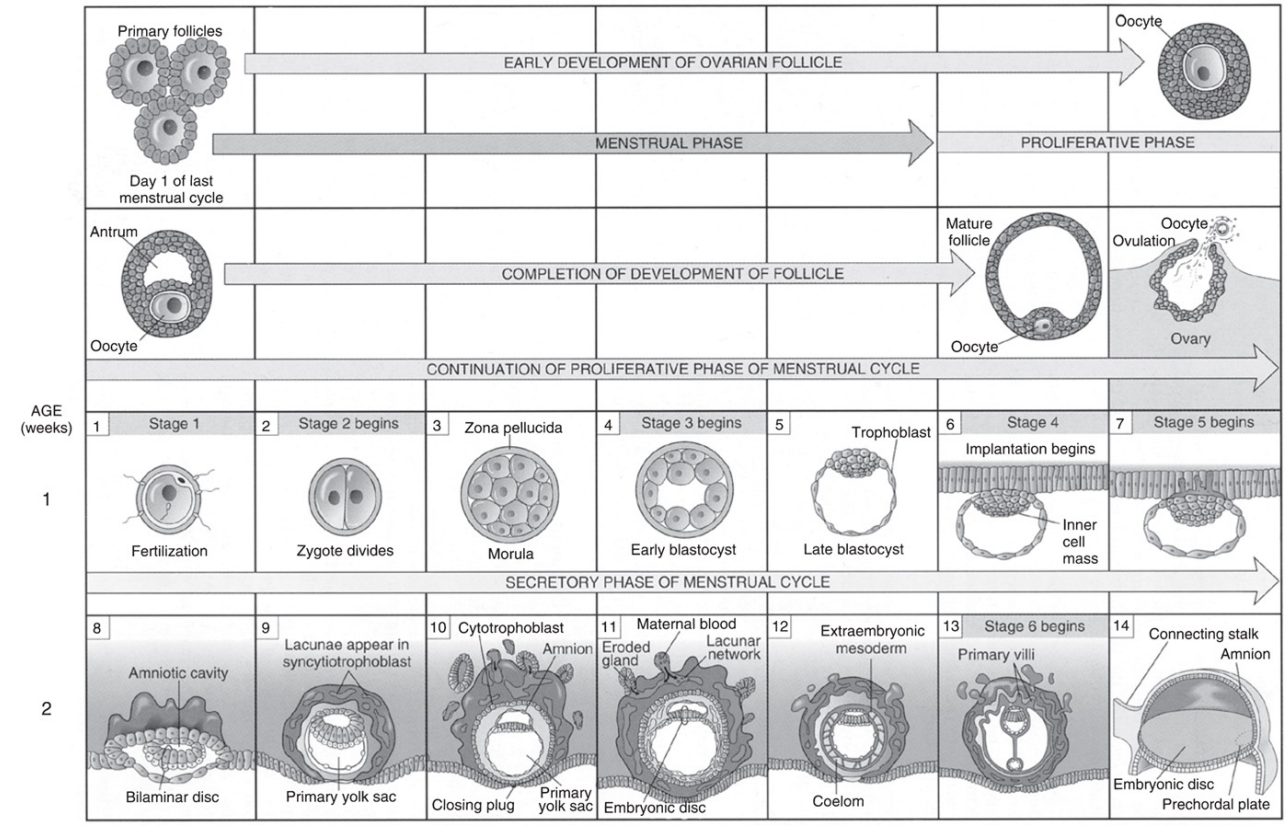
Fertilization usually occurs in the fallopian tube and takes approximately 18 to 24 hours. The fertilized oocyte becomes known as a *zygote*. The zygote begins as a single cell that contains 46 chromosomes: 23 from the ovum and 23 from the sperm. At this stage, the genetic code for that individual is formed. The 23rd pair of chromosomes determines the fetus's sex. The ovum contains only an X chromosome, so the X or Y chromosome that pairs with the maternal X chromosome is donated by the sperm.

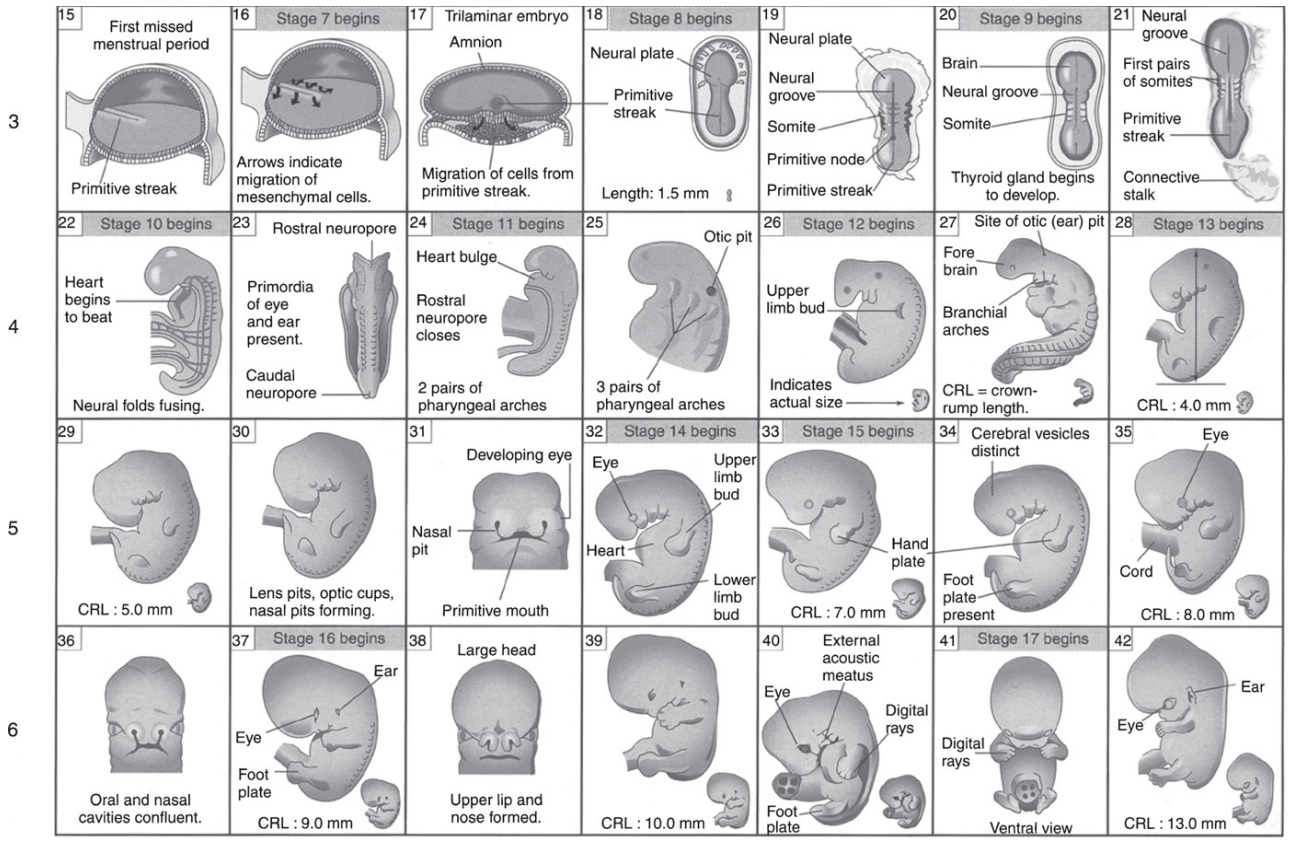
Blastocyst

As the zygote moves through the fallopian tube into the uterine cavity, the cells divide (rapid mitotic activity) and create additional cells. These cells, known as blastomeres, are held together by the zona pellucida (an extracellular glycoprotein matrix) and form a solid ball of 12 to 16 cells known as the *morula*. As the morula enters the uterus, which occurs approximately 4 days after fertilization, intracellular fluid increases and a central cavity forms. The zygote is now called a *blastocyst*. The blastocyst is composed of four components: (1) the zona pellucida, (2) an inner cell mass, (3) an outer layer of cells called the trophoblast, and (4) a fluid-filled cavity. The trophoblast eventually forms the placenta and chorion, while the inner

cell mass develops into the embryo and amnion.



The blastocyst is said to “hatch” when it sheds the zona pellucida. At approximately 10 to 12 days post conception or 1 to 2 gestational weeks, the blastocyst implants in the decidua.[25] The blastocyst is guided to a receptive area, usually in the fundus, for implantation. It orients itself so that the embryonic pole is closest to the endometrium, and the process of implantation begins.



The Trophoblast and Implantation

The trophoblast is unique tissue playing an essential role in pregnancy. The trophoblast, in contact with the endometrium, first differentiates into two distinct tissues: the syncytiotrophoblast and the cytotrophoblast. The *syncytiotrophoblast* is a syncytium or multinucleate protoplasmic mass formed by the fusion of cells, some of which were endometrial decidual cells. The syncytiotrophoblast burrows into the endometrium and remains in contact with maternal blood throughout gestation.[25] This tissue becomes the primary source of hCG.[26] The implantation process can result in light vaginal bleeding or spotting, referred to as “implantation bleeding,” and can be mistaken for a light menses.

As the syncytiotrophoblast invades the endometrium, it disrupts maternal endometrial capillaries, portions of which are engulfed and become the lacunae. This process initiates the lacunar stage, which is marked by growth of small vacuoles in the syncytiotrophoblast that multiply and eventually fuse to form a system of *lacunae*. Initially, these lacunae fill with a substance derived from glandular secretions of the endometrium and a filtrate of maternal blood that diffuses through the trophoblastic tissue and serves to nourish the embryo. The lacunar networks enlarge and communicate with each other as they evolve into the intervillous space (IVS). *The intervillous space* will fill with maternal blood and bathe the placental villi as they form into this space (**Figure 19-6**).[27]

TIMETABLE OF HUMAN PRENATAL DEVELOPMENT
1 TO 6 WEEKS

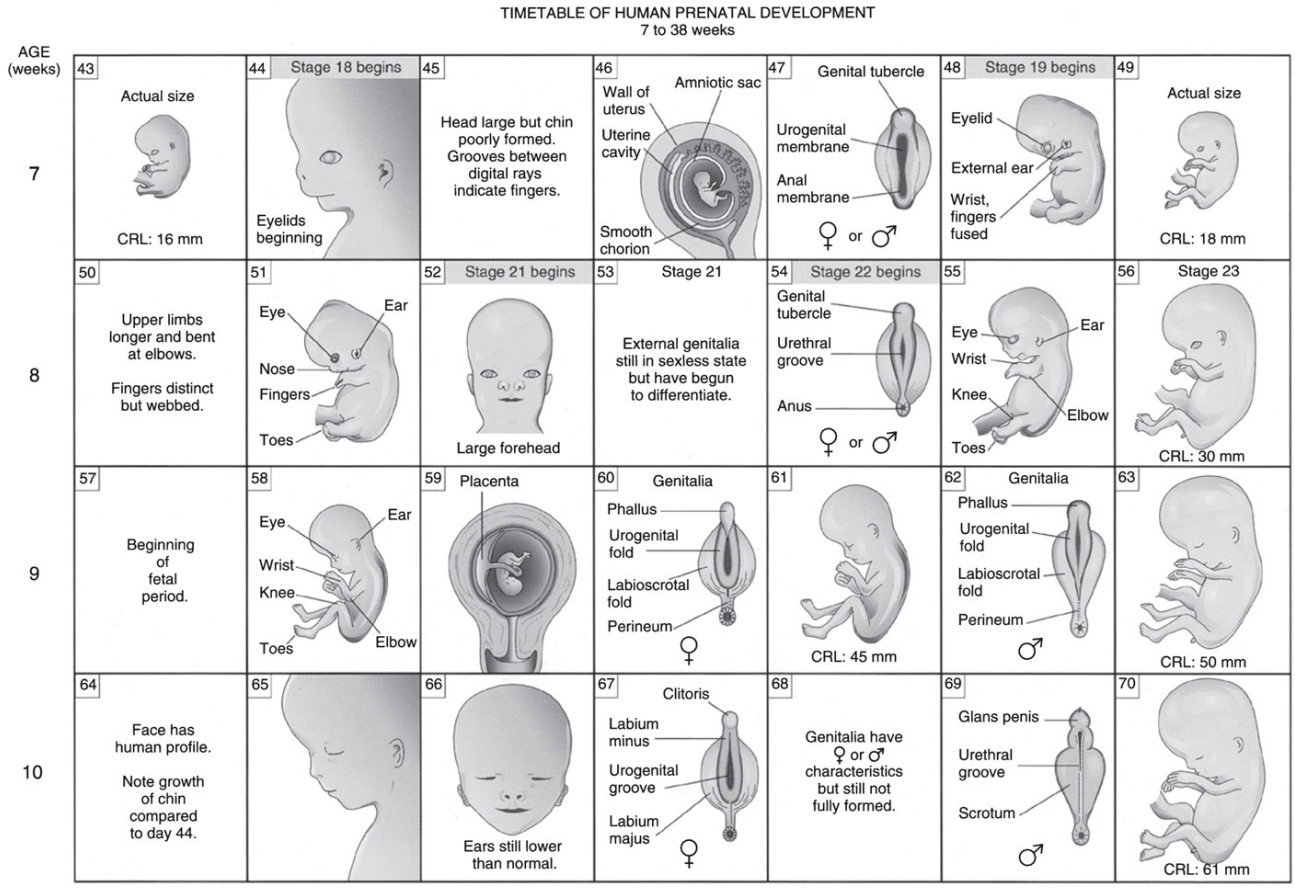


Figure 19-6 Development of an ovarian follicle containing the oocyte, ovulation, and phases of the menstrual cycle are illustrated. Human development begins at fertilization, approximately 14 days after the onset of the last menstruation. Cleavage of the zygote in the uterine tube, implantation of the blastocyst, and early development of the embryo are shown.

Reproduced with permission from Moore KL, Persaud TVN, Torchia MG. *The Developing Human: Clinically Oriented Embryology*. 10th ed. Philadelphia, PA: Elsevier; 2015.[27]

The *cytotrophoblast* tissue is the point of contact between fetal and maternal tissues. The cytoblast differentiates into extravillous trophoblasts, and these trophoblasts then form columns of cells that become the anchoring villi of the placenta (**Figure 19-7**).[17,25] Proliferative extravillous cytotrophoblast cells also invade the spiral arteries, that developed in the luteal phase to provide blood to the endometrium. When the cytotrophoblastic cells reach the spiral arteries, the cytotrophoblastic cells replace the endothelial layer of the spiral artery and begin the process of remodeling those arteries into the low-pressure, high-volume deinnervated open vessels needed to sustain the developing fetus.[28-30]

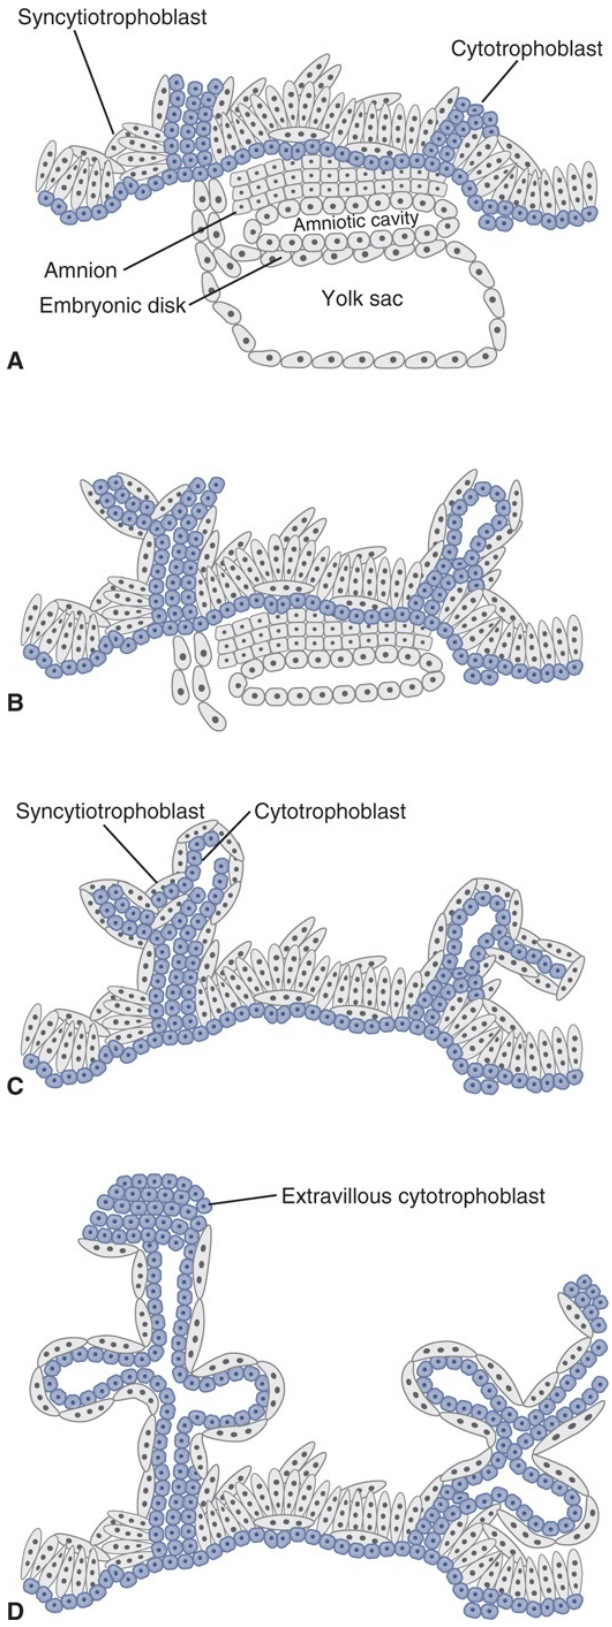

Figure 19-7 **A.** Cytotrophoblast columns in early implanted embryo. **B.** Extension of columns and differentiation of peripheral cells. **C.** Folding of extensions caused by shape of syncytiotrophoblast cells. **D.** Formation of trophoblastic villi.

This cytotrophoblastic invasion of the spiral arteries occurs in two waves. The first wave takes place in the first weeks following implantation, as cytotrophoblast cells move down the endothelial lining of the spiral arteries in the decidua. The second wave occurs between 12 and 20 weeks of gestation.[25] During this wave, the cytotrophoblast extends into the myometrial portion of the spiral arteries (**Figure 19-8**).[28-31] The changed spiral artery architecture accommodates a remarkable change in uterine blood flow. Prior to pregnancy, uterine blood flow is approximately 50 mL per minute; by comparison, at the end of pregnancy, uterine blood flow is approximately 750 mL per minute.

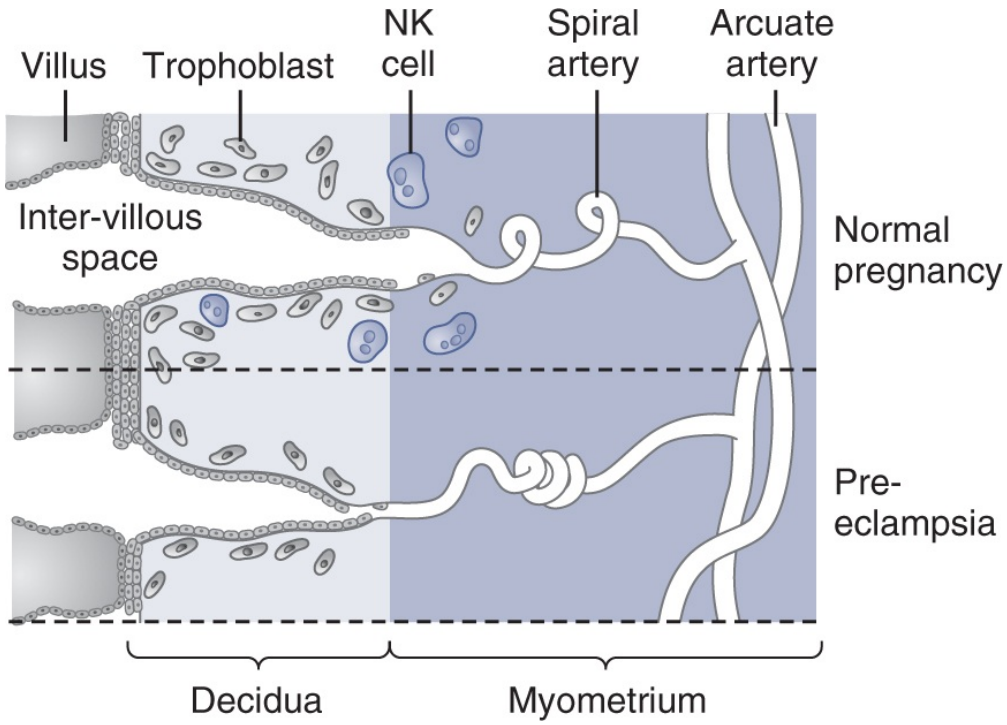

Figure 19-8 Spiral artery invasion in normal and preeclamptic pregnancies.

Based on Jain A. Endothelin-1: a key pathological factor in pre-eclampsia. *Reprod BioMed Online.* 2012;25:443-449.[31]

Complications of pregnancy can occur if cytotrophoblast cells fail to fully invade or deinnervate the spiral arteries.[29] The genesis of preeclampsia is cytotrophoblast invasion, wherein the second wave does not occur and the maternal spiral arteries remain small, high-resistance vessels. These vessels culminate in a small placenta secondary to limited maternal blood flow. The effects of preeclampsia become evident when the nutritional needs of the fetus are no longer met by the small placenta.[31] When the trophoblastic tissue invades indiscriminately, without the normal complex immunologic checks and balances that occur between the maternal and trophoblastic tissues, placenta accreta can develop. Abnormal placentation can also cause fetal growth restriction and has more recently been associated with preterm premature rupture of membranes and preterm labor.[31]

The Placenta

The placenta has been recognized as an important organ for centuries and has been imbued with many different meanings. In some cultures, the placenta is considered the alter ego or "secondary self."[32] In early Egypt, the placenta was described as the "external soul." In other cultures, it is referred to as "the tree of life," because the vessels that branch out from the insertion point on the maternal surface of the placenta look like branches of a tree.

At term, the placenta weighs approximately 500 grams, is 18 to 22 centimeters in diameter, and is approximately 2 to 2.5 centimeters thick.[33,34] This organ has a villous surface area of approximately 1.8 m^2 at term.[33] Clinical implications of common variations in placental gross anatomy and systematic evaluation of the placenta following birth are reviewed in the *Third Stage of Labor* chapter.

The placenta is a vital endocrine, hemochorial, villous organ with four well-known functions:

- Produces hormones critical for maintenance of pregnancy, and other bioactive substances.[25]
- Transports substances between the maternal and fetal circulations, including acting as the respiratory organ for gas exchange.
- Metabolizes and synthesizes agents necessary for sustaining pregnancy.
- Provides an immunologic barrier between the maternal and fetal systems.

Many of these functions overlap (**Figure 19-9**).

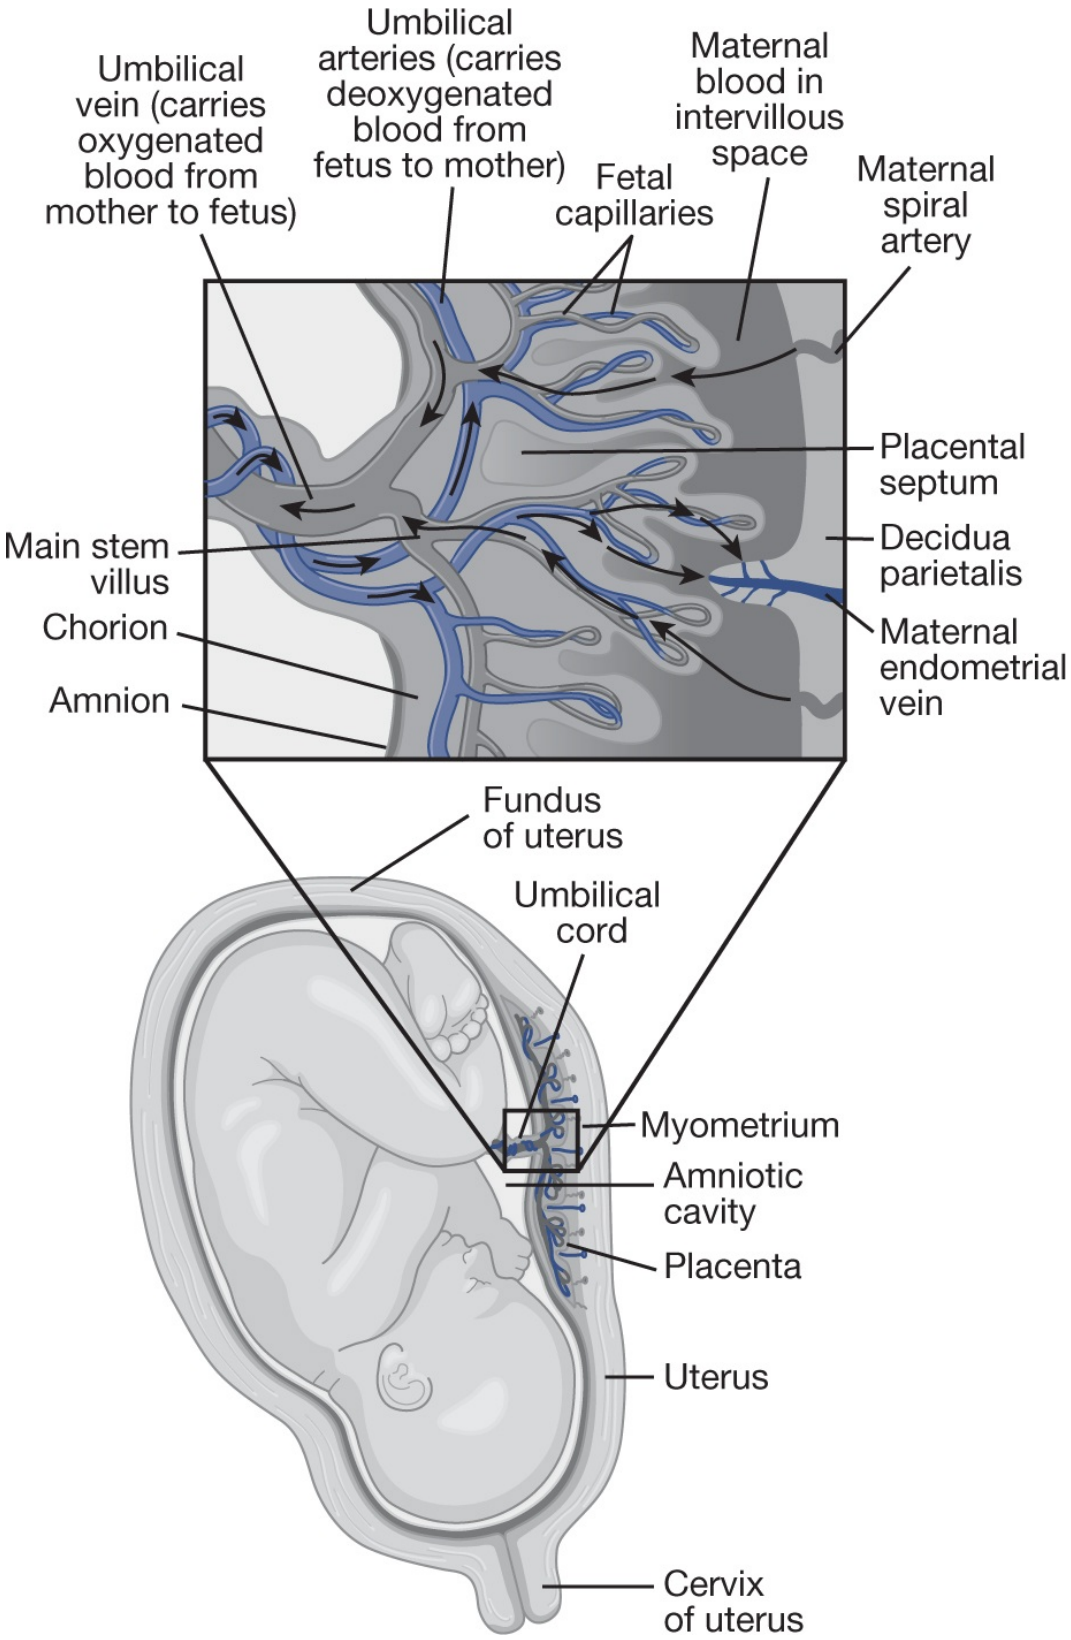

Figure 19-9 Transverse view of a placenta at a full-term pregnancy. Maternal blood flows into the intervillous spaces in spurts from the spiral arteries, and exchange of nutrients and gases occurs with the fetal blood as the maternal blood flows around the branch villi. The two umbilical arteries carry poorly oxygenated fetal blood to the placenta; the one umbilical vein carries oxygenated blood to the fetus. The placental cotyledons are separated from each other by septa projections of the decidua basalis. Each cotyledon consists of two or more main stem villi and branches.

Recent research regarding placental function suggests that the placenta may also play a more complex role during pregnancy. Instead of being just a passive filter or barrier, which has historically been the perceived role of the placenta, this amazing organ integrates a wide range of chemical messages produced by the fetal and maternal systems and actively adapts to different conditions.[25,35] In short, the placenta plays an active and independent role in fetal growth and development.

Development of the Placenta

The cytotrophoblast lines the decidua and firmly anchors the placenta. The extraembryonic mesoderm—another tissue from the original blastocyst—grows into the cytotrophoblastic columns to form villi that float freely in the intervillous space. The fetal vessels that form within the villi are separated from maternal blood by three layers of cells: (1) fetal endothelial cells, (2) connective tissue, and (3) cytotrophoblastic cells that are eventually called the chorionic villi epithelium.

Blood flow begins in the placenta when the intervillous spaces become filled with maternal blood. Initially, the preponderance of fluid in the intravillous space consists of maternal serum and secretions from the endometrial glands, until fetal vessels begin to function at 8 to 9 weeks' gestation. Common variations in placental morphology that have clinical implications are reviewed in the *Third Stage of Labor* chapter.

Placental Transport Mechanisms

Placental function involves multiple transport mechanisms, including facilitated diffusion, passive diffusion, active transport, pinocytosis, endocytosis, bulk flow, solvent drag, accidental capillary breaks, and independent movement.[25,35] These mechanisms are described in **Table 19-2**.

Table 19-2 Placental Transport Mechanisms

Transport Mechanism	Description of Mechanism	Examples of Substances Transported via This Mechanism
Simple diffusion	Transfer of substances across a membrane down a concentration gradient (from an area of higher concentration of the substance to an area of lower concentration of the substance)	Oxygen, carbon dioxide, electrolytes, water, certain medications including analgesic and anesthetic agents
Facilitated diffusion	Transfer of substances across a membrane down a concentration gradient (such as diffusion), but in a manner that allows for more rapid or more specific transfer	Substances such as glucose that are essential for rapid fetal growth but are present in low concentrations in the maternal blood
Active transport	Transport against a concentration gradient, which requires energy	Transfer to the fetus of substances that are present in higher concentrations in the fetus than in the pregnant woman, such as iron and ascorbic acid
Pinocytosis	A form of endocytosis that allows small particles to be brought into a cell. The cell membrane folds around the	Immunoglobulin G (IgG) maternal antibodies, phospholipids used to make cell membranes,

	particle and becomes an intracellular membrane.	lipoproteins used to transport cholesterol
Breaks between cells	Active capillary breaks allow fetal and maternal cells to mix	Cell trafficking may play a role in fetal immunity and in maintaining maternal tolerance to the fetal allograft
Bulk flow	Movement of water and some solutes in water via aqueous pores	Free movement of water and some solutes maintains equal osmolality in the fetal and maternal compartments

Uteroplacental Circulation and Fetal Respiration

The uteroplacental circulation is the lifeline for the fetus. As such, physiology affecting fetal respiration deserves detailed attention. Fetal respiration depends on four factors: (1) adequate maternal blood flow into the intervillous space; (2) sufficient functional placental villi for gas exchange; (3) adequate diffusion, facilitated diffusion, and active transport of gases, nutrients, and fetal waste products; and (4) unimpaired fetal circulation through the placenta and umbilical cord.

The fetus can use either oxygen or glucose to produce the energy needed for growth and metabolic processes. Carbon dioxide (CO_2) and water (H_2O) are the end products of using oxygen for aerobic metabolism. When the fetus does not have sufficient oxygen, glucose is used to create adenosine triphosphate (ATP) for energy. This process is called anaerobic metabolism, and one of its end products is lactic acid ($C_3H_6O_3$), which has important clinical implications that are reviewed in more detail in the *Fetal Assessment During Labor* chapter.

Immunology of the Placenta

The fetus is considered a semi-allogenic graft, meaning that it consists of foreign tissue from the same species but has different antigens. The processes that ensure the woman's body does not reject the fetus have not been yet fully identified. Most importantly, the trophoblast does not express the cell surface antigens that are the usual targets for maternal antibodies. Additionally, the hormones of pregnancy alter the maternal immune response in ways that enable tolerance to contact with the cytotrophoblast and syncytiotrophoblast.

There appears to be more cellular traffic between the fetus and the pregnant woman than was originally hypothesized.[36] Fetal cells can be found in many maternal tissues and can persist in a mother for decades. Similarly, maternal cells enter the fetal circulation via mechanisms that have not been fully elucidated and may support the development of fetal immunity. The implications of this microchimerism are unknown.[36]

Role of the Placenta in Fetal Development and Programming

The placenta synthesizes many substances, including glycogen, cholesterol, and fatty acids, which contribute nutrients and energy for the embryo and growing fetus. Placental metabolism uses approximately 40% to 60% of the oxygen and glucose that is delivered into the intervillous spaces.[35] The placenta can also alter its metabolism in the presence of stressors

such as hypoxia.[35] More importantly, the placenta is instrumental in making heritable changes in gene expression (e.g., epigenetic changes) of the fetal genome that affect postnatal life.[37,38] This developmental plasticity in placental function is an area of current research interest.

Fetal Origins of Adult Disease/Fetal Programming

In the 1990s, physician and researcher David Barker published a theory that was later known by various names. Initially, it was best known as "Barker's hypothesis." Today, alternative nomenclature—such as "developmental origins of health and disease" (DOHaD), "fetal programming," and "the thrifty genotype"—is more commonly used because research has established that Barker's work is no longer a hypothesis. Barker's major finding was that fetuses who were undernourished in utero were at increased risk for chronic diseases such as obesity, diabetes, coronary heart disease, and hypertension when they grew to adulthood in a country with abundant food.[38] His work linked birth records with later health and death records in the United Kingdom. Approximately a decade after his initial publication, Barker described his basic methodology and acknowledged his debt to the meticulous and complete records of midwives, without whom he would not have had adequate data to discover the associations.[39]

Subsequent to Barker's initial work, many links have been discovered between the fetal environment and several major chronic diseases that arise during adulthood.[40-47] When a pregnant woman experiences poor nutrition, such as during war or related to severe poverty, her placenta will lower production of enzymes that protect the fetus from cortisol. More exposure to cortisol in utero enables the fetus to survive low protein intake during gestation, but increases the risk of cardiovascular disorders when that fetus becomes an adult.[43] Specific physiologic changes related to these processes are under investigation and much remains to be learned.

Current research suggests many types of prenatal stresses—not just nutrition—can permanently affect fetal physiology and infant development, especially in the areas of vascular, metabolic, and endocrine changes. Prenatal stressors may include stress hormones, environmental toxins, and even paternal genes. Currently, DOHaD is the subject of a great deal of research, including that which focuses on the evaluation of epigenetic mechanisms and the investigation of maternal, paternal, and fetal genes.

Barker's work is of importance to midwifery because it underscores the importance and complexity of preconceptional and prenatal care. In an era when prenatal visits are becoming fewer in number and shorter in duration, it is the midwife's responsibility to promote health care both for the current generation of women and for the future of society's health.

Role of the Placenta in Pregnancy-Related Complications

In the short-term, the placenta plays a central role in many pregnancy-related complications. As described, the origins of preeclampsia occur early in pregnancy although signs and symptoms develop much later. Poor maternal nutrition can result in small, poorly functioning placentas that provide inadequate nutrients to the fetus, resulting in fetal growth restriction.

Women with diabetes and hyperglycemia may experience microvascular and macrovascular placental changes, such as thickening of the basement membrane of cells, and these placentas also may not sustain normal fetal growth.

A more complex example is illustrated in the relationship between obesity and poor maternal and newborn outcomes. The placentas of women who are obese express placental genes differently than the placentas of women who are lean, and they tend to show metabolic and oxidative stress leading to cell injury and inflammation of the placenta.[48] The low-level inflammation damages the endothelial cells that line blood vessels, which in turn, adversely affects delivery of oxygen and nutrients to the fetus.

Amniotic Fluid

Amniotic fluid serves multiple functions during pregnancy, including cushioning and protecting the fetus, providing space for fetal movement and growth, and maintaining consistent temperature and pressure.[49] Substances found in amniotic fluid include electrolytes, urea, creatinine, bile pigments, renin, glucose, hormones, fetal cells, lanugo, and vernix caseosa. The fluid's osmolality and composition evolve throughout the course of the pregnancy and are similar to the characteristics of dilute fetal urine in a term gestation.

In the latter half of pregnancy, amniotic fluid is primarily produced by the fetus in the form of urine (700–800 mL) and lung fluid. The average amount of amniotic fluid at term is 700–800 mL.[50] Amniotic fluid is removed via fetal swallowing and diffusion across the placenta. The fluid secretions from the fetus's lungs contain phospholipids, including lecithin and sphingomyelin, which are components of surfactant—a substance that is essential for the function of the neonatal lungs. As pregnancy advances, the absolute and relative amounts of lecithin in amniotic fluid increase. The ratio of lecithin to sphingomyelin is used as means of assessing fetal lung maturity to help guide decisions about delivery prior to term. While the amount of fluid varies in the third trimester and begins to decrease after 40 gestational weeks, the amount of fluid that is turned over (produced and removed) remains relatively constant, at approximately 1000 mL per day.

Amniotic fluid is essential for normal fetal growth. *Oligohydramnios* at term is defined as an amniotic fluid index of 5 centimeters or less (via ultrasound assessment). Oligohydramnios in the second trimester can inhibit normal fetal lung development. Etiologies of this disorder include fetal renal abnormalities, heart disease, and fetal growth restriction. Maternal conditions that can cause oligohydramnios include severe hypertension, dehydration, and renal disorders.

Polyhydramnios is defined as an amniotic fluid index of more than 24 centimeters and is caused by too much production or too little removal of amniotic fluid. Modest polyhydramnios can be idiopathic, whereas oligohydramnios is most likely to be associated with an abnormal condition in the fetus or the pregnant woman. Conditions that can cause polyhydramnios include maternal hyperglycemia, obstructed fetal swallowing, fetal cardiac failure, and severe fetal anemia.

The Umbilical Cord

The umbilical cord has two arteries and one vein surrounded by a gelatinous collagen material called *Wharton jelly*. The vessels within the cord are longer than the cord itself, so they coil in a spiral fashion as the cord lengthens. This coiling may protect the blood flow within the cord if it is subjected to tension or compression. The maximum length of the cord averages 55 to 60 centimeters. The cord epithelium, which is formed by the amnion, typically inserts into the placenta centrally but may insert at many portions of the placenta. The only clinically relevant aspect of cord insertion occurs when the cord inserts marginally (at the placental edge) or when the insertion is velamentous, wherein the cord inserts into the membranes. With velamentous cord insertion, fetal vessels run through the membrane unprotected by Wharton's jelly. When umbilical cord vessels run through the membranes across the cervix, the presentation is termed vasa previa. Although vasa previa is very rare, fetal mortality occurs approximately 50% of the time when the vessels rupture.[51]

The Embryo

Organogenesis

Returning to the blastocyst, the *embryonic period*, which is the period of organogenesis, occurs between 2 and 8 weeks following fertilization. The *fetal period*, marked by growth and tissue differentiation, starts at 8 weeks after fertilization and extends to birth. The age of the embryo in "gestational weeks" refers to the number of weeks after fertilization in the embryology and basic science literature. Clinical obstetric texts use the term "gestational weeks" to define the number of weeks after the woman's last menstrual period. This 2-week discrepancy can be confusing unless the reader understands which terminology the author is using. This chapter follows the convention used by embryologists for this section of this chapter.

The embryonic disc within the blastocyst gives rise to three germ layers: (1) the endoderm, (2) the mesoderm, and (3) the ectoderm. The third week of embryo development is marked by a period of rapid growth, during which the mesoderm, ectoderm, and endoderm begin to undergo the dramatic transformations that form specific embryonic structures (**Table 19-3**). Most functional organs and organ systems are formed from all three embryonic germ layers. Each germ layer contributes a specific feature, but the germ layers do not produce specific structures separately from each other.

Table 19-3 Differentiation of Embryonic Germ Layers

Ectoderm	Mesoderm	Endoderm
Central and peripheral nervous system	Connective tissues	Epithelium of the digestive system (except the mouth and anus, which are involutions of the ectoderm)
Epidermis including hair, nails, and sebaceous glands	Muscle tissue	Liver and pancreas
Epithelium of sensory organs	Skeleton (bone)	Respiratory system, including alveolar cells of the lung
Nasal and oral cavities	Cardiovascular	Thymus, thyroid, parathyroid, and pancreas
Salivary glands	Lymphatics	
Adrenal medulla	Urogenital structures (gonads and kidney)	
Parts of the pituitary gland	Serous lining of body cavities (peritoneum, pleural, and pericardium)	

Morphogenesis

The genetically controlled process during which cells and cell groups take on a specific form, shape, and function is known as *morphogenesis*. Initially, the cells in the embryoblast are all the same; that is, they are stem cells, capable of becoming any type of body cell. These unspecialized cells must proceed through two distinct phases: (1) determination, which restricts the cell to a specific type, and (2) differentiation, in which the morphologic and functional characteristics specific to that cell type develop.

Cell differentiation often involves a process called induction wherein cells in a local environment signal one another to develop in a specific manner. The signaling cell is called the inductor, and the cells that respond to induction are called the inducers. If disruption occurs during any of the differentiation sequences, the next step in the process will not proceed in the usual fashion and an abnormality will develop. Complete organ agenesis may occur when the process is disturbed at an early stage. For example, anencephaly is a form of organ agenesis wherein the brain does not form. Some disruptions in differentiation sequences will result in termination of the pregnancy, whereas others may produce a fetal defect that can be undetectable, minor, or clinically significant.

In addition to cell differentiation and induction, several other cellular mechanics are involved in morphogenesis, including proliferation, migration, adhesion, and folding. Some of these processes are summarized in **Table 19-4**.

Table 19-4 Selected Cellular Mechanisms Involved in Morphogenesis

Cell Mechanism	Description	Congenital Defects That May Result from Faulty Mechanism
Cell proliferation (hypertrophy)	A rapid increase in the number of cells by cell division and growth	Inhibition of cell proliferation can occur when there is a lack of space. A diaphragmatic hernia will allow abdominal contents to be in the thoracic cavity; pulmonary hypoplasia occurs when the lungs are not allowed to continue cell proliferation.
Cell differentiation	Process by which pluripotent cells become more specialized cells	Prenatal exposure to high levels of methylmercury is thought to result in failure of cell differentiation in the central nervous system, causing neurologic and developmental defects.
Apoptosis	A genetically determined process of cell self-destruction. Cells produce enzymes that lead to their dissolution.	Excessive enzymatic release can lead to excessive cellular destruction and result in defects such as limb shortening; deficient enzymatic release can lead to defects such as bowel atresia, syndactyly, or imperforate anus.
Migration	A dynamic and cyclical process in which layers migrate to a strategic location along the developing embryo. The cell extends protrusions at its front and attaches to the substratum on which the cell is migrating.	Central nervous system abnormalities, such as lissencephaly (lack of grooves on the brain)
Adhesion	The interaction of specific mechanisms on one cell and complementary adhesion molecules on the membrane of another cell	Cleft palate and neural tube defects occur as a result of alteration in cell recognition and the adhesion process.
Folding	As new cells form, the embryo is forced to conform to the available space. The embryo folds in both the transverse and longitudinal planes. Structures within the embryo also must fold to conform to the space available to them.	Congenital heart defects Diverticula

The Fetus

Fetal Growth

All major organs have formed by the beginning of the fetal period. Fetal growth involves both hyperplasia (cellular division that yields a significant increase in cell numbers) and hypertrophy (an increase in cell size). At approximately 32 weeks' gestation, hypertrophy dominates.[52] The rate and amount of fetal growth are determined by many factors, including genetics, placental metabolism, maternal conditions, maternal behavior, and environmental factors. For example, there is a well-known correlation between maternal smoking and impaired fetal growth.[53]

Adequate fetal growth is also directly associated with optimal functioning of the placenta and the uterine vascular system. Alterations in the trophoblastic invasion of the maternal spiral arterioles as well as inadequate development of the chorionic villus can result in impaired fetal growth.

Fetal Movement and Behavioral States

Limb movement develops at 9 weeks, with reflective leg movements occurring at 14 weeks. Hand-to-face movements become apparent by 12 to 13 weeks, while limb, head, and torso movements develop by 12 to 16 weeks. Fetuses begin to suck on fingers by 15 weeks and continue to develop more complex movement patterns after 24 weeks, when respiratory movements occur.[54]

Discrete fetal behavior states involving sleep–wake patterns and behavioral patterns begin to occur by 32 weeks. Distinct fetal heart rate patterns, eye movement, gross body movement, and quiet states have been catalogued.[55,56] Although women often report less fetal movement close to term, the underlying fetal physiology of this maternal perception is likely the development of fetal cycling, in which the fetus exhibits distinct quiet states and distinct active states. The average time the fetus spends in the quiet state ranges from 20 to 40 minutes.[54,55]

Maternal Adaptations to Pregnancy

Pregnant women experience a wide variety of anatomic and physiologic alterations over the course of pregnancy and postpartum. While many of these changes are normal symptoms of pregnancy, others herald the onset of an abnormal processes. A thorough knowledge of the maternal anatomic and physiologic adaptations that occur during pregnancy is, therefore, an essential foundation for midwifery practice. This section presents a broad overview of some of the clinically important anatomic and physiologic pregnancy adaptations. Management of pregnancy symptoms are described in the *Prenatal Care*, *Pregnancy-Related Conditions*, and *Medical Complications in Pregnancy* chapters.

Musculoskeletal Changes

The musculoskeletal changes that occur during pregnancy are primarily related to weight gain, the growing uterus, the softening effects of progesterone on cartilage in joints, and the laxity of ligaments induced by estrogen and relaxin.[56] These changes result in lordosis, kyphosis, and altered gait that gradually increase as pregnancy progresses.

Changes within the pelvic girdle are the most profound. The sacroiliac joint widens and has more mobility. The symphysis also widens, and the pelvis develops an anterior tilt. Many of the common complaints of pregnancy can be attributed to these anatomic changes, including pelvic pain, sciatica back pain, and carpal tunnel syndrome. A careful history and physical examination is needed to rule out more serious problems for which pregnant women are at increased risk, such as herniated discs and peripheral nerve injury.

Integumentary Changes

Pregnancy is associated with many changes in the integument. Hyperpigmentation occurs as estrogen, progesterone, and melanocyte-stimulating hormone induce melanocytes to make and deposit pigment. This phenomenon results in darkening of the areola, the change of the linea alba to the *linea nigra*, and *melasma* or *chloasma* (irregular areas of pigmentation on the cheeks), which is also called the “mask of pregnancy.”[57-59] Intertriginous areas such as the axillae, genitalia, perianal region, and inner thighs may also become darker during pregnancy.[59]

Thinning of the elastin fibers in connective tissue under the skin predisposes pregnant women to striae gravidarum (stretch marks). As the size of the abdomen and breasts increase, elastin fibers at the dermal–epidermal junction stretch and shift from perpendicular to parallel, which can create striae.

Vascular nevi called spider angiomas are common as blood vessels dilate and proliferate. These small red lesions have a central puncta and branches that extend from the center and disappear after birth.

Cardiovascular Changes

Cardiovascular changes in the pregnant woman begin early in the first trimester.[57] Blood volume increases by 40% to 50% over the course of pregnancy, reaching a maximum by 32 weeks' gestation. Plasma accounts for 75% of this increase. Cardiac output increases 30% to 50% to approximately 4 to 6 L/min, primarily as a result of increased stroke volume.[60] The increase in cardiac output begins in the first trimester and peaks at approximately 25 to 30 weeks' gestation, when the total blood volume is approximately 5000 to 6000 mL. Heart rate increases by approximately 10 beats/min, and blood pressure decreases gradually from prepregnancy values as early as 7 weeks' gestation. This decrease reaches a nadir in the second trimester. The decrease in blood pressure is presumed to occur in concert with expansion of the low-pressure placental compartment, and lower systemic vascular resistance induced by progesterone.[60]

Anatomically, the heart is displaced upward (cephalad) and rotated to the left as the uterus enlarges. Mild pulmonic or tricuspid regurgitation often occurs. Several common signs and symptoms are related to these changes. Systolic ejection murmur that is loudest along the left sternal boarder is a common finding in pregnant women and is attributed to the dramatic increase in cardiac output. These murmurs are clinically benign. A third heart sound may be auscultated in many pregnant women. The decrease in systemic vascular resistance in combination with pressure on the vena cava from the growing uterus is responsible for the dependent edema that most pregnant women experience in the third trimester and contributes to the development of varicosities, hemorrhoids, labial varicosities, and increased risk for venous thrombosis.

Careful monitoring of cardiovascular changes can facilitate early detection of abnormalities. For example, if a woman's blood pressure fails to decrease during the second trimester, she may have chronic hypertension or be at increased risk for developing preeclampsia. Cardiovascular changes can also increase the risk for adverse outcomes in women who have preexisting cardiomyopathies; these women should be referred promptly to a physician.[58]

Hematologic Changes

Two aspects of hematologic changes in pregnancy have important clinical implications. First, pregnancy is a hypercoagulable state, as evidenced by the increased clotting factors, decreased fibrinolysis, and decreased anticoagulant activity noted in the pregnant woman. Clotting factors I, II, VII, VIII, IX, and XII are more abundant in such women, whereas protein S levels and activated protein C levels fall. These alterations in the coagulation cascade are likely protective, geared toward preventing hemorrhage at birth. Nevertheless, they increase a woman's risk for venous thromboembolism in the prenatal and postnatal periods. In addition, significant placental damage and obstetric hemorrhage are associated with early onset of disseminated intravascular coagulation (DIC), which is not a common component of surgical or traumatic hemorrhage. DIC occurs because the tissue factor in the placenta acts as a potent activator of the coagulation cascade, which is already in a hypercoagulable state.[58]

The second clinically important hematologic change in pregnancy relates to iron metabolism and iron-deficiency anemia. During pregnancy, the plasma volume increases and this expansion exceeds the increase in red cell mass, which results in a physiologic hemodilution. The

physiologic hemodilution has a positive effect on placental perfusion, with blood becoming less viscous.[61] In addition, the maternal hemoglobin (Hgb) concentration decreases by approximately 2% to 10%. The drop in hemoglobin occurs because the fetal uptake of iron is usually more than maternal absorption of iron can replace. The net result is a decrease in the woman's hematocrit of approximately 3% to 5%, which reaches a nadir late in the second trimester or early in the third trimester.

Because iron is not easily absorbed, fetal uptake can deplete a woman's iron reserves despite the fact that iron absorption in the second and third trimesters increases more than fivefold.[62] Thus iron stores can be easily depleted in pregnancy and, in turn, iron-deficiency anemia is common in pregnancy.

Additional hematologic changes include a decrease in the concentration of plasma proteins, especially albumin. Lower albumin result in lower colloid oncotic pressure, which in tandem with decreased venous resistance, facilitates the development of dependent edema.

Respiratory Changes

Pregnant women commonly experience dyspnea even when at rest. The actual etiology is unknown, but most sources assume this condition arises secondary to the added respiratory effort and work of breathing.[63] Pregnancy is associated with an increase in minute ventilation (i.e., the volume of air inhaled and exhaled in a minute) and in pulmonary blood volume, both of which can contribute to the sensation of dyspnea. The etiology of these changes is largely unknown, but it is thought to relate to an enhanced sensitivity to carbon dioxide levels as well as to hypoxia. As the uterus expands into the abdominal cavity in the second and third trimesters, the respiratory effort required by the woman further contributes to dyspnea. Physiologic dyspnea can be distinguished from pathologic dyspnea by the respiratory rate. Tachypnea is a sign of possible respiratory compromise.

An increase in thoracic diameter and cephalad rise in the diaphragm (as much as 4 centimeters) changes the pregnant woman's lung capacity. Tidal volume increases by 30% to 40%, and vital capacity increases slightly (**Figure 19-10**).[63,64] This hyperventilation probably occurs secondary to the effects of progesterone and places the woman in a state of respiratory alkalosis, which has the effect of improving carbon dioxide transfer from the fetus to the maternal circulation.

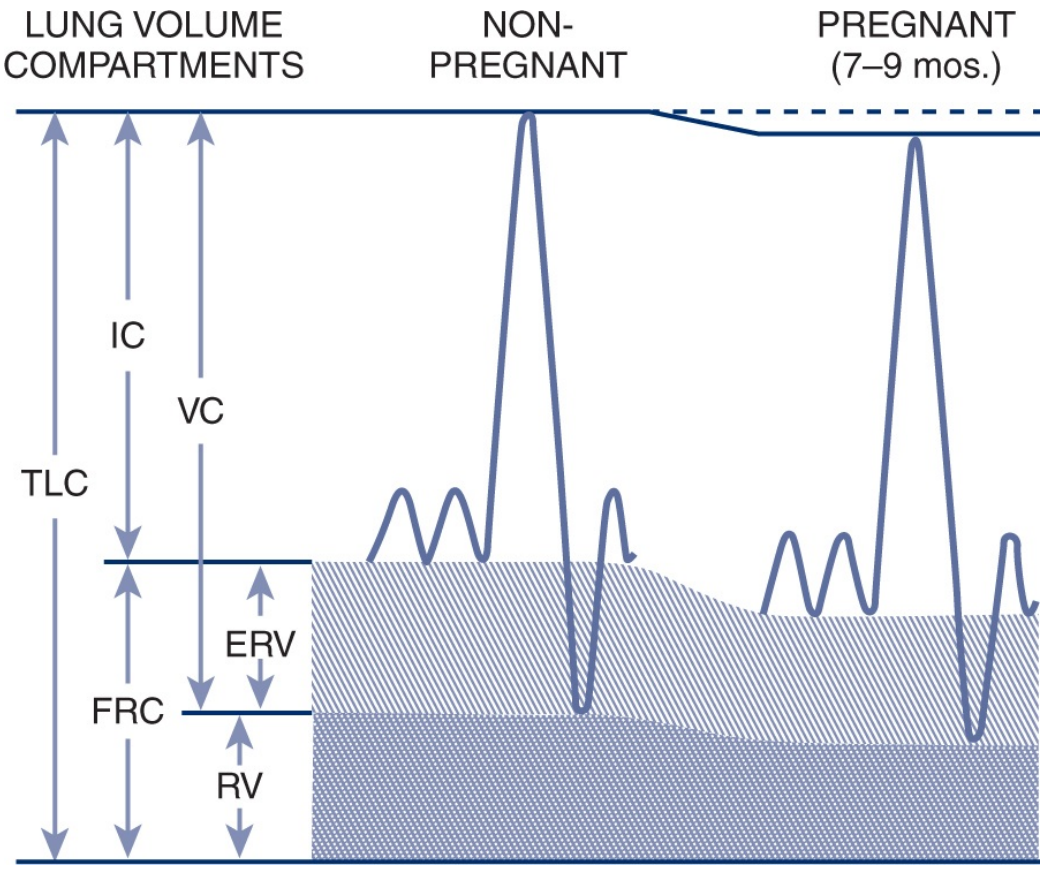

Figure 19-10 Changes in lung volumes in women who are 7–9 months pregnant compared with volumes in nonpregnant women.

Abbreviations: ERV, expiratory reserve volume; FRC, functional residual capacity; IC, inspiratory capacity; RV, residual volume; TLC, total lung capacity; VC, vital capacity.

Under the influence of estrogen and increased blood volume, nasal passages become edematous and hyperemic in pregnancy. Women often report more congestion and/or rhinitis, sometimes confusing the symptoms with an upper respiratory infection or allergies.

Changes in the Oral Cavity

During pregnancy, bleeding gums, especially after brushing teeth, is related to estrogen- and progesterone-mediated inflammation and hyperemia. Elevated levels of estrogen create a favorable environment for the growth of bacteria that can cause gingivitis and gingival inflammation. Women should receive regular dental care during pregnancy.

Gastrointestinal Changes

During pregnancy, decreased peristalsis caused by relaxation of the smooth muscle of the large bowel in the presence of increased amounts of progesterone, as well as changes in fluid reabsorption increases the risk of constipation. The displacement and compression of the bowel by the enlarging uterus or presenting part may also contribute to decreased motility in the gastrointestinal tract and, therefore, to constipation. Specifically, the stomach is moved superiorly and the intestines are displaced laterally. Another factor that may contribute to

constipation is the decrease in gastric emptying time and gastric motility secondary to the smooth muscle relaxation effects of progesterone. Thus, constipation is common, especially in the first trimester when the growing uterus also places pressure on the descending colon.

Several physiologic changes of pregnancy predispose the pregnant woman to heartburn (pyrosis): The lower esophageal sphincter is relaxed, gastrointestinal motility is slower, esophageal function and peristalsis change, and the angle of the gastroesophageal junction is altered as the stomach is displaced by the enlarging uterus. Women with preexisting gastroesophageal reflux disorder may find the condition aggravated throughout pregnancy. Flatulence and gas pain is more common during pregnancy due to decreased motility from the effect of progesterone relaxing smooth muscle and from the displacement of and pressure on the intestines by the enlarging uterus.

Renal Changes

Two different aspects of renal changes in pregnancy are responsible for symptoms that must be carefully evaluated to determine normal versus abnormal alterations. First, a marked increase in renal plasma flow is the natural consequence of arterial vasodilation and increased cardiac output. Renal blood flow increases 60% to 80% above prepregnant levels in the first and second trimesters, and 50% above prepregnant levels in the third trimester. The glomerular filtration rate (GFR) increases by 50% over prepregnant levels, peaking at 12 gestational weeks.[65] The obvious physiologic consequences of these changes are the commonly reported symptoms of urinary frequency and nocturia that frequently occur at two different times during the prenatal period. Frequency during the first trimester is due to hormonal changes affecting levels of renal function as well as developing hypervolemia and bladder compression within the pelvis due to uterine growth. Bladder compression resolves as the uterus becomes an abdominal organ in the second trimester. Urinary frequency during the third trimester occurs most often among primiparous women, after engagement has occurred when the presenting part descends into the pelvis and causes direct pressure against the bladder.

Nocturia also can be caused by increased urine production at night. Venous return from the extremities is facilitated when the woman lies in a recumbent lateral position while sleeping at night, when the uterus is not pressing against the pelvic vessels and inferior vena cava, which results in an increase in urinary output. Additionally, pregnant women have an increase in sodium excretion at night, with an associated increase in fluid excretion, which may also explain nocturia.

The increased flow may be great enough that the descending tubule is unable to reabsorb all glucose. This resultant physiologic glycosuria is usually intermittent, but it affects as many as 20% of pregnant women. Similarly, protein reabsorption is not as efficient as it is in the nonpregnant state. A small amount of urinary protein in a sample of concentrated urine can cause a dipstick test to be positive, which may be falsely interpreted as a urinary tract infection or even proteinuria associated with preeclampsia. Serum creatinine likewise falls; thus, plasma values for creatinine that would be considered normal in a nonpregnant woman may actually reflect renal dysfunction in a pregnant woman.

Pregnant women are at increased risk for urinary tract infections because the ureters,

urethra, and bladder dilate under the influence of progesterone and ascending infections can occur, including pyelonephritis. The bladder becomes hyperemic and urinary stasis can occur, which occasionally results in stress incontinence. Thus, physiologic changes in pregnancy cause symptoms that may be normal, a sign of urinary tract infection, or a sign of renal dysfunction. Urinary tract infections are also associated with preterm labor. Therefore, careful attention to the history, physical examination, and adjunct measures of urinary function are necessary to adequately care for women with urinary symptoms.

Metabolic Changes

Among the many important endocrine and metabolic changes in pregnancy are changes that occur in the hypothalamus, pituitary, and adrenal glands, often in an interrelated manner. Calcium metabolism and the renin–angiotensin system both exhibit significant alterations in ways that facilitate fetal growth and development.

Thyroid Metabolism

Although all endocrine organs undergo changes in pregnancy, thyroid changes are particularly of note. Because both hypothyroid and hyperthyroid states can adversely affect the fetus, it is critical that a euthyroid state be maintained throughout pregnancy.

The thyroid is the first endocrine gland to appear in the fetus, but the fetus does not start secreting thyroid hormone until approximately 18 to 20 weeks' gestation.[66,67] Consequently, the fetus is dependent on maternal thyroid hormone for the critical metabolic functions fulfilled by this hormone. A woman's thyroid slightly increases in size early in pregnancy and may be palpable on an initial prenatal visit as a smooth and regular-shaped mass. The basal metabolic rate also increases by 20% to 25% during pregnancy.

Several changes occur in the production and transport of thyroxine during pregnancy. The alpha unit of hCG stimulates the thyroid in the same manner as TSH, which causes an increase in total thyroxine (T_4) levels (i.e., subclinical hyperthyroidism). Sensing the increase in total thyroxine, the pituitary reduces production of TSH. At the same time, higher levels of plasma albumin and thyroxine-binding globulin (TBG) bind more thyroxine in serum. Overall, the level of free thyroxine remains normal despite lower levels of TSH and higher levels of total thyroxine (**Figure 19-11**).[67,68]

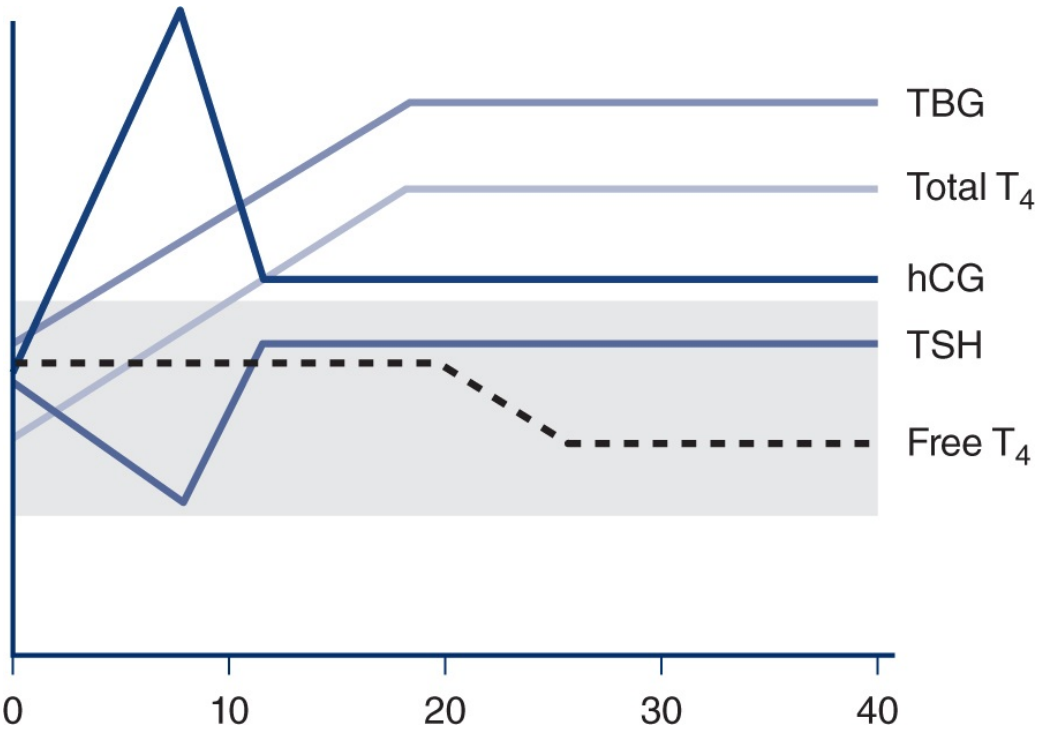

Figure 19-11 The pattern of changes in serum concentrations of thyroid function studies and hCG according to gestational age. The shaded area represents the normal range of thyroid-binding globulin, total thyroxine, thyroid-stimulating hormone, or free T_4 in the nonpregnant woman.

Abbreviations: hCG, human chorionic gonadotropin; T_4, thyroxine; TBG, thyroid-binding globulin; TSH, thyroid-stimulating hormone.

Reproduced with permission from Casey MB, Leveno K. Thyroid disease in pregnancy. *Hil Obstet Gynecol.* 2006;108:1283-1292.[67]

The TSH level reaches a nadir at approximately 10 gestational weeks.[66-68] Subsequently, as hCG levels decline, TSH levels rise to reach the nonpregnant level by the third trimester and total thyroxine levels decline to a normal value. Plasma values for thyroid function are trimester specific and cannot be determined via one measurement. In general, an assessment of TSH and free T_4 or total T_4 is needed to interpret thyroid function during pregnancy.[66-68]

Glucose and Lipid Metabolism

Glucose metabolism is significantly altered in pregnancy. Glucose is the primary energy source for the fetus and placenta, and is transferred across the placenta via facilitated diffusion. Thus, glucose delivery to the fetus depends on a concentration gradient between the maternal and fetal circulations. The hormone hPL induces maternal insulin resistance and hepatic glucose formation, both of which raise glucose levels in maternal circulation. hPL acts by initiating hyperplasia within the beta cells of the maternal pancreas, which in turn enables greater production of insulin. Hepatic glucose production increases by as much as 30% in the third trimester. Because of the ongoing fetal use of glucose provided by the maternal circulation, a pregnant woman will experience fasting glucose levels that are lower than usual, yet because of the insulin resistance, postprandial glucose levels can be higher.[69]

Lower fasting blood glucose levels can worsen nausea and vomiting in early pregnancy but

may also contribute to the pregnant woman's enhanced appetite and her need to eat more often. As the placenta increases in size and function, maternal hyperinsulinemia must likewise increase to keep pace. Women who are unable to sufficiently raise their insulin production will develop gestational diabetes in the latter half of pregnancy.

Lipid metabolism is also altered significantly during pregnancy.[70] Body fat accumulates during the first two-thirds of pregnancy, but this growth then stops or declines during the last third of pregnancy. Thus, the pregnant woman is first in an *anabolic* state and then later in a *catabolic* state.[71] During the period of rapid lipolysis, free fatty acids and glycerol are generated. Free fatty acids are converted to ketones, and glycerol is converted to glucose. The free fatty acids are used to synthesize triglycerides, which causes triglyceride levels to increase.[71]

Immunologic Changes

Pregnancy is essentially an immunologic paradox: First, how does the pregnant woman avoid rejecting the fetus given that fetal cells and maternal cells are in direct contact in the maternal spiral arteries and intervillous space? Second, how do the immunologic changes that take place to accommodate the fetus, a semi-allograft, affect the maternal immune response? Immunologic changes in pregnancy are implicated in several important clinical disorders, including recurrent miscarriage, Rh sensitization, and preeclampsia.

The immune response is usually subclassified as either innate immunity or adaptive immunity; the latter is subdivided into two components called cell-mediated immunity and antibody-mediated immunity. The innate immune response is the first line of defense against "non-self" invaders, which includes inflammation and phagocytosis. *Cell-mediated immunity* is responsible for elimination of intracellular microbes and involves several immune lymphocytes, including natural killer (NK) cells and T cells. *Antibody-mediated immunity* involves the production of antibodies by B cells; these antibodies then target extracellular microbes or antigens.

In general, innate immunity is enhanced during pregnancy, whereas adaptive immunity is less functional. In particular, cell-mediated (T helper 1) responses are somewhat suppressed compared to antibody-mediated (T helper 2) responses, which are more responsive. This change in the cell-mediated and antibody-mediated responses is referred to as a *Th1 to Th2 shift*.[71-73] These changes increase the risk of maternal infection, especially with regard to viral infections such as influenza or varicella. At the same time, the Th1 to Th2 shift results in improvement of some autoimmune disorders such as rheumatoid arthritis.

Chemotaxis is delayed in the pregnant woman, which can delay the maternal response to some infections. The total white blood cell count is elevated largely due to increased numbers of polymorphonuclear neutrophils, monocytes, and granulocytes. Many of the bioactive agents produced by the fetus and placenta effect subtle shifts in maternal immunity. Although little overall change occurs in the maternal immune response, subtle changes in each of the three types of immunity have important clinical implications (**Table 19-5**).

Table 19-5 **Changes in the Immune System During Pregnancy**

Primary Host Defense Mechanisms
Increased number of white blood cells (primarily polymorphonuclear leukocytes), which enhances the pregnant woman's nonspecific immune response.
Delayed chemotaxis (the movement of phagocytes to the site of foreign invasion), which may delay the maternal response to infection.
Decreased number of natural killer cells, which may delay the maternal response to infection.
Reduced levels of plasma IgG. The hemodilution of pregnancy and passive transfer of Ig antibody to the fetus reduces maternal blood levels of IgG.
Cell-Mediated Immunity
Although the overall number of lymphocytes remains unchanged, there is a decreased number of T-helper cells (CD4 cells) relative to the number of T-suppressor cells (CD8 cells).
With fewer CD4 cells, the B-cell function may be slightly impaired.
Antibody-Mediated Immunity
Overall, the antibody-mediated response is unchanged.
Clinical Implications
Small increase in risk for developing gram-negative organism infections and mycotic or fungal infections
Increased morbidity from gram-negative infections, H1N1 flu virus, and varicella if infection occurs
Increased infectivity with certain pathogens, including herpes simplex virus, poliovirus, cytomegalovirus, malaria, and hepatitis
Changes in autoimmune disease characteristics (rheumatoid arthritis often improves during pregnancy, while systemic lupus erythematosus is more likely to flare)

Abbreviation: IgG, immunoglobulin G.

The Fetus as an Allograft

The first part of the pregnancy immunologic story occurs during implantation and is not yet fully understood. In simple terms, trophoblastic tissue does not express the cell membrane proteins that would stimulate an innate or cellular immune response. The mechanisms by which the fetus eludes detection as a foreign object are quite complex.[72] In addition, changes in the cell-mediated immune response result in a concentration of NK cells in the decidua; these cells, however, are a variant of NK cells that have minimal cytotoxic abilities but a refined ability to control trophoblast invasion and remodel uterine vasculature. T cells and B cells become scarce in the uterine environment during this period.

Fetopelvic Relationships

The fetus can lie in numerous positions in relationship to the maternal abdomen pelvis. A few of these positions preclude a vaginal birth; others are associated with a longer labor. For this reason, it is important to know all possible fetopelvic relationships and their clinical significance. The terminology used to describe fetopelvic relationships is listed in **Table 19-6**.

Table 19-6 Fetopelvic Relationships

Term	Definition
Asynclitism	Oblique presentation of the fetal head. When the fetal head is tilted laterally toward the fetal shoulder, the biparietal diameter is not parallel to the planes of the pelvis. The sagittal suture will not be palpable as midway between the front and back of the pelvis. Asynclitism is called anterior when the anterior parietal bone is the point of presentation; it is called posterior when the posterior parietal bone is the presenting part of the fetal head.
Attitude	Relation of fetal parts to each other. The basic attitudes are flexion and extension. The fetal head is flexed when the chin is close to the chest; it is extended when the occiput is closer to the cervical spine.
Cephalic Prominence	Fetal part of head most easily felt (prominent) during Leopold's maneuvers and used to determine attitude. When the cephalic prominence is felt on the same side as fetal small parts, the head is flexed; when on the same side as fetal back, the head is extended. When the cephalic prominence is not palpable on one side or the other, it often is called a military attitude.
Denominator	An arbitrarily chosen point on the presenting part of the fetus that is used to describe fetal position. The denominator for a vertex presentation is the occiput; for a breech presentation, it is the sacrum. The denominator of a face presentation is the mentum or chin.
Engagement	The point at which the widest diameter of the presenting part is at or below the pelvic inlet.
Lie	Relationship of the long axis of the fetus to the long axis of the pregnant woman. The three possible lies are longitudinal, transverse, or oblique.
Position	Relationship of the denominator to the front, back, or sides of the maternal pelvis.
Presentation	The part of the fetus that presents first to the maternal pelvis. The three possible presentations are cephalic, shoulder, and breech. Breech presentations are further subdivided based on presentation of the buttocks or feet.
Presenting part	The most dependent part of the fetus that is closest to the maternal cervix.
Station	The number of centimeters above or below the plane between the ischial spines of the presenting part. The ischial spines are designated as 0 station; the centimeters above the spines are –1, –2, –3, –4, and –5; and the centimeters below the ischial spines are +1, +2, +3, +4, and +5, which is when the fetal presenting part is visible at the vaginal introitus.

The Fetal Skull

The fetal skull is composed of five bones—two frontal bones, two parietal bones, and one occipital bone—that may be palpated during labor to identify the position of the fetus and assess labor progress. In addition, the two temporal bones are located inferior to the parietal bones on each side but are not involved in the anatomic markers important during labor assessment (**Figure 19-12**). The bones meet at the frontal suture, located between the two

frontal bones; at the sagittal suture, located between the two parietal bones; at the two coronal sutures, where the parietal and frontal bones meet on either side of the head; and at the two lambdoid sutures, where the parietal bones and the upper margin of the occipital bone meet on either side of the head.

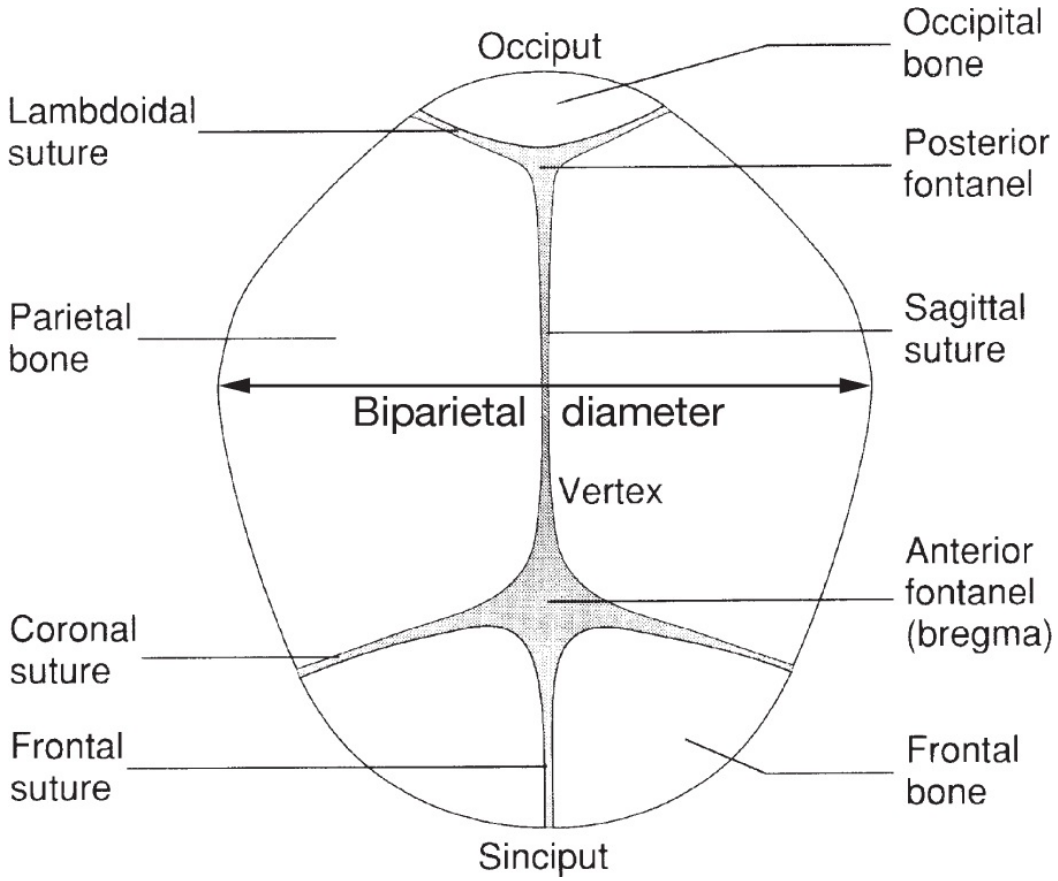

Figure 19-12 Fetal skull: landmarks, bones, fontanelles, sutures, and biparietal diameter.

Two fontanels—areas formed by the meeting of sutures—are found on either end of the sagittal suture. The anterior fontanel is the largest, formed as the frontal, sagittal, and two coronal sutures come together in a diamond-like shape.

The four sutures can be palpated coming from the four corners of diamond shape, with markers of the frontal suture being more subtle and sometimes difficult to palpate. The sagittal and two lambdoid sutures meet to form the posterior fontanel in a triangle shape; the sagittal and lambdoid sutures can be palpated from the three corners of the triangle.

The fetal head also has several diameters of importance in providing maternity care, which are shown in **Figure 19-12** and **Figure 19-13**.

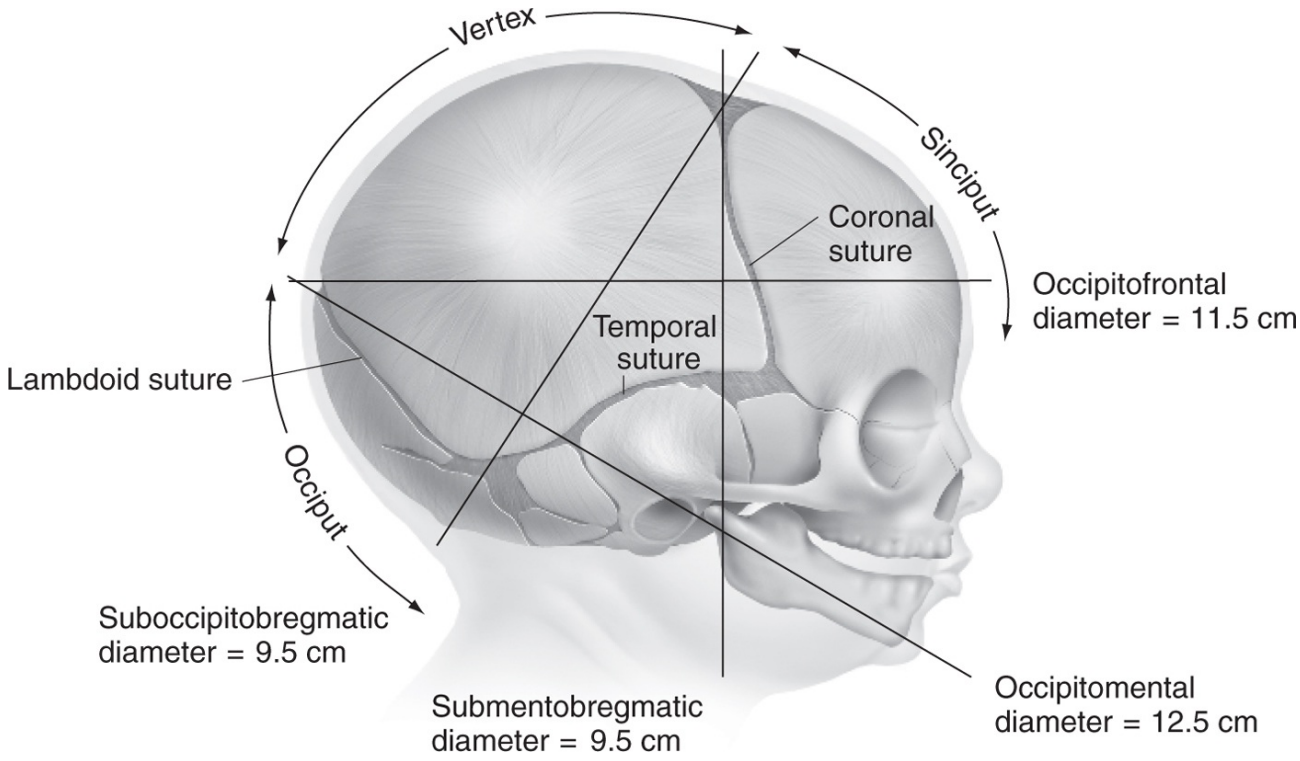

Figure 19-13 Average diameters of the full-term fetal head.

Lie, Presentation, Denominator, and Position

Determination of the lie, presentation, and position of the fetus require an understanding of terms and the anatomic landmarks of the fetal skull in relation to the maternal pelvis.

Lie is the relationship of the long axis of the fetus to the long axis of the pregnant woman. Three possible lies are longitudinal, transverse, and oblique (**Figure 19-14**). Transverse and oblique lies in labor are abnormal conditions requiring collaboration with or referral to a physician because they will likely necessitate cesarean section.

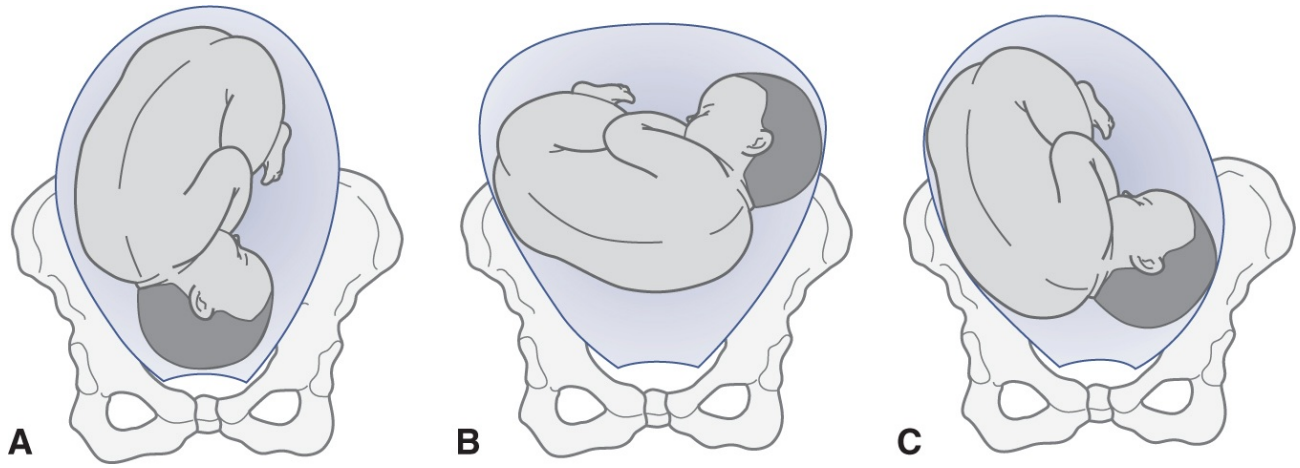

Figure 19-14 Lies. **A.** Longitudinal. **B.** Transverse. **C.** Oblique.

Presentation is determined by the presenting part—that is, the part of the fetus that first

enters the pelvic inlet. The three possible presentations are cephalic, breech, and shoulder. Cephalic and breech presentations are each further subdivided: A cephalic presentation can be vertex, sinciput, brow, or face (**Figure 19-15**), and a breech presentation can be frank (legs extended), full/complete (legs flexed), or footling (single or double). Approximately 3.0% to 3.5% of women enter labor with a breech presentation and 0.5% with a face presentation. Approximately 0.5% of women enter labor with a shoulder presentation. The midwife collaborates with a physician in the management of women with a noncephalic presentations.

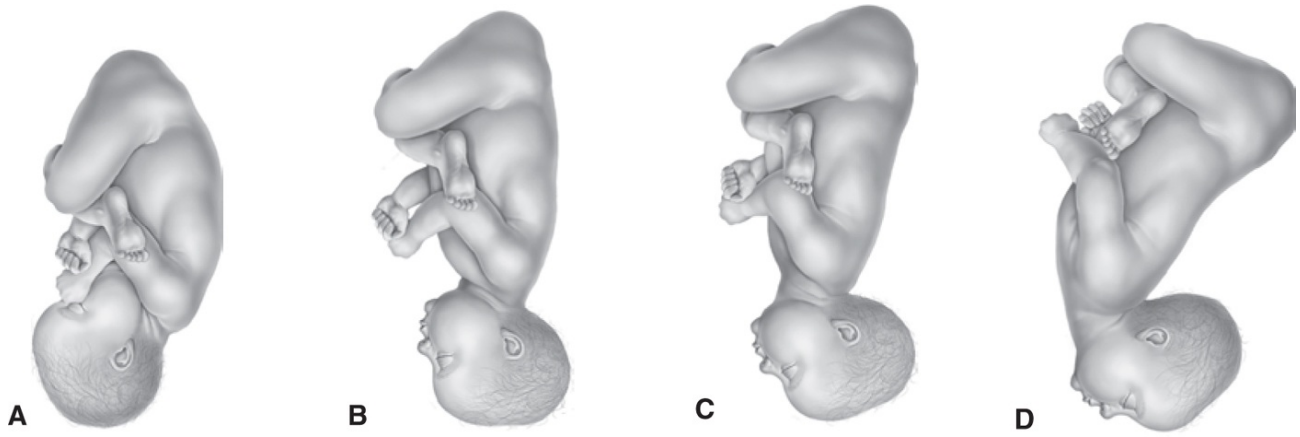

Figure 19-15 Attitude of the fetus in various presentations. **A.** Vertex. **B.** Sinciput (military). **C.** Brow. **D.** Face.

The *attitude* of the fetus is its characteristic posture, determined by the relationship of the fetal parts to one another and the effect this has on the fetal vertebral column. The attitude of the fetus varies according to its presentation. For example, a fetus in a vertex presentation has a well-flexed head, flexion of the extremities over the thorax and abdomen, and a convex curved back. By comparison, the straight upright attitude of a fetus with a sinciput presentation has resulted in the classically defined military attitude. Finally, a fetus with a face presentation has an acutely extended head, flexion of the extremities on the thorax and abdomen, and a vertebral column that is arched to some degree.

Fetal *position* is named using three letters in the following order: the first reference is to the side of the maternal pelvis (**L**eft or **R**ight); the second reference is the denominator (**O**cciput, **S**acrum, or **M**entum); and the third reference is where in the maternal pelvis the denominator lies (**A**nterior, **T**ransverse, **P**osterior). These designations serve as a shorthand description for describing the lie, presentation, and position of the denominator within the circle of the pelvis (**Figure 19-16**). For example, the designation LOA indicates that the lie is longitudinal, the presentation is cephalic, and the denominator, which is the occiput, is in the anterior portion of the left side of the pelvis. The possible fetal relationships to the maternal pelvis for each lie and presentation are summarized in **Table 19-7**.

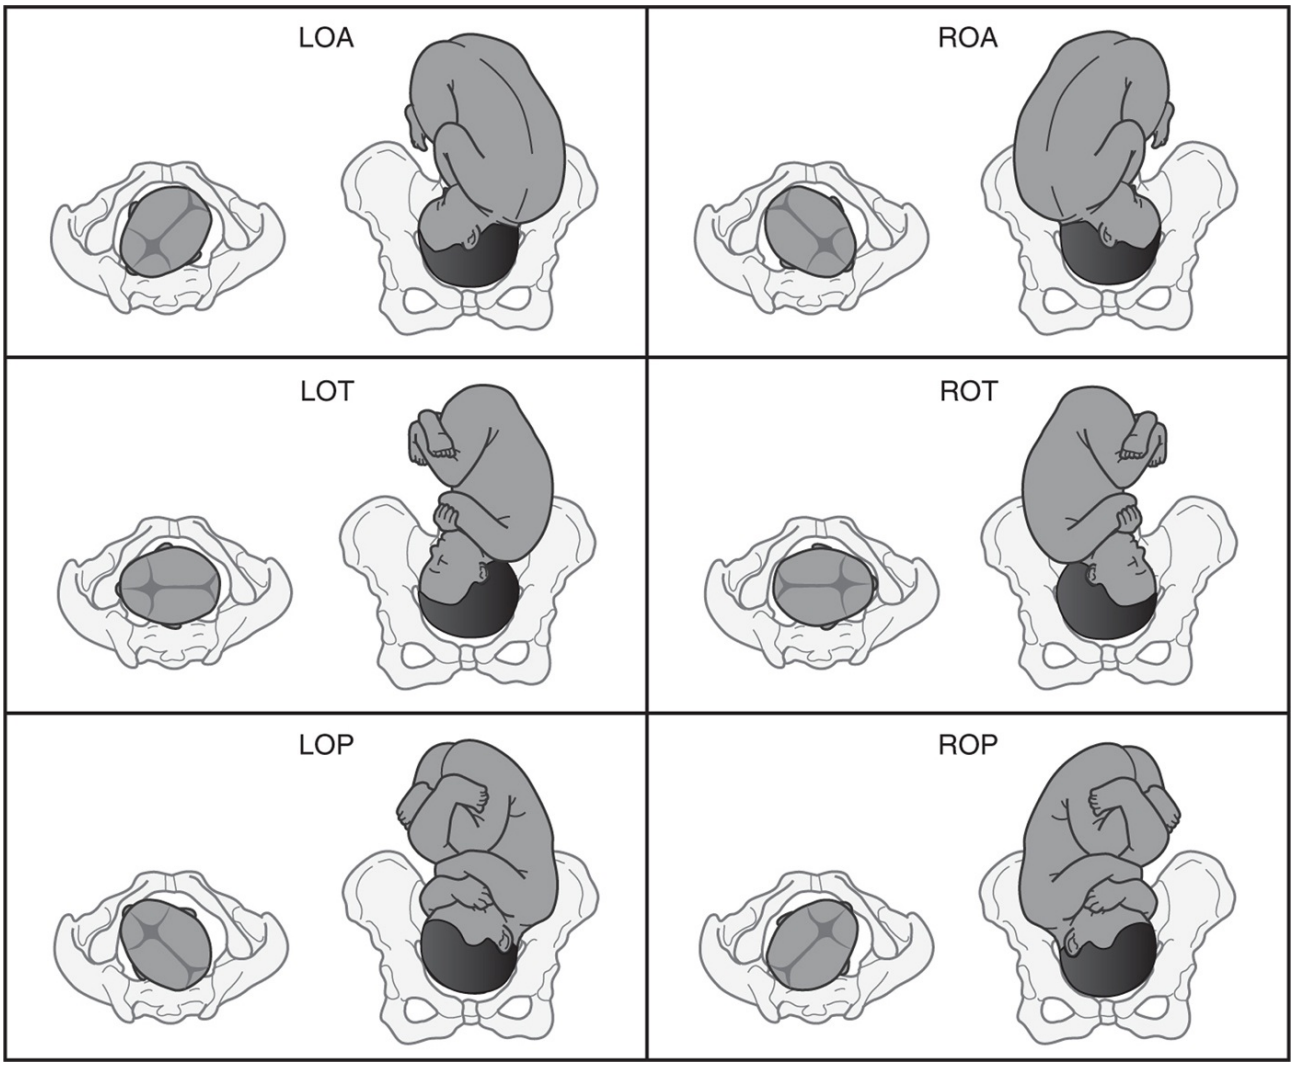

Figure 19-16 Fetal position for occiput presentations.

Abbreviations: LOA, left occiput anterior; LOP, left occiput posterior; LOT left occiput transverse; ROA right occiput anterior; ROP, right occiput posterior; ROT, right occiput transverse.

Table 19-7 **Possible Fetal Relationships to the Maternal Pelvis for Each Lie and Presentation**

Lie	Presentation	Denominator	Designation for Position
Longitudinal	Cephalic		
	Vertex	Occiput	ROA LOA
			ROT LOT
			ROP LOP
	Sinciput	Sinciput (bregma, anterior fontanel)	Sinciput and brow presentations usually convert to either a vertex or a face presentation.
	Brow	Brow	
	Face	Mentum (chin)	RMA LMA
			RMT LMT
			RMP LMP
	Breech		
	Frank	Sacrum	RSA LSA
			RST LST
			RSP LSP
	Full/complete	Sacrum	Same as frank presentation
	Footling	Sacrum	Same as frank presentation
Transverse	Shoulder	Acromion	RAA LAA
			RAP LAP
			A transverse variety is not possible.
Oblique	With an oblique lie, the midwife will feel nothing at the inlet. There is no presentation, position, or variety associated with an oblique lie, which is usually a transitory condition.		

Abbreviations: LMA, left mentum anterior; LMP, left mentum posterior; LMT, left mentum transverse; LOA, left occiput anterior; LOP, left occiput posterior; LOT left occiput transverse; LSA, left sacrum anterior; LST, left sacrum transverse; ROA, right occiput anterior; ROP, right occiput posterior; ROT, right occiput transverse; RSA, right sacrum anterior; RSP, right sacrum posterior; RST, right sacrum transverse; RMA, right mentum anterior; RMP, right mentum posterior; RMT, right mentum transverse.

Vertex is the presentation most often associated with a longitudinal lie; it has an incidence of approximately 95%. Approximately two-thirds of all fetuses will be positioned with the occiput in the left side of the maternal pelvis (LOA, LOT, LOP) by the last month of pregnancy; one-third will be positioned with the occiput in the right side of the woman's pelvis (ROA, ROT, ROP). Because the head usually enters the inlet with the occiput directed to the transverse portion of the maternal pelvis, the most common position of the fetus at the onset of labor is left occiput transverse (LOT).

In a vertex presentation, the fetal head usually enters the pelvis with the biparietal diameter parallel to the plane of the pelvis. If the fetal head is tilted laterally toward the fetal shoulder, the head will enter the pelvis at an oblique angle which is referred to as *asynclitism.*

Estimated Fetal Weight

When assessing fetopelvic relationships, a midwife is also able to estimate a fetal weight

(EFW). The average EFW at 30 gestational weeks is approximately 3 pounds or 1360 grams. A fetus usually reaches 4 pounds at approximately 33 weeks (1900 grams); and at 37 weeks it is 5 pounds 8 ounces or 2500 grams. The latter is important since it is the international definition for low birth weight. Fetal weight is important for fetopelvic relationships, since a small fetus (either constitutionally or due to disease) is more likely to present abnormally such as in a breech presentation. Conversely, a large fetus can have difficulty navigating even an average-sized pelvis.

Conclusion

Remarkable physiologic changes occur during pregnancy. Knowledge regarding physiologic pregnancy changes must inform every aspect of pregnancy care. A deep understanding of these changes will allow the midwife to interpret signs and symptoms accurately, enabling reassurance and guidance regarding managing common pregnancy discomforts or initiation of assessment for pathology. These are essential steps in the provision of quality maternity health care.

Genetics

Introduction

Essentially all health and disease conditions have a genetic component, and the provision of midwifery care increasingly will include genetics within the context of prevention, screening, diagnosis, and treatment selection. Furthermore, genetic disorders are not rare occurrences. Approximately 3% to 7% of the population will be identified with a genetic disorder at some point in life.[1] Chromosomal abnormalities occur in approximately 10% to 20% of pregnancies and are an important contributor to pregnancy loss; 95% of conceptions affected by chromosomal abnormalities are miscarried before term.[2] Approximately 6% of all newborns have a major congenital malformation; in these newborns, 15% of the anomalies are "familial," 10% are chromosomal, 3% to 4% are related to single gene mutations, 23% are multifactorial (i.e., involve multiple genetic and environmental components), and 3% are due to teratogens.[2,3] Thus, genetic effects are a substantial contributor to newborn/infant mortality.

A solid understanding of genetics and available technology, as well as essential skills necessary for genetic risk assessment, screening, diagnostic testing, basic counseling, and appropriate referral, are needed for clinical midwifery practice. However, because genetic science and technology is evolving rapidly, it can be challenging to stay current with the knowledge necessary for clinical practice.[4] This chapter reviews basic genetics and contemporary approaches to genetic testing for women contemplating pregnancy and during pregnancy.

Foundations in Genetics

The foundations of molecular genetics and heredity provide the basis for understanding perinatal genetics specifically. This section reviews basic principles in molecular genetics, as well as inheritance patterns and the meaning of genetic mutations, gene expression, and chromosomal structure. **Table 20-1** provides a glossary of commonly used genetics-related terms.[5-7] Readers are also encouraged to access the many excellent genetics resources currently available in print as well as online for more in-depth information. A select list of online resources can be found at the end of this chapter.

Table 20-1 Genetics Glossary

Term	Definition/Description
Allele	One of the two or more versions of a genetic sequence that encodes for the same protein or function at a specific location on a chromosome. An individual normally inherits one allele from each parent and these matching alleles contain the genes that code for the same characteristic.
Aneuploidy	A chromosomal condition in which there is an abnormal number of chromosomes in the complement of 23 pairs, secondary to either a deletion or an addition of a chromosome.
Autosome	A chromosome that is not a sex chromosome. Autosomes appear in pairs.
Base pair	Two nitrogenous bases paired together in double-stranded DNA (i.e., adenine paired with thymine, and guanine paired with cytosine). Sequences of various lengths of base pairs make up the various genes.
Cell-free fetal DNA	Fetal genetic material (DNA) that is not contained within cells and that circulates freely in the blood of a pregnant woman. Cell-free fetal DNA is derived primarily from the placenta and can currently be used to test for aneuploidy in high-risk women.
CFTR	The gene that encodes for chloride channel transmembrane regulation. Several variations of mutations in this gene are known, including those that directly cause cystic fibrosis.
Chromosomal abnormality	An alteration in the number or structure of a chromosome. Chromosomal abnormalities can be inherited or occur de novo. Most common chromosomal abnormalities, such as trisomy 21, are not heritable.
Chromosomal microarray analysis (CMA)	A technique for identifying chromosomal abnormalities, including those that are too small (i.e., microdeletions) to be detected by conventional karyotyping. CMA requires direct testing of fetal tissue, so it can be offered only when chorionic villus sampling (CVS) or amniocentesis is performed.
Chromosomal microdeletion	A very small deletion of a part of a chromosome or sequence of DNA, which results in a loss of genetic material. These microdeletions are usually not fatal, but they frequently result in physical and mental abnormalities depending on the genetic material that is lost. Conventional karyotyping is not able to identify microdeletions. Cri-du-chat syndrome is caused by a microdeletion on the short arm of chromosome 5.
Chromosomal translocation	A rearrangement of chromosomal segments between different chromosomes. These can be *balanced* (even exchange of material) or *unbalanced* (unequal exchange of material, resulting in extra or missing genetic material). Although there is frequently no effect on phenotype, individuals with chromosomal translocations may have an increased risk of nonviable conception and trisomy 21.
Deoxyribonucleic acid (DNA)	The double-stranded helix of nitrogenous base pairs within cells that provides instructions for all cell activity, and is passed on from generation to generation. The DNA strand comprises the collection of genes within a chromosome.
Dominant allele	An allele that, if present, leads to expression of the phenotype associated with that allele.

	Dominant alleles can mask the presence of a recessive allele.
Epigenetics	Changes in the regulation of gene expression that occur due to modifications in DNA, rather than changes in DNA sequence. Methylation—the attachment of methyl groups to DNA at cytosine bases—is one example of a DNA modification that alters gene expression.
Exon	The segment of the gene that codes for a specific amino acid. By comparison, introns are generally considered noncoding segments of DNA and are normally spliced out of the sequence prior to formation of amino acids.
Expressivity	Phenotypic variation (severity) among persons who have a specific genotype.
Gene	The fundamental unit of heredity. An ordered sequence of DNA constitutes a gene; it is found on a specific location on a specific chromosome. Each gene encodes for a specific functional protein.
Gene expression	The process by which information from a gene is used to produce a functional gene product (usually a protein); it is how a genotype results in a particular phenotype. Not all genes are expressed.
Genetic disorder	Alterations in genes that code for a particular protein, which results in a heritable disorder.
Genome	The entire DNA sequence and set of genetic instructions found within each cell. The genome is different for each organism. The Human Genome Project documented the entire DNA sequence of the approximately 25,000 genes held within the 23 pairs of chromosomes in humans.
Genotype	A person's complete collection of specific genes. A person's genotype is largely responsible for determining the phenotype.
Heterozygous	Referring to an individual who has a mutant allele on only one of a pair of specific genes. A specific phenotype in a heterozygous individual is the result of a dominant gene mutation, requiring only one mutant allele. Conversely, a heterozygous individual with a recessive gene mutation is referred to as a "carrier" and does not exhibit the phenotype.
Homozygous	Referring to an individual who has a mutant allele on both genes in a specific gene pair (one from each parent). Autosomal recessive inheritance of a trait, condition, or disease occurs only when an individual is homozygous for the specific gene. Cystic fibrosis and sickle cell anemia, for example, occur only in individuals who are homozygous for the specific disease gene.
Incomplete penetrance	Genetic mutation that does not always result in the phenotype associated with that mutation. Often the expression of a gene with incomplete penetrance depends on the presence of other environmental factors.
Karyotype	An individual's full set of chromosomes. Also, the standardized laboratory result or visual display (i.e., a photograph) of an individual's set of chromosomes.
Meiosis	Cell division that results in sperm or ova. Each daughter cell contains only half the original number of chromosomes.
Monosomy	A chromosomal condition in which a single chromosome is found when there should be a chromosome pair. These mutations are almost always lethal when found in autosomal chromosomes.
Multifactorial disease	A condition caused by the interactions between several genes and several environmental factors. Cancer, type 2 diabetes mellitus, and heart disease are all multifactorial conditions.
Mutation	A change in DNA sequence that may or may not result in a change in the protein product. Mutations may affect only one base pair or a larger segment in the DNA sequence via deletion, insertion, repetition, or duplication. Genetic mutations cause such disorders as cystic fibrosis, Tay–Sachs disease, and sickle cell anemia.
Nondisjunction	Failure of chromosome pairs to separate properly during meiosis. Meiosis is the type of cell reproduction that results in gametes (eggs and sperm), in which each gamete has only one set of 23 chromosomes rather than a full complement of 46 chromosomes in 23 paired sets.
Penetrance	The proportion of persons with a specific genotype who also express the expected phenotype. For example, if a particular gene mutation has 95% penetrance, then 95% of persons with that mutation will have the associated phenotype.
Phenotype	The observable traits or physical expression of an individual's genotype, which is also influenced

	by environmental factors.
Recessive allele	An allele that expresses a particular phenotype only if both alleles in the pair are recessive.
Ribonucleic acid (RNA)	A single-stranded nitrogenous molecule that mirrors the DNA sequence. RNA is essential for moving DNA instructions out of the nucleus (via transcription and translation) and into the cell cytoplasm, and for subsequent construction of amino acids into final protein products.
Sex-linked	A gene that is located on an X or Y sex chromosome.
Single-nucleotide polymorphism (SNP)	Pronounced “snip”; any of the common variations found in a single nucleotide of genomic DNA sequence between individuals, as well as between different populations.
Transcription	The synthesis of an RNA strand from a sequence of DNA; the first step in gene expression.
Translation	During protein synthesis, the process through which the sequence of bases in a molecule of messenger RNA is read to create a sequence of amino acids.
Trisomy	A chromosomal condition in which three chromosomes occur where there should be only a pair. Trisomy is a form of aneuploidy. The occurrence of trisomy increases in infants born to older mothers. A common trisomy condition is trisomy 21 (Down syndrome).

Genes, Genome, DNA, and Chromosomes

Genes—the basic unit of inheritance—consist of *deoxyribonucleic acid (DNA)* that is found within the cell nucleus; genes are contained within the 46 chromosomes found in every cell in the human body, except ova and sperm cells, which contain 23 chromosomes. *Chromosomes* consist of long segments of DNA that are tightly wrapped around proteins (**Figure 20-1**).[8] The human cell normally contains 46 chromosomes that are organized in 23 paired sets. In each of these sets, one chromosome is contributed by the individual’s biological mother and the other is contributed by the individual’s biological father. Twenty-two of those pairs are called *autosomes* and are the same in males and females. The last pair consists of the sex chromosomes: Females have two X chromosomes and males have an X and a Y chromosome.

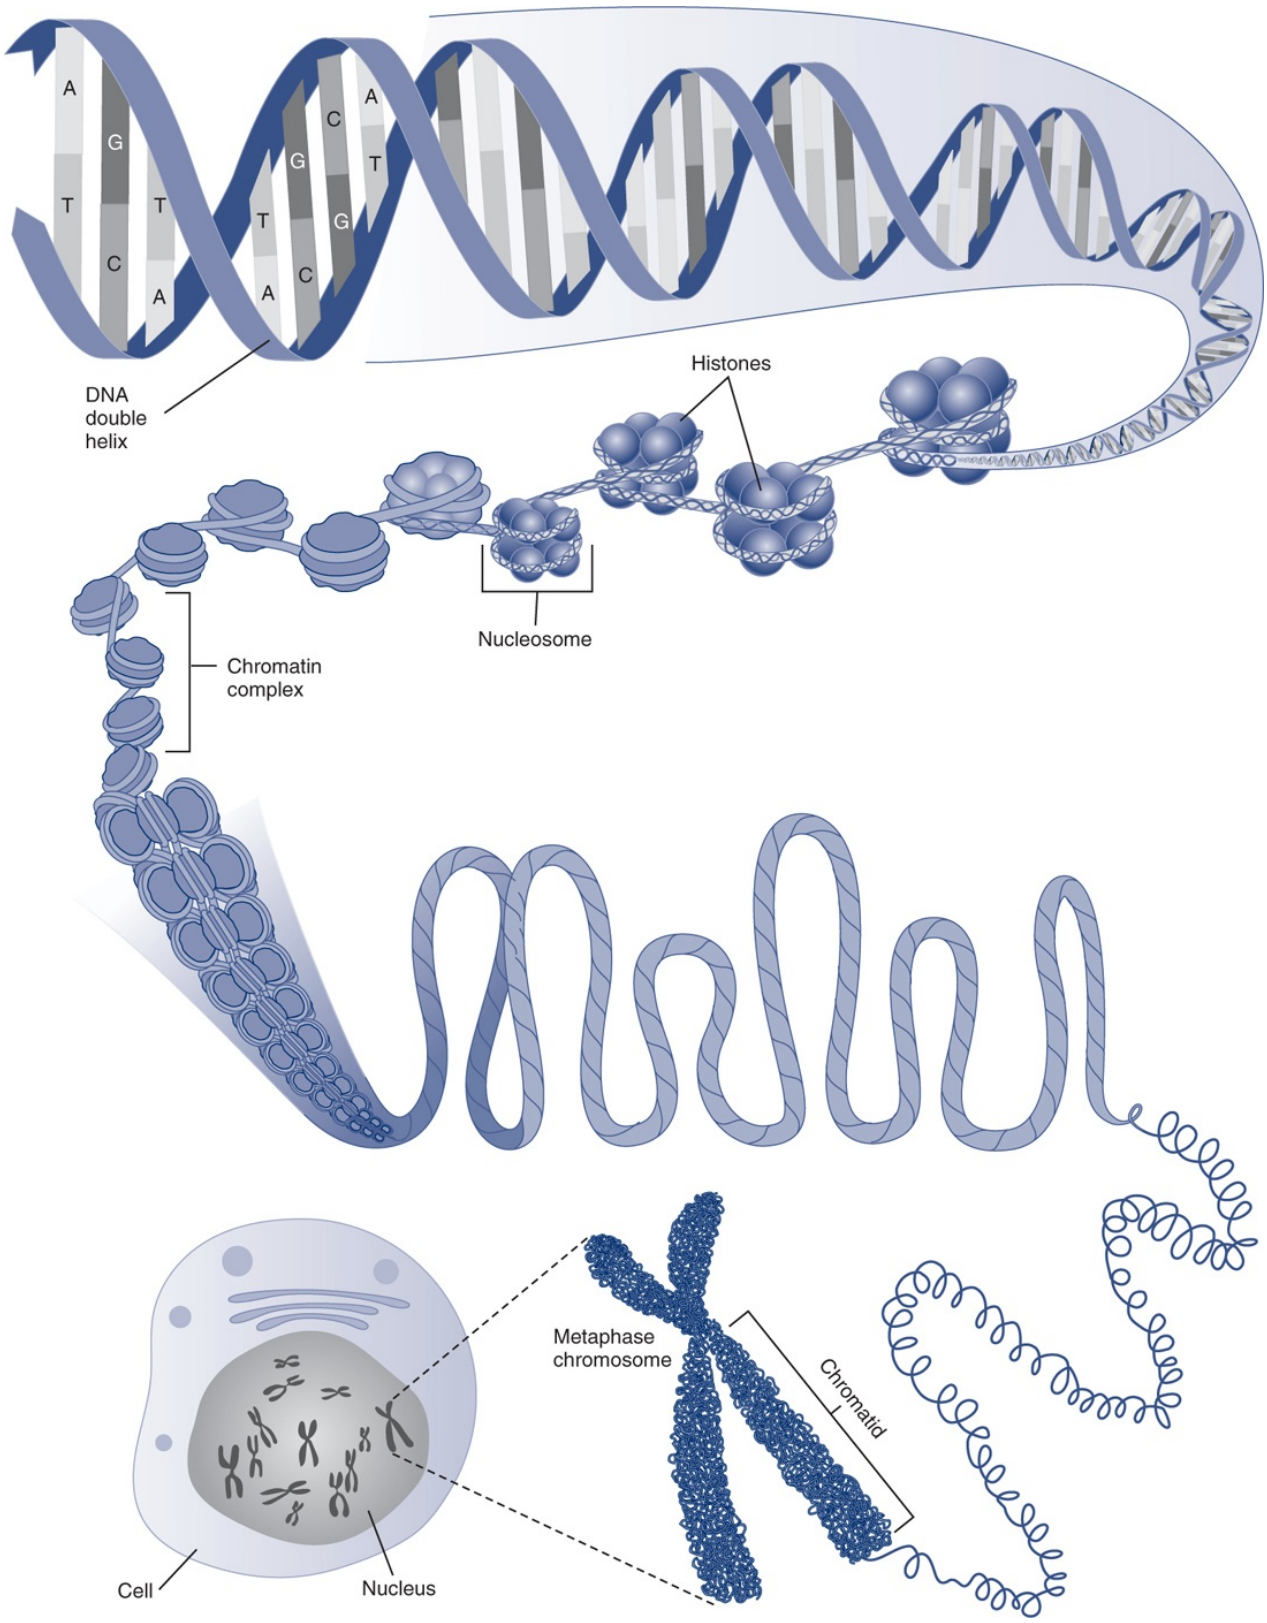

Figure 20-1 Patterns of DNA coiling. DNA is wound around eight histone cores (proteins) to form nucleosomes. Nucleosomes make up the chromatin complex, which is tightly coiled into a chromatid. The chromosome is made up of chromatids, which are held together by a centromere.

The entire collection of genes in an individual, referred to as the *genome*, provides a complete set of "instructions" for directing all biologic functions within the living organism.

The end product of gene instruction is the production of a protein, via the processes of *transcription* and *translation* of the DNA that occur as the instructions are used to construct actual proteins.[9] Every gene comprises a sequence of nitrogenous base pairs—molecules of cytosine, thymine, adenine, and guanine—that form the double-stranded DNA molecule, and each genetic sequence encodes for a specific protein with a specific function. The single-stranded *ribonucleic acid (RNA*) contributes to this process by providing a template for the eventual assembly of amino acids into proteins within the cell's cytoplasm.

The human genome has approximately 20,000 genes in chromosomes and 37 genes in the mitochondria of each nucleated cell. Approximately 1% of these genes are translated into proteins. The rest are involved in regulation or repression of the protein-coding genes.[10]

Gene expression refers to the eventual production of a gene product, although not all genes are expressed in every cell or in precisely the same way. For example, an epithelial cell (a skin cell) does not look or function the same way as a myocyte (a muscle cell). Although both cell types contain the exact same set of genetic instructions, only those genes that are expressed will contribute to the unique structure and function of the specific cell type.[11] Gene expression is regulated by a complex set of signals within an organism. This allows undifferentiated cells (i.e., fetal stem cells) to evolve into a wide variety of cells with differing structures and functions. The term *epigenetic* refers to the regulation of gene expression via modifications of the DNA structure (i.e., histones or chromatin, as noted in **Figure 20-1**), but not modification of the DNA sequence itself.[12] Environmental signals, both internal and external to an organism, are now known to make tremendous contributions to the regulation of gene expression.[10-12]

Genetic Mutations

Mutation refers to a permanent alteration in the DNA sequence within a gene, either by deletion, insertion, repetition, or duplication of a single base pair or larger segments of the DNA strand, entire genes, or pieces of chromosomes. Mutations occur rather frequently, and are often repaired by the body; a large number of them do not result in a clinical effect or disease.[1,10] However, a genetic mutation that causes a change in the protein product can subsequently alter the function of the cell. This change results in the disease *phenotype*, which refers to clinically or physically observed signs or symptoms that are reflective of the *genotype* within the individual. Genetic mutations can occur spontaneously or can be inherited from parent to child.

Alleles and Penetrance

All of the genes on a given maternally inherited chromosome correspond to the same gene in the same location (*allele*) on the paternal chromosome counterpart. Individuals with a mutant allele on only one of the pair of genes are referred to as "heterozygous," while those with a mutant allele on both genes in the pair are referred to as "homozygous."

Penetrance refers to the percentage of individuals with a specific disease genotype who also express the expected phenotype (the observable characteristics of the genotype). For example, a genetic mutation that is not associated with an expected phenotype 100% of the time

has “incomplete penetrance,” whereas a penetrance of 50% indicates that only half of the individuals with a specific disease genotype will exhibit the phenotype. The variation in phenotype (i.e., severity) of a particular genetic disorder, which is called *expressivity*, can be influenced by modifier genes, and perhaps aging or the environment. Expressivity contributes to the wide range of abilities that is observed among individuals with Down syndrome, for example. Knowledge about penetrance and expressivity helps to answer the question of why all individuals with the same genotype do not have the same phenotypic characteristics or severity of the genetic disorder.

Inheritance Patterns of Genetic Mutations

Genes, as the basic unit of inheritance, contribute significantly to an individual's characteristics, including disposition for health and disease in addition to aspects of physical appearance, such as height, eye color, and hair color. Mutations that occur in somatic cells are called acquired mutations and are significant when they lead to malignant transformation of the cell such as occurs in cancer. Genetic mutations that occur in sperm or eggs can be inherited, and there are several different patterns of inheritance.

Patterns of inheritance are either *autosomal*, which means the inherited genes are located on the first 22 pairs of chromosomes, or *sex-linked*, which means the inherited genes are located on the X or Y chromosome.[13] In addition, they are either dominant or recessive. Many well-known heritable genetic disorders are caused by a mutation in a single gene. These conditions are referred to as classic *Mendelian* disorders, after the early geneticist Gregor Mendel. Mendel was an Austrian monk who is usually called the "father of genetics" because he was one of the first scientists to clearly establish that physical traits are heritable from one generation to the next.[1,13] The classic Mendelian patterns of inheritance are autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked.

In contrast, most chromosomal abnormalities are not heritable. This clinical distinction is important because tests for chromosomal abnormalities are often inaccurately referred to as "genetic tests." Use of the word "genetics" when referring to tests for both genetic disorders and chromosomal abnormalities can mistakenly convey the idea that chromosomal abnormalities are inherited. Thus, when a midwife discusses genetic testing with individuals and their families, inheritance is an important concept to include in the discussion.

Autosomal Dominant Inheritance

Disease phenotypes expressed only in *heterozygous* individuals (i.e., those persons with only one mutant allele in a specific gene pair) reflect an autosomal dominant inheritance pattern.[1,13] Only one copy of the mutant allele is required for expression of such a disorder. Examples of autosomal dominant disorders include achondroplasia (commonly known as dwarfism), neurofibromatosis, Marfan's syndrome, and Huntington disease. An individual who has an autosomal dominant condition has a 50% probability of having a child with the same disease-causing mutation. This is true for both males and females. The existence of an autosomal dominant condition is usually well known to the affected family because it is commonly observed within all generations of the family tree, unlike autosomal recessive disorders.

The occurrence of spontaneous mutations in either the egg or the sperm explains why autosomal dominant disorders can occur in individuals with no family history of the condition. Since the mutation has not been inherited from the parents, the affected individual is the first in the family to experience the disorder. Although the disorder has not been inherited from the individual's parents, the affected individual will now have a 50% probability of transmitting the mutation to offspring. The parents of an individual who has an autosomal dominant disorder resulting from a spontaneous mutation have a low risk of having another child with the mutation.[2]

A diagram referred to as a Punnett square is often used to demonstrate the probability of inheritance in offspring of affected and unaffected parents, as shown in **Figure 20-2A**. A typical corresponding pedigree reflective of autosomal dominant inheritance is shown in **Figure 20-2B**.

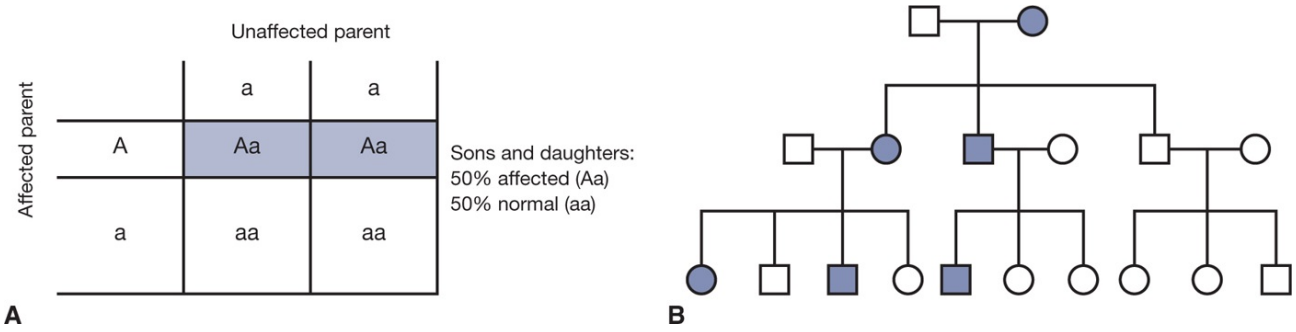

Figure 20-2 A. Probability of offspring inheriting an autosomal dominant disorder. This diagram demonstrates the probability of offspring inheriting an autosomal dominant disorder from a heterozygous (affected) parent and an unaffected parent. Shading indicates affected individuals. **B.** The corresponding dominant pedigree pattern. Pedigree showing inheritance pattern of an autosomal dominant disorder. Both genders are equally affected. Solid shapes represent affected individuals and open shapes represent unaffected individuals. Circles represent females and squares represent males.

Abbreviations: A, chromosome with a dominant disease allele; a, chromosome with a normal allele.

Autosomal Recessive Inheritance

Disease phenotypes expressed only in homozygous individuals (i.e., those persons with two mutant alleles in the specific gene pair) indicate an autosomal recessive inheritance pattern.[13] Individuals who are heterozygous for an autosomal recessive inheritance pattern are considered “carriers” and are largely unaffected by the disease. However, these carriers can pass the genetic mutation to their offspring. A carrier’s single working gene is sufficient for normal function. Cystic fibrosis (CF), Tay–Sachs disease, and sickle cell anemia are examples of autosomal recessive disorders.

A man and a woman who have the same autosomal recessive mutation will have a 25% probability that any pregnancy achieved from their union will result in a child who is affected with the disorder—that is, a child who is homozygous for the mutation (two mutant alleles). Additionally, any child from this same union has a 25% probability of being an unaffected noncarrier (no mutant alleles) of the mutation and a 50% probability of being an unaffected carrier (one mutant allele). Since autosomal recessive mutations have an inheritance pattern that results in less frequent occurrence of the disorder (frequently skipping generations in which the condition is observed), families are often unaware that the disease mutation exists. No one in the immediate family may have the disorder, and therefore, families are not aware of the possibility that a family member will have the disorder until an affected child is born.

The number of persons who are carriers for an autosomal recessive disorder varies greatly by race and ethnicity. Although carrier status for some autosomal recessive disorders is quite common among some populations, the incidence of newborns being affected with the disorder actually is much lower as noted in **Table 20-2**. **Figure 20-3A** demonstrates the probability of

inheritance in the offspring of parents who are carriers of an autosomal recessive disorder, and **Figure 20-3B** shows a typical corresponding pedigree.

Table 20-2 Autosomal Recessive Carrier Frequency in Specific Populations and Associated Incidence in Newborns

Genetic Disease	Ethnic Group	Carrier Frequency	Newborn Incidence
Tay–Sachs disease	Ashkenazi Jews	1/30	1/3600
Sickle cell disease	African Americans	1/12	1/600
Cystic fibrosis	Northern Europeans	1/25	1/2500
β-Thalassemia	Greeks/ Italians	1/30	1/3600
α-Thalassemia	Southeast Asians, Chinese	1/25	1/2500

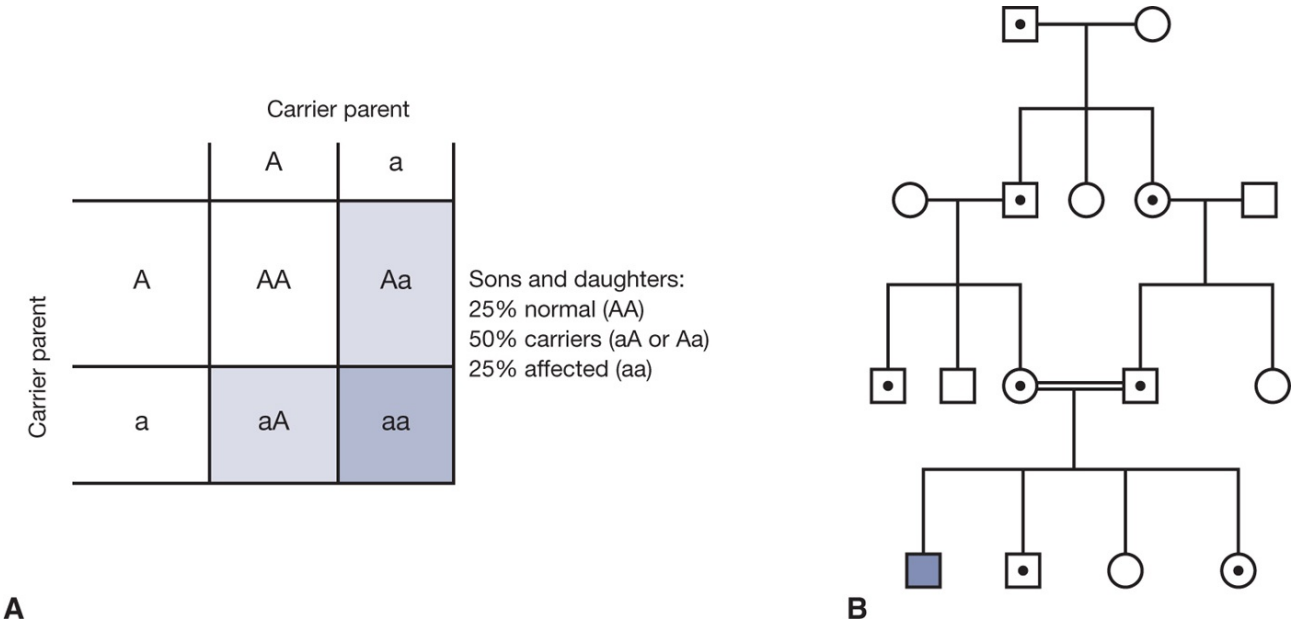

Figure 20-3 A. Probability of offspring inheriting an autosomal recessive disorder. Diagram

demonstrating the probability of offspring inheriting an autosomal recessive disorder from two heterozygous (carrier) parents. Light shading indicates carrier status and heavy shading indicates affected individuals. **B.** The corresponding autosomal recessive pedigree pattern. Pedigree showing the inheritance pattern of an autosomal recessive disorder. Consanguinity is denoted as a double line in this figure, but should not be interpreted as a requirement for inheritance. Solid shapes represent affected individuals and open shapes represent unaffected individuals. Circles represent females and squares represent males. Shapes containing a dot represent carriers of an autosomal recessive mutation.

Abbreviations: A, chromosome with a normal allele; a, chromosome with the disease allele.

Sex-Linked Inheritance

Disorders caused by mutations on the sex chromosomes are inherited differently than disorders inherited via autosomal mutations. Since females do not have a Y chromosome, Y-linked disorders do not occur in biological females. The Y chromosome also contains far fewer genes than the X chromosome, creating far fewer opportunities for mutation among biological males. Therefore, Y-linked disorders are extremely rare. In contrast, X-linked disorders are more common and predominantly affect males who do not have the paired normal X chromosome that females have. A paired X chromosome, as occurs in females, could contribute a normally functioning allele to compensate for a mutant allele. The inheritance pattern of X-linked mutations results in unaffected female carriers of the mutation and affected males with a Y chromosome that cannot compensate for the mutation occurring on the X chromosome. In the male, the single mutation on the X chromosome is sufficient to cause the disorder.

A female who is a carrier for an X-linked recessive mutation has four possible pregnancy outcomes (assuming a male partner without an X-linked disorder): a 25% chance for an unaffected carrier female (one mutant X allele and one normal X allele), a 25% chance for an unaffected noncarrier female (two normal X alleles), a 25% chance for an affected male (one mutant X allele, one normal Y allele unable to compensate), and a 25% chance for a healthy male (normal X and Y alleles).[13] An affected male has two possible outcomes for his offspring (assuming a female partner who is not a carrier for an X-linked disorder): a carrier female (one mutant X allele and one normal X allele) and an unaffected, noncarrier male (males contribute only a Y chromosome to their male offspring). **Figure 20-4A** illustrates the inheritance probabilities for X-linked disorders among offspring of a carrier mother and an unaffected father, by far the most common occurrence. **Figure 20-4B** shows a typical corresponding pedigree.

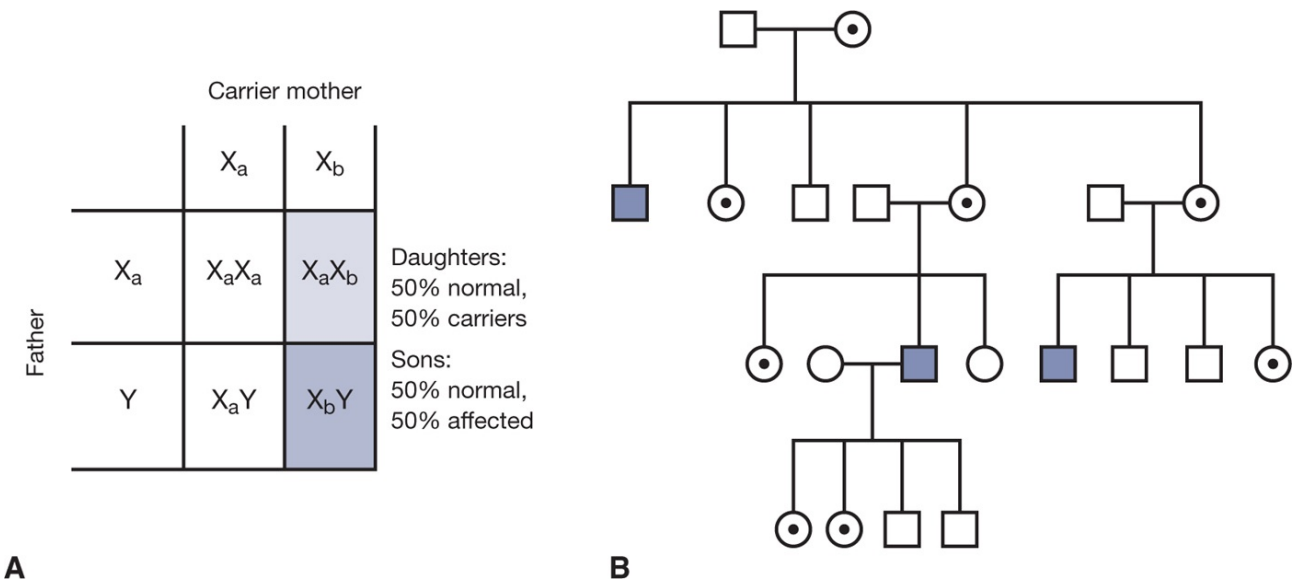

Figure 20-4 A. Probability of offspring inheriting an X-linked recessive disorder. Diagram demonstrating the probability of offspring inheriting an X-linked recessive disorder from a heterozygous mother (carrier) and an unaffected, noncarrier father. Light shading indicates carrier status. Heavy shading indicates an affected individual. **B.** The corresponding X-linked recessive pedigree pattern. Pedigree showing inheritance pattern of an X-linked recessive disorder. Only males are affected. Only females are carriers. For offspring of a carrier mother and a normal father, in each pregnancy there is an independent chance that for males there is a 50% chance the male will be affected and a 50% chance the male will be unaffected. For females there is a 50% the daughter will be a carrier, and a 50% chance the daughter will be unaffected. For offspring of affected males, 100% of daughters are carriers and 100% of sons are normal. Solid shapes represent affected individuals and open shapes represent unaffected individuals. Circles represent females and squares represent males. Shapes containing a dot represent carriers of an autosomal recessive mutation.

Abbreviations: Xa, chromosome with a normal allele; Xb, chromosome with the disease allele.

Hemophilia A and Duchenne muscular dystrophy are among the more common X-linked disorders. One way to distinguish X-linked from autosomal dominant conditions when analyzing a pedigree is to determine whether affected males have affected sons. Male-to-male transmission is observed with autosomal dominant conditions but not with X-linked recessive traits.

X-linked dominant disorders exist, but appear rarely in the population. These conditions also affect heterozygous females. Upon pedigree analysis, none of the sons but all of the daughters of affected males will be affected.

Multifactorial Inheritance

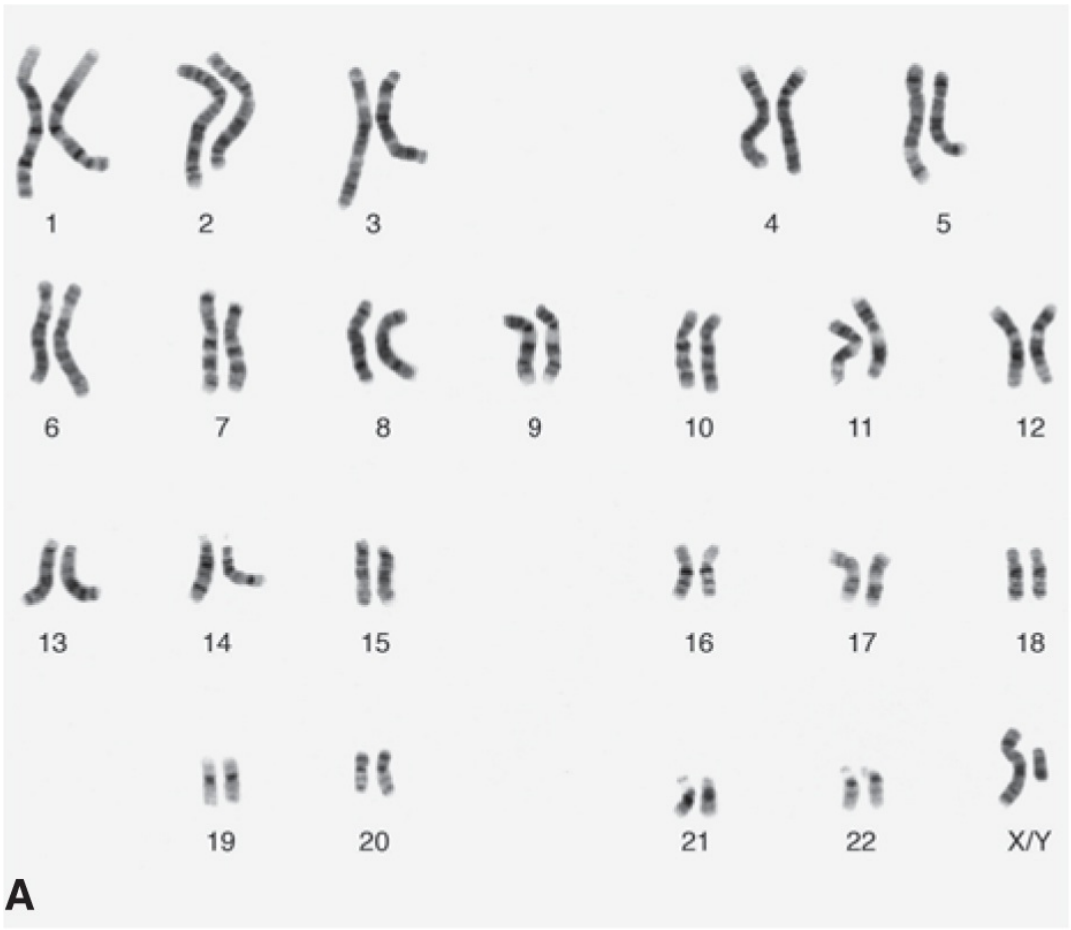
Many common conditions and disorders occur due to multifactorial inheritance, meaning that they are caused by the combined effects of several genes (genetic predisposition) and several environmental factors.[1] It is also generally accepted that a “threshold” must be reached for the disease or condition to become manifest. In other words, an additive effect of genetic predisposition and increasing environmental “load” will cause an individual to reach a certain “tipping point” when the disease phenotype will occur. Gender, age, socioeconomic status, lifestyle, nutrition status, geographic area, and ethnic background frequently influence the

occurrence of a multifactorial condition or disease. Neural tube defects (spina bifida and anencephaly) and congenital pyloric stenosis are common examples of multifactorial conditions that are present at birth. Cancer, type 2 diabetes mellitus, and heart disease are multifactorial conditions that usually manifest in adulthood.

Neural Tube Defects

Neural tube defects (NTDs) are examples of multifactorial conditions that contribute significantly to adverse birth outcomes. NTDs occur when the neural tube fails to develop and close properly during very early embryonic life (2–6 weeks' gestational age).[11] Multiple genes —particularly those associated with folate metabolism—contribute to a genetic predisposition for NTDs; environmental factors, such as maternal age, diet, geographic area, drug exposure, and socioeconomic status, are associated with these defects as well.[11] Spina bifida (protrusion of the spinal tissue through the vertebral column) and anencephaly (partial or complete absence of the cranial vault and partial or complete absence of the cerebral hemispheres) are the most common NTDs observed.[14] These two conditions are also referred to as open neural tube defects to differentiate them from the rarer closed neural tube defects, in which skin covers the spinal abnormality.

The prevalence of NTDs varies widely among different populations, from 1 to 2 persons per 1000 live births, to as high as 6 persons per 1000 live births in northern Chinese populations. While the pathophysiologic basis for NTDs is complex and not well understood, it is known that folic acid supplementation can reduce the occurrence of NTDs by 60% to 70%. This recognition has led to the widespread recommendation for folic acid fortification of enriched cereal products and supplementation (400–800 mcg per day) prior to conception, as well as during the first 8 weeks of pregnancy.[13] Although women who have had an affected child have a risk of reoccurrence in subsequent children of approximately 2% to 5%, 95% of all NTDs occur in previously unaffected families.[15]



Individuals with spina bifida—the most common NTD—have varying degrees of physical and mental challenges, including hydrocephalus (which is independently associated with increased risk for physical and intellectual disability). The severity of disability increases with the severity of the defect. Approximately 35% of infants born with spina bifida do not survive to 10 years. Surgical repairs of the defect are the usual approach for improving prognosis.

Anencephaly has an extremely high level of mortality. The majority of infants with anencephaly are stillborn, and those who are born alive die soon after birth.[16]

Chromosomal Disorders

Chromosomal disorders are not the result of single-gene mutations, such as the autosomal dominant and recessive disorders, but rather reflect changes in the number or structure of the chromosomes.[2] Chromosomal abnormalities are relatively common, occurring in an estimated 1 in 150 live births and approximately 50% of first-trimester spontaneous abortions.[2] Such abnormalities frequently are associated with common phenotypic and physical characteristics, thereby aiding in their early identification, including during fetal ultrasound examination. However, chromosomal evaluation via a *karyotype* (a visual display of the full complement of an individual's chromosomes) or *chromosomal microarray analysis* provides the definitive diagnosis.

The most common numeric chromosomal aberrations are caused by *aneuploidy*—an addition or deletion of an entire chromosome in a normal set of 23 pairs of chromosomes. Aneuploidy most often occurs due to nondisjunction during cell division in the egg or sperm.[17] The resulting absence of one chromosome (monosomy) in a set is almost always lethal, so such a mutation is rarely observed in live-born children. In contrast, the addition of a chromosome (trisomy) leads to one of several disorders depending on which chromosome pair receives the extra genetic material. The most common trisomy is trisomy 21 (Down syndrome), which is caused by an extra chromosome added to the 21st pair of chromosomes. **Figures 20-5A** and **20-5B** contrast the 21st chromosomes in a normal female karyotype and one with trisomy 21. Phenotypic characteristics of individuals with trisomy 21 include specific facial features, such as small upturned eyes, small flat nose, small mouth with large tongue, and small ears (**Figure 20-6**). Intellectual and physical disabilities of varying severity are also observed. Congenital heart defects, obstructions of the gastrointestinal tract, and frequent respiratory infections are associated with trisomy 21. Trisomy 18 (Edwards syndrome) and trisomy 13 (Patau syndrome) are less frequently encountered aneuploidies, but both result in severe physical and intellectual disability in offspring, and are usually lethal during gestation or shortly after birth.[2,18]

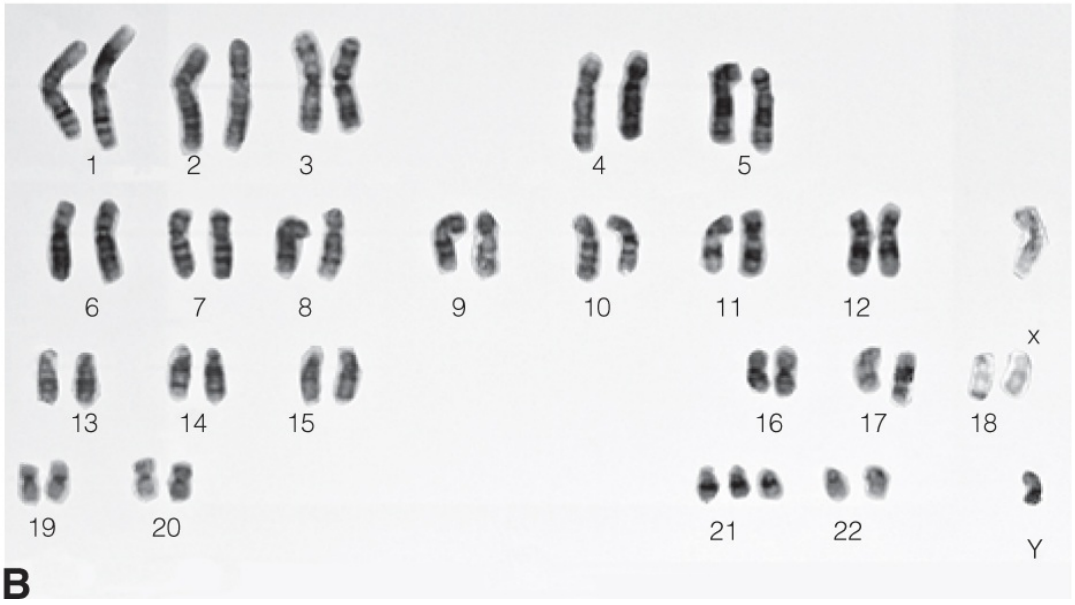


Figure 20-5 Karyotype. **A.** A full complement of 23 pairs of chromosomes in a female individual. **B.** An extra chromosome is observed in this female individual with trisomy 21 (Down syndrome).

Other common aneuploid disorders include sex chromosomal aberrations, such as Turner syndrome (XO), Klinefelter syndrome (XXY), trisomy X (XXX), and 47, XYY syndrome. Aneuploidy of sex chromosomes frequently results in less severe consequences than does autosomal aneuploidy, but the resulting conditions are associated with sex characteristic effects (including sterility, feminization, or virilization), and frequent minor physical changes specific to the disorder.[18] Many individuals who are mildly affected are not identified with a

chromosome abnormality for much of their lives unless health care is sought for a seemingly unrelated condition (e.g., infertility) and a karyotype is performed to identify the potential genetic etiology of the condition.[2,19,20] The gain of an entire haploid set of chromosome (e.g., 69, XXY) also occurs in a partial hydatiform mole.

Rearrangements, inversions, small deletions, or microdeletions of portions of a chromosome are considered structural abnormalities. They contribute to infrequently occurring genetic conditions, such as cri-du-chat syndrome, the result of a deletion of a portion of chromosome 5; Wolf-Hirschhorn syndrome, the result of a deletion of a portion of chromosome 4; Prader-Willi syndrome, a microdeletion of a portion of chromosome 15; and Williams syndrome, a microdeletion of a portion of chromosome 7.[21] Each abnormality has phenotypic characteristics specific to the condition.

Birth Defects, Incidence, and Risk Identification

Genetic disorders and chromosomal disorders are not rare occurrences. An individual's risk for a genetic disorder is based on several factors, including age, gender, and ethnic background. For example, cystic fibrosis has a prevalence of 1 case per 2500 persons among whites of Northern European descent, while sickle cell disease has a prevalence of 1 case per 400 to 600 persons among blacks of African descent. Another example of a factor affecting the risk for chromosomal disorders is maternal age: Women have an increased risk of having a child with trisomy 21 as the woman ages.[22] **Table 20-3** and **Table 20-4** list several conditions and diseases with a genetic component, along with their prevalence in specific populations. Understanding particular risks among specific populations and groups can prompt the midwife to probe further when obtaining a medical and family history, provide accurate patient education, recommend specific testing to women and families, or make a referral to a genetic counselor, as appropriate.

Table 20-3	Selected Chromosomal and Genetic Disorders with Approximate Incidence Rates
Condition/Disease	**Approximate Incidence**
Chromosome Abnormalities	
Klinefelter syndrome	1/1000 males
Trisomy 21 (Down syndrome)	1/700 to 1/1000
Trisomy 18 (Edwards syndrome)	1/6000
Trisomy 13 (Patau syndrome)	1/10,000
Turner syndrome	1/2500 to 1/10,000 females
Single-Gene (Mendelian) Disorders	
Achondroplasia (dwarfism)	1/25,000
Cystic fibrosis	1/2000 to 1/4000 (persons of European descent)
Duchenne muscular dystrophy	1/3500 males
Hemophilia A	1/5000 to 1/10,000 males
Huntington disease	1/20,000 (persons of European descent)
Neurofibromatosis	1/3000 to 1/5000
Sickle cell disease	1/400 to 1/600 African Americans; as many as 1/50 in persons from Central Africa
Tay–Sachs disease	1/3000 in persons of Ashkenazi Jewish descent
Thalassemia	1/50 to 1/100 (South Asian and circum-Mediterranean populations)

Table 20-4	Selected Multifactorial Disorders with Approximate Incidence Rates

Condition/Disease	Approximate Incidence
Congenital Malformations	
Cleft lip with or without cleft palate	1/500 to 1/1000
Club foot (congenital talipes equinovarus)	1/1000
Congenital heart defects	1/200 to 1/500
Neural tube defects (spina bifida, anencephaly)	1/200 to 1/1000
Pyloric stenosis	1/300
Adult Diseases	
Alcoholism	1/10 to 1/20
Alzheimer disease	1/10 persons in the United States older than 65
Bipolar affective disorder	1/100 to 1/200
Cancer (all types)	1/3
Diabetes (types 1 and 2)	1/10
Heart disease or stroke	1/3 to 1/5
Schizophrenia	1/100

Modified with permission from Jorde L, Carey J, Bamshad M. Background and history. In: Jorde L, Carey J, Bamshad M, eds. *Medical Genetics*. 5th ed. Philadelphia, PA: Elsevier; 2016:1-5.[1]

Age

Women who are older than 35 years have a well-documented increase in the risk for having a fetus with a chromosomal abnormality, particularly for aneuploidy such as trisomy 21 (Down syndrome).[23] The graph in **Figure 20-7** demonstrates the escalating risk of a pregnancy being affected by a chromosomal anomaly as maternal age increases. By the maternal age of 45 years, the risk for any chromosomal disorder is approximately 5.3% (the majority being trisomy 21), compared to approximately 0.25% for women who are younger than age 30 years. Presented another way, **Table 20-5** shows that 1 in 30 infants born to women age 45 years will have trisomy 21, compared to 1 in 1250 infants born to women age 25 years.[22] The risk for any chromosomal disorder for infants born to women age 45 years is 1 in 20.

Table 20-5 **Maternal Age and Risk of Chromosomal Disorders (Live Births)**

Maternal Age (years)	Risk for Trisomy 21	Risk for Any Chromosomal Disorder
20	1 in 1667	1 in 526
25	1 in 1250	1 in 476
30	1 in 952	1 in 384
35	1 in 385	1 in 204
40	1 in 106	1 in 65
45	1 in 30	1 in 20
49	1 in 11	1 in 7

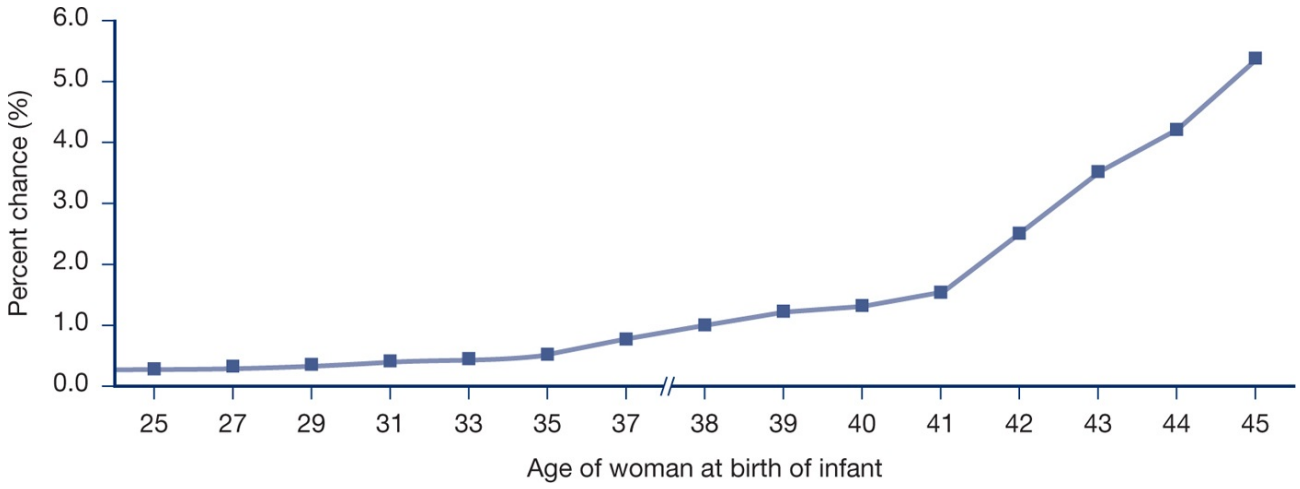

Figure 20-7 Maternal age and risk of chromosomal abnormality.

Data from Hook EB. Rates of chromosomal abnormalities. *Obstet Gynecol*. 1981;58(3):282-285.[23]

Although a few studies have shown a very slight increase in the risk of genetic disorders for children born to older men (primarily autosomal dominant disorders such as achondroplasia and neurofibromatosis), most research has not revealed that older fatherhood is associated with an increased risk for chromosomal anomalies.[24,25] Furthermore, unlike the risk associated with advanced maternal age, no clear consensus exists for when a man is considered to be of advanced paternal age. A commonly used criterion is age 40 years, but there are no specific recommendations for couples wherein the biologic father is of advanced paternal age.

Maternal Disorders

Exposure to teratogens may be a risk factor for birth defects depending on the level and type of exposure (i.e., duration, strength, potency).[22] A *teratogen* is a drug, virus, chemical, or other substance that can interfere with normal embryonic or fetal development and cause malformations. A list of medications that are known or suspected to be teratogens can be found in the *Pharmacotherapeutics* chapter. Selected maternal conditions that are known or highly suspected contributors to birth defects are listed in **Table 20-6**.[26]

Table 20-6 Selected Maternal Conditions That Are Teratogenic

Teratogen	Associated Defects	Percentage of Pregnancies Affected
Maternal Infections		
Cytomegalovirus	Mental retardation, microcephaly	10–15%
Rubella	Deafness, cataracts, heart defects, mental retardation	Up to 85%

Syphilis (untreated)	Abnormal teeth and bones, mental retardation	Not established
Toxoplasmosis	Hydrocephaly, blindness, mental retardation	5–6%
Varicella	Limb reduction defects, skin scarring, muscle atrophy, chorioretinitis	1%
Zika	Microcephaly, decreased brain tissue, joints with limited range of motion, restrictive muscle tone, damage to back of the eye	6% overall 11% for exposure during first trimester
Maternal Conditions		
Active alcoholism	Miscarriage, fetal alcohol syndrome (minor facial changes, heart defects), IUGR, developmental delay	Up to 50%
Diabetes mellitus	Heart defects, microcephaly, neural tube defects, skeletal defects, and defects in the urinary, reproductive, and digestive systems	HbA1c < 7.9%: 3.2% HbA1c 8.0–9.9%: 8.1% HbA1c > 10%: 23.5%
Hyperthermia (fever); early pregnancy only	Neural tube defects, heart and abdominal wall defects, oral cleft	Not established
Seizure disorder (treated)	Cleft lip with or without cleft palate, heart defects	6–8%
Systemic lupus erythematosus (uncontrolled)	Miscarriage, stillbirth, congenital heart block, IUGR, prematurity	Not established

Abbreviations: HbA1c, hemoglobin A1c; IUGR, intrauterine growth restriction.

Based on Teratology Society: Organization of Teratology Information Specialists (OTIS). MotherToBaby fact sheets. 2017. Available at: https://www.teratology.org/OTIS_fact_Sheets.asp. Accessed February 21, 2017.[26]

Environmental Teratogens

A number of environmental chemicals such as mercury, polychlorinated biphenyls [PCBs], some paints, and phthalates have been linked to teratogenic or fetotoxic effects.[27] Most of these agents have suspected adverse effects on fertility, spontaneous abortion, and impaired neurodevelopment. Although evidence that firmly establishes some of these compounds as teratogens is varied, these associations are the subject of current research. Adverse reproductive outcomes associated with specific environmental toxins and pollutants are discussed in more detail in the *Preconception Care Visit* appendix of the *Health Promotion Across the Lifespan* chapter.

Teratogens may cause genetic mutations, but it is thought that an alteration in gene expression during critical embryonic and fetal developmental periods is the more likely mechanism contributing to genetic disorders that are secondary to teratogen exposure.[28] This is an important distinction because epigenetic regulation of gene expression is an increasingly documented and plausible mechanism that may explain some of the link between environmental exposures and birth.[28] For example, epigenetic regulation of gene expression may be the mechanism underlying the link between chronic hyperglycemia, found among women with poorly managed diabetes (gestational or otherwise), and an increased risk of birth defects, such as heart defects and NTDs.[29,30] Moreover, epigenetic modifications may endure and

confer risk for more than one generation.[31]

The major concern is for exposures to women during pregnancy, particularly during the first trimester. As yet, little to no evidence has been published suggesting that paternal exposure is associated with increased occurrence of birth defects, although there may be some association with adverse health outcomes during childhood.[32]

Family History and Pedigree Evaluation as Risk Assessment Tools

One of the most effective, low-cost approaches to genetics risk assessment is to obtain a thorough personal health and family history that includes evaluation of a three-generation pedigree. A personal and family history is a "free, well-proven, personalized genomic tool that . . . can serve as the cornerstone for individualized disease prevention."[33] Many clues that indicate the need for further evaluation, testing, or referral to a genetic counselor can be found by obtaining a thorough family history (**Table 20-7**).[34] Furthermore, a number of consumer-completed family genetics history tools (see the Resources section at the end of this chapter) are available, both in print and online, to facilitate collection of personal and family histories. Such participation tools can be completed by an individual prior to a prenatal care appointment with the midwife and can be an effective and efficient way for identifying genetic risk.

Table 20-7 Personal and Family History That May Warrant Genetic Testing and/or Referral to Genetic Counseling

Maternal age
High-risk ethnic heritage
Consanguinity (blood relationship of parents)
Family history (maternal and/or paternal) of a known or suspected genetic condition
Multiple affected family members (maternal and/or paternal) with the same or related disorders
Any major malformations (e.g., heart, kidney, brain) or other birth defects occurring in mother, father, grandparents, offspring, or close relatives (brothers/sisters)
Congenital blindness or deafness in family members
Extremely tall or short stature of mother, father, or their relatives
Developmental delays or intellectual disability occurring in mother, father, offspring, or close relatives
Recurrent pregnancy losses (two or more) in the woman or first-degree family members
Environmental exposure to known or suspected teratogens
Infertility or premature ovarian failure

Based on The New York – Mid-Atlantic Guide for Patients and Health Professionals. Indications for a genetic referral. In: *Understanding Genetics: A New York, Mid-Atlantic Guide for Patients and Health Professionals*. Washington, DC: Genetic Alliance; 2009. Available at: https://www.ncbi.nlm.nih.gov/books/NBK115563/pdf/Bookshelf_NBK115563.pdf. Accessed June 26, 2017.[34]

Constructing and evaluating a three-generation pedigree for genetic risk is a basic skill for all healthcare professionals, including midwives.[35] Instructions for how to obtain a three-generation pedigree can be found in **Appendix 20-A**.

Screening Tests Versus Diagnostic Tests

Diagnostic tests provide a definitive answer to whether an individual has a particular disorder. In contrast, screening tests simply separate those persons who "might" from those persons who "probably don't" have the specific condition being tested. Screening tests are *not* diagnostic. Screening results usually aid in determining the level of risk for a specific disorder, and they identify individuals who might be advised to undergo further, definitive diagnostic testing.

For example, the results of a maternal serum screening test for trisomy 21 during the first trimester are not simply reported as "normal" or "abnormal." Instead, the results will indicate the chance (e.g., 1 in 40, 1 in 400, 1 in 4000) of having a fetus with trisomy 21. This chance is based on the level of pregnancy-associated plasma protein A (PAPP-A) and human chorionic gonadotropin (hCG) in maternal serum in conjunction with nuchal translucency measurement identified on ultrasound performed at a specific gestational age. Such screening test results give the woman the information necessary to help decide whether diagnostic testing will be chosen as the next step.

Screening tests have six critical components: (1) sensitivity, (2) specificity, (3) false-positive rate, (4) false-negative rate, (5) positive predictive value, and (6) negative predictive value (**Table 20-8**). The *sensitivity* refers to the number of individuals with the disorder who have a screening test that is positive for that disorder. *Specificity* is the number of individuals without the disorder who have a negative screening test. Again, using first-trimester maternal serum screening (without adding nuchal translucency ultrasound) as an example, such screening has the demonstrated ability to detect approximately 70% of the fetuses who have trisomy 21.[36] Thus, approximately 30% of fetuses with trisomy 21 will not be detected with this screening test; this is the *false-negative rate*. In contrast, the *false-positive rate* reflects the chance of a positive test result indicating a high likelihood for trisomy 21 when a healthy fetus is actually present. The false-positive rate for first-trimester screening for trisomy 21 is approximately 5%,[37] and is a significant contributor to unintended parental anxiety during the prenatal period and potentially unnecessary interventions.

Table 20-8 Sensitivity, Specificity, Positive Predictive Value, and Negative Predictive Value

Test Results	Disease Present	No Disease	
Screen test positive	A (true positive)	B (false positive)	A ÷ A and B Positive predictive value
Screen test negative	C (false negative)	D (true negative)	D ÷ C and D Negative predictive value
	A ÷ A and C Sensitivity	D ÷ B and D Specificity	

Many factors affect test results, including gestational age, maternal age, presence of multifetal gestation, certain medical conditions such as diabetes, and other coexisting congenital or genetic disorders.[38] In addition, the prevalence of a disorder varies for different

groups of women (e.g., based on ethnicity or geographical location). These differences must be taken into account to accurately interpret test results and contribute to determining the positive predictive value and negative predictive value, as illustrated in **Figure 20-8**. Continuing the example of first-trimester screening for Down syndrome, the *positive predictive value* is the proportion of all positive tests that truly indicate a baby *with* trisomy 21; it is calculated as the number of women with a positive test divided by the total number of women in the population tested who had a positive screening test result. In contrast, the *negative predictive value* is the proportion of all negative tests that truly indicate a baby without trisomy 21, calculated as the number of persons without the disease who had negative results divided by the total number of women tested who had negative results.

Chart A: Sensitivity (87%), specificity (95%), and predictive value of first-trimester screening (nuchal translucency and maternal serum) for trisomy 21 when the prevalence rate is 1 per 1250, as it is among women age 25 years[a]

	Trisomy 21 Present	Trisomy 21 Absent	Interpretation (Predictive Value)
Positive test result	87 will have a true-positive test	6235 will have a false-positive test	A 25-year-old woman with a positive test for trisomy 21 has a 1.4% chance of actually having a fetus with trisomy 21 (out of 6322 positive tests, 87 fetus had trisomy 21 and 6235 tests were false alarms). This is the positive predictive value.
Negative test result	13 will have a false-negative test	118,665 will have a true-negative test	A woman with a negative test result has a 99.9% chance of *not* having a fetus with trisomy 21 (out of 75,918 negative tests, 13 fetuses actually had trisomy 21). This is the negative predictive value.
	100 fetuses affected	124,900 not affected	Out of 125,000 fetuses in women who are 25 years old, 100 will have trisomy 21 and 124,900 will not have a fetus with trisomy 21.

Chart B: Sensitivity (87%), specificity (95%), and predictive value of first-trimester screening (nuchal translucency and maternal serum) for trisomy 21 when the prevalence rate is 1 per 30, as it is among women age 45 years[a]

	Trisomy 21 Present	Trisomy 21 Absent	Interpretation (Predictive Value)
Positive test result	87 will have a true-positive test	145 will have a false-positive test	A 45-year-old woman with a positive test for trisomy 21 has a 37.5% chance of actually having a baby with trisomy 21 (out of 232 positive tests, 87 babies had trisomy 21 and 145 tests were false alarms). This is the positive predictive value.
Negative test result	13 will have a false-negative test	2755 will have a true-negative test	A woman with a negative test result has a 99.3% chance of *not* having a fetus with trisomy 21 (out of 2768 negative tests, 13 babies actually had trisomy 21). This is the negative predictive value.
	100 babies affected	2900 babies not affected	Out of 3000 babies born to 45-year-old mothers, 100 will have trisomy 21 and 2900 will not have a fetus with this chromosomal abnormality.

Figure 20-8 The impact of prevalence on the predictive value and interpretation of first-trimester

screening for trisomy 21 among women of differing age.[a]

[a] Test performance (specificity and sensitivity) is the same in both charts. However, the positive predictive value and the negative predictive value are different in the two charts because the prevalence rate for trisomy 21 is different for women who are 25 years old (chart A) and women who are 45 years old (chart B). The interpretation is therefore different for women of different ages as represented in each of these charts.

This type of multifactorial input into test results is also illustrated with the use of the maternal serum alpha-fetoprotein (MSAFP) or alpha-fetoprotein (AFP) test. AFP is a protein made by the fetal liver and found in the amniotic fluid. It passes through the placenta and circulates into the maternal blood, thereby enabling assessment of AFP through maternal serum sampling. MSAFP is a screening test for NTDs, but also is used to identify risk for trisomy 21. High levels of MSAFP are associated with increased risk of NTDs, whereas lower levels are associated with elevated risk for trisomy 21.[39] In this case, one of the additional factors influencing the interpretation of results is an accurate estimation of gestational age. The MSAFP test has different normative values at different gestational ages. Thus, if a woman has the test done at 15 weeks' gestation, it will be interpreted based on 15-week norms. However, if the gestational age has not been accurately determined and the pregnancy is actually at 13 gestational weeks, the test results will appear abnormal because they have been interpreted incorrectly. Similarly, there are different normative values for women who have a multifetal gestation. This situation has prompted clinicians to use multiple biochemical markers as screening tests, rather than relying on a single marker, such as MSAFP.

Factors That Influence Women's Decision Making

Women are faced with many difficult decisions in healthcare settings, and prenatal genetic screening and testing are not exceptions. Many factors, such as individual, family, religious and cultural values, will play a role in how a woman perceives screening and diagnostic testing for genetic defects. Midwives can ease this process by engaging in evidence-based, shared decision making when offering prenatal testing, interpreting test results, and discussing options. Women and their families should have their questions answered adequately and candidly, but with compassion and respect for individual values and wishes.

Prenatal tests can screen for some structural abnormalities, genetic disorders, and chromosomal abnormalities. The aim of prenatal screening and diagnostic testing is to provide families with the information necessary to make well-informed reproductive health decisions. The clinical implications of test results can be complicated, and sharing information with women both before and after tests are performed is a necessary skill.

Pre- and Post-Test Counseling When Screening for Genetic and Chromosomal Disorders

Genetic and genomic health care is changing rapidly as new technologies are incorporated into clinical practice. The number of tests and algorithms promoted as part of prenatal testing continues to increase, and best practices for incorporating new tests are being studied. A standard algorithm for prenatal testing based on professional guidelines and the tests commonly available today is presented in the *Prenatal Care* chapter. This chapter reviews the process of counseling women about these tests and the characteristics of the screening and diagnostic tests that are currently in use.

Pre- and post-test counseling is recommended for all women who have prenatal screening tests for genetic disorders. Women who might have an elevated risk for a genetic or chromosomal disorder (as indicated in **Table 20-7**) and any women who want more detailed information should be referred for genetic counseling. Most healthcare settings offer genetic counseling to any woman who has a positive screening test.

Table 20-9 provides an overview of the questions that women most often ask and key topics to address in pretest counseling.[40-47] The most important question for a woman is, "What will I do with the information?" This question will need to be answered by the woman for herself with support from her significant others and her midwife. Answering this question can assist her to make the ultimate decision as to whether she will undergo screening tests, diagnostic tests, or both.[45] A woman can often arrive at an answer by addressing additional, very personal questions: "Would I terminate this pregnancy if I know my baby is affected with (fill in the blank)?" "Do I want to know that my baby is affected before the baby is born?" "Would testing simply make me more anxious, rather than less anxious?" "Am I willing to accept the increased risk of miscarriage associated with a diagnostic test such as chorionic villus sampling or amniocentesis?" "Am I strongly opposed to pregnancy termination even if I have a baby affected with (fill in the blank)?" "Why should I have screening or diagnostic tests if I am fine with any outcome the baby might have?" It often helps women to self-identify their stance when

the midwife offers statements that begin with “Some women choose to have these tests because . . .” and “Some women choose not to have these tests because . . . .”

Table 20-9 Key Topics for Pretest Counseling

Questions Women Ask	Essential Information for Pretest Counseling
Why is this test offered?	Review the conditions being tested for, including common phenotype and variability in phenotype
	Type of testing offered (screening, carrier screening, diagnostic test)
	Alternative testing options, including the risks, benefits, and limitations of each alternative
How are the results communicated?	Review how test results are shared with the woman and timing for getting results
What will I do with the information?	Possible results of testing: positive, negative, unclear (inconclusive), unexpected
What if there is a positive result?	Availability of genetic counseling to provide additional information and assist decision making
	Review that genetic counseling will address diagnosis of the condition, options for the woman if a disorder is diagnosed, and treatments for the condition
How much does the test cost and will insurance cover the cost?	Discuss cost of testing and insurance coverage
	Address the effect on health insurance if a disorder is diagnosed
When does the test have to be done?	Review timing for performing the test
Who will know about the results?	Review patient confidentiality and discuss implications of sharing information with a partner and family

Based on Fonda Allen J, Stoll K, Bernhardt BA. Pre- and post-test genetic counseling for chromosomal and Mendelian disorders. *Semin Perinatol.* 2016;40(1):44-55.[45]

Tests for Genetic and Chromosomal Disorders

The number and types of tests that screen or diagnose genetic or chromosomal disorders have increased rapidly in the last several years. These tests can be applied to carrier screening, preimplantation testing, prenatal screening, diagnostic testing, or newborn screening. In general, these tests can be classified into one of three categories:

- *Biochemical tests* evalute the proteins or enzymes produced by the genetic code, but not the genes themselves. Biochemical tests can be performed on maternal or fetal cells and may be used for screening or diagnosis purposes.
- *Cytogenic testing* examines the chromosomes to identify structrual abnormalities. The traditional karyotype cultures cells and stains the chromosomes to detect changes in structure. Fluorescent in situ hybridization (FISH) targets specific chromosomes to detect aneuploidy or smaller abnormalities such as deletions.
- *Molecular testing* is a direct analysis of DNA that detects small DNA mutations. Molecular DNA testing may use polymerase chain reaction (PCR)–based assays to amplify the DNA present. Chromosomal microarray analysis is a molecular DNA test applied to fetal cells to detect aberrations in chromosomal structure that may not be visible on a normal karyotype.

Carrier Screening

The purpose of carrier screening is to detect couples at risk for having a child with a genetic condition that is not evident in either of the parents. Carrier screening for autosomal dominant or autosomal recessive disorders is ideally performed preconceptionally, but often is first addressed during pregnancy.

Carrier screening can be performed for one disorder or multiple disorders at one time.[47] Specific carrier screening tests have traditionally been offered to individuals from racial and ethnic populations that have an increased prevalence of the disorder, a form of screening referred to as *ethnic-specific screening*. An ethnic-based screening strategy has multiple problems. For example, in today's multiracial society, it may be difficult to determine ethnicity. Furthermore, ethnicity does not identify all persons with an elevated risk and therefore, this screening strategy can miss many persons who would benefit from such testing. *Panethnic screening* refers to a strategy of offering carrier screening to all individuals regardless or race or ethnicity. Panethnic screening is an acceptable strategy.

New sequencing technologies have created the ability to screen for large numbers of conditions simultaneously. Nevertheless, such *expanded carrier screening* also has several unresolved problems. Many of the conditions covered by expanded carrier screening panels vary greatly in the expressed phenotype or disability, so counseling women about results can be quite complex. In addition, some of the expanded carrier screening panels screen for conditions that are rare and for which diagnostic tests are not well established. Furthermore, different commercially marketed panels screen for different disorders. Current professional association guidelines recommend ethnic-specific, panethnic, or expanded carrier screening. Factors such as severity of condition, prevalence carrier frequency, detection rates, and residual risk following screening results as described in **Table 20-10** contribute to the choice of screening strategy.[47]

Table 20-10 Carrier Screening

Disorder	Indications	Clinical Considerations
Ashkenazi Jewish population, prevalent conditions: Tay–Sachs disease, cystic fibrosis, Canavan disease, familial dysautonomia, Niemann–Pick (type A), Bloom syndrome, Fanconi anemia group C, mucolipidosis IV, Gaucher disease	Ashkenazi Jewish population	
Cystic fibrosis	Offer screening to all women of reproductive age	
Hemoglobinopathies	African ancestry Mediterranean ancestry Southeast Asian ancestry	African ancestry: Perform hemoglobin electrophoresis. Mediterranean or Southeast Asian ancestry: If anemic and mean corpuscular volume < 80 fL, evaluate for iron deficiency. Perform hemoglobin electrophoresis if iron studies normal.

		Southeast Asian ancestry: If hemoglobin electrophoresis is normal, perform molecular testing for alpha-thalassemia.
Fragile X syndrome	Individuals with a family history of intellectual disability or unexplained developmental delay, autism, or primary ovarian insufficiency	Offer genetic counseling for persons with a family history.
Spinal muscular atrophy	Offer screening to persons with a family history of spinal muscular atrophy[a]	Offer genetic counseling for persons with a family history.
Tay–Sachs disease	Ashkenazi Jewish ancestry French Canadian ancestry Cajun ancestry	

Based on Edwards JG, Feldman G, Goldberg J, et al. Expanded carrier screening in reproductive medicine: points to consider: a joint statement of the American College of Medical Genetics and Genomics, American College of Obstetricians and Gynecologists, National Society of Genetic Counselors, Perinatal Quality Foundation, and Society for Maternal–Fetal Medicine. *Obstet Gynecol*. 2015;125(3):653-662.[47]

Screening Tests

There are several time points during pregnancy at which specific screening and diagnostic tests can be performed so that the most accurate results can be obtained. The decision whether to engage in any testing is always the individual woman's choice. The midwife's role is to provide as much information as needed to facilitate an individual's decision making about what is personally best, as well as best for the family. **Table 20-11** provides a comprehensive list of both screening and diagnostic tests for the most common congenital disorders, including the appropriate timing for tests that are regularly offered in the United States, as well as some that are expected to be adopted soon.[48]

Table 20-11 **Prenatal Screening and Diagnostic Tests Currently Available**

Gestational Age When Test Is Performed	Test	Testing Available for These Conditions			
		Aneuploidy	NTDs	Genetic Mutation	Congenital Anomalies
First-Trimester Screening					
10–14 weeks	Ultrasound: nuchal translucency (thickness)	✓			✓
10–14 weeks	Maternal serum: PAPP-A and hCG	✓			
10+ weeks	cfDNA (maternal serum)[a]	✓			
Second-Trimester Screening					
15–23 weeks (optimal at 18 weeks)	Ultrasound: anatomic examination	✓	✓		✓
15–18 weeks	Maternal serum: multiple marker (quad): AFP, hCG, uE3, and inhibin-A	✓	✓		
Integrated screening	Combines first- and second-trimester screening as a comprehensive risk assessment	✓	✓		✓
Sequential	First-trimester screening, followed by second-trimester screening, as desired, based on first-trimester results	✓	✓		✓
Anytime	cfDNA (maternal serum)[a]	✓			
First-Trimester Diagnostic Tests					
10–14 weeks	CVS For karyotype and/or direct DNA[b] and cytogenetic (chromosomal)[c] testing	✓		✓	
Second-Trimester Diagnostic Tests					
15–22 weeks	Amniocentesis for karyotype and/or direct DNA[b] and cytogenetic[c] testing, and amniotic fluid AFP level	✓	✓	✓	
Anytime Prepregnancy or During Pregnancy (for parents), Newborn, and Children					
Direct diagnostic testing for an individual (i.e., DNA[b] for autosomal recessive carrier status, cytogenetic[c] testing)	Blood, saliva, and skin cells from parents prior to or during pregnancy, or in the newborn or siblings	✓		✓	

Abbreviations: AFP, alpha-fetoprotein; cfDNA, cell-free DNA; CVS, chorionic villus sampling; DNA, deoxyribonucleic acid; hCG, human chorionic gonadotropin; NTDs, neural tube defects; PAPP-A, pregnancy-associated plasma protein A; uE3, unconjugated estriol.

[a] cfDNA, often referred to as noninvasive prenatal testing (NIPT), is the most recently developed screening test for trisomy 21, 18, and 13, sex chromosome aneuploidy, and some microdeletions.

[b] DNA testing for genetic deletions, insertions, rearrangements, duplications, and other mutations can be accomplished using laboratory techniques, such as polymerase chain reaction (PCR) DNA amplification, hybridization of labeled probes to DNA, and microarray analysis, among others.

[c] Cytogenetic (chromosomal) structural aberrations, including microdeletions and aneuploidy, can be identified by karyotyping, chromosomal banding, fluorescence in situ hybridization (FISH), chromosomal microarray, and comparative genomic hybridization (CGH).

Historically, women who were younger than 35 years were offered screening tests and women older than 35 years were offered screening or diagnostic tests based on their higher baseline risk for trisomy 21. Currently, it is recommended that both screening and diagnostic testing be offered to all pregnant women, regardless of age or risk factors present.[49] This recommendation was made in light of the low-risk, reliable, noninvasive methods currently available, as well as the belief that all women should have a choice in testing—not just women with risk factors.

First-Trimester Screening for Aneuploidy

Screening for aneuploidy—particularly trisomy 21, 18, and 13—can be done in the first trimester and is best performed between 10 and 14 weeks' gestation. **Table 20-12** reviews the detection and false-positive rates of currently available screening and diagnostic tests for aneuploidy.[48] Risk for aneuploidy can be determined by measuring maternal serum levels of PAPP-A and hCG (expressed as multiples of the median) in relation to maternal weight and age, and gestational age. Generally, an increased risk of trisomy 21 is associated with lower PAPP-A levels and higher hCG levels.[39]

Table 20-12 **Detection and False-Positive Rates for Currently Available Prenatal Tests for Aneuploidy**[a]

Test	Detection Rate[b] % (trisomy type)	False-Positive Rate[c] % (trisomy type)
First-Trimester Screening		
NT alone	68 (trisomy 21)	5 (trisomy 21)
	68 (trisomy 18)	0.5 (trisomy 18)
	72 (trisomy 13)	
Maternal serum markers alone	67 (trisomy 21)	5 (trisomy 21)
	80 (trisomy 18)	0.5 (trisomy 13 and 18)
	59 (trisomy 13)	
Combined NT measurement and maternal serum markers	90 (trisomy 21)	5 (trisomy 21)
	97 (trisomy 18)	0.5 (trisomy 13 and 18)
	84 (trisomy 13)	
Second-Trimester Screening		
Maternal serum markers alone (quad)	80 (trisomy 21)	5 (trisomy 21)
	70 (trisomy 18)	0.2 (trisomy 13 and 18)
	19 (trisomy 13)	2–5 (ONTD)
	75–90 (ONTD)	
	95 (anencephaly)	
Anatomic US alone	73 (trisomy 21)	4 (trisomy 21)
	93-100 (trisomy 18)	4 (trisomy 18)
	90-100 (trisomy 13)	0.5 (trisomy 13)
Maternal quad screen and US	83 (trisomy 21)	5 (trisomy 21)
	100 (trisomy 18)	0.4 (trisomy 18)
	100 (trisomy 13)	0.5 (trisomy 13)
Integrated Screening		
First- and second-trimester maternal serum *without* NT	86 (trisomy 21)	2 (trisomy 21)
	86 (trisomy 18)	0.5 (trisomy 13 and 18)
	49 (trisomy 13)	
First- and second-trimester maternal serum *with* NT	95 (trisomy 21)	4 (trisomy 21)
	92 (trisomy 18)	0.5 (trisomy 13 and 18)
	72 (trisomy 13)	
CVS	98 (aneuploidy)	< 0.04
Amniocentesis	99.5 (aneuploidy)	< 0.04
	96–99 (ONTD)	2 (ONTD)
Fetal Cell-Free DNA[d]	99 (trisomy 18 and 21)	0.3–1 (overall)
	92 (trisomy 13)	
Direct DNA Testing	99.9	< 0.04
Saliva, blood, placental, or skin cell sample for identification of genetic mutation and carrier status		

Abbreviations: CVS, chorionic villus sampling; DNA, deoxyribonucleic acid; NT, nuchal translucency (thickness); ONTD, open neural tube defects; US, ultrasound.

[a] Detection and false-positive rates can vary depending on population risk and the risk cut-off used in testing.
[b] Detection rate reflects test sensitivity—that is, the "accuracy" or ability of a test to correctly identify those who have a disorder.
[c] False-positive rate reflects test specificity—that is, the ability of a test to correctly identify those who do not have a disorder.
[d] Fetal cell-free DNA, frequently referred to as noninvasive prenatal testing (NIPT).

Reproduced with permission from Latendresse G, Deneris A. An update on current prenatal testing options: first trimester and non-invasive prenatal testing. *J Midwifery Womens Health*. 2015;60(4):360-371.[48] © 2015, with permission from Wiley.

Increased risk for aneuploidy can also be calculated during ultrasound measurement of nuchal translucency between 10 and 14 weeks' gestation. More than 3 mm of fluid retention in the nuchal fold is associated with an increased risk of trisomy 21, other aneuploidies, and perhaps other defects, such as heart defects, diaphragmatic hernias, skeletal dysplasia, and a variety of genetic syndromes.[38,50] Absence of the fetal nasal bone is also associated with trisomy 21; thus, some facilities include ultrasound assessment of the nasal bone.[39]

Fetal cell-free DNA (cfDNA) testing, often referred to as noninvasive prenatal testing

(NIPT), is a recent screening option for identification of trisomies 13, 18, and 21, and sex chromosome aneuploidy. This test has become widely available since its introduction in 2011.[51,52] Testing of cfDNA involves collection of maternal blood any time after 10 weeks' gestation; this blood contains small fragments of circulating cell-free fetal DNA. The test amplifies the fetal DNA and makes it possible to identify the extra genetic material that exists when aneuploidy is present in the fetus.[45] Some laboratories include testing for a few chromosomal microdeletions, but the performance of these tests is of concern.[53] Because cfDNA is a screening test rather than a diagnostic test, it is recommended that any positive result be followed with CVS or amniocentesis to confirm diagnosis.[53]

Although the trisomy 21 detection rate with cfDNA (99%) nearly matches that of CVS (98%) and amniocentesis (99.5%), the positive predictive value (PPV) is important to note. For example, a 25-year-old woman with a positive cfDNA test has a 33% chance of having a fetus with trisomy 21, whereas a 40-year old woman with a positive cfDNA test has an 87% chance of having a fetus with trisomy 21. The PPV is much lower in cfDNA testing for trisomy 13 and 18. Because of this wide variance in PPV, the American College of Obstetricians and Gynecologists (ACOG) does not currently recommend routinely offering cfDNA testing to pregnant women considered at low risk for aneuploidy.[53] Nevertheless, many other sources advocate that all women, regardless of risk status, should have this option among those already available to them, such as first- and second-trimester maternal serum markers and ultrasound, as well as invasive chorionic villus sampling (CVS) and amniocentesis.[54] Some predict that, given the rapidly advancing technology, cfDNA will be used as a noninvasive diagnostic test in the not too distant future, and will likely include full genomic testing of the embryo/fetus for genetic mutations and all chromosomal abnormalities.[54]

Second-Trimester Testing

Screening for aneuploidy and NTDs in the second trimester currently includes measurement of several markers in maternal serum. Commonly referred to as a maternal serum, multiple marker, or quad screen, this test includes the measurement of maternal serum levels of alpha-fetoprotein, uE3 (unconjugated estriol), human chorionic gonadotropin, and inhibin-A. The last three of these markers are hormones produced by the placenta and secreted into the maternal circulation. In contrast, AFP is a protein made by the fetus. The MSAFP test has been in use longer than the other tests included in the quad screen. Fetal cell-free DNA testing also can be conducted at any time during the second trimester.

Screening options over the past 20 years have moved rapidly from a single serum marker test (MSAFP) to the addition of other markers as multiple markers were recognized as more effective in detecting abnormalities; they also decrease the risk of false-negative results compared to a single marker.[55]

Integrated, Combined, or Sequential Prenatal Testing for Aneuploidy

First- and second-trimester screening can be combined (ultrasound and maternal serum markers) in an effort to improve the ability to detect trisomy 21 and other trisomies.[33,48]

Results can be calculated and returned to the pregnant woman after all testing has been completed (i.e., integrated/combined), or after each trimester's results are known (i.e., sequentially). Calculation of the risk that the fetus has trisomy 21 after all test results are known, however, would preclude the woman's choice to have a CVS, if diagnostic testing is indicated. In contrast, the sequential screen calculates risk based on first-trimester screening tests and returns the results to the woman before proceeding with further screening tests. One advantage of a sequential screen is that a woman and her prenatal care provider can decide whether to continue with the second-trimester screening or to proceed with diagnostic testing (CVS or amniocentesis) if the first-trimester results indicate high risk for chromosomal abnormalities.[39,56]

Diagnostic Tests

Diagnostic procedures for aneuploidy and direct DNA genetic testing include chorionic villus sampling and amniocentesis. The screening and diagnostic tests performed on fetal cells following CVS or amniocentesis are briefly described in **Table 20-13**.

Table 20-13 Screening and Diagnostic Tests Performed on Fetal Cells

Test	Description	Results	Clinical Considerations
Karyotype	Cytogenic test Metaphase analysis of cultured cells	All aneuploidies and chromosome abnormalities that are larger than 5–10 megabases	Diagnostic test Relies on culture so results are not available for 7–14 days May not detect mosaicism
Fluorescence in situ hybridization (FISH)	Cytogenic test Fluorescent-labeled probes identify specific chromosomes Performed on uncultured cells	Tests chromosomes 13, 18, 21, X, and Y May detect deletions if a probe for a specific deletion is requested	Considered a screening test because the test can be falsely positive or falsely negative Results are available in 2–3 days
Chromosomal microarray (CMA)	Molecular DNA Performed on cultured or uncultured cells to detect copy number variants	Detects aneuploidy, unbalanced translocations, microdeletions, and microduplications	Results available in 3–5 days Primary test for women who have amniocentesis following detection of structural anomaly on ultrasound; approximately 6% of fetuses that have a normal karyotype will have a chromosomal abnormality detected by CMA

First-Trimester Diagnostic Testing

Chorionic villus sampling entails collection of placental tissue between 10 and 14 weeks' gestation, transcervically or transabdominally, and completion of karyotyping for detection of aneuploidy using the placental tissue. Other technologies besides the karyotype may be required to detect smaller chromosomal abnormalities, such as microdeletions and translocations in the fetal cells obtained via CVS. Techniques such as fluorescent in situ hybridization (FISH), spectral karyotyping, and comparative genomic hybridization (CGH) can be used to examine chromosomal structure more thoroughly.

One advantage of CVS over amniocentesis is that it can be performed earlier in the pregnancy. This early testing allows more time to consider options and to make decisions including pregnancy termination, particularly if a woman desires to make those decisions before the pregnancy becomes known to others. The disadvantage of CVS is that it does not obtain amniotic fluid, which can be tested to detect the presence of a neural tube defect. The best screening for NTDs consists of MSAFP testing followed by measurement of AFP in amniotic fluid collected during an amniocentesis. The best diagnostic test for NTDs is

anatomic ultrasound examination of the fetus.

Figure 20-9A depicts collection of placental tissue for diagnostic testing, which should be performed by an obstetrician or maternal–fetal medicine specialist. A separate direct DNA test can be completed to identify genetic mutations (e.g., Tay–Sachs disease, cystic fibrosis, hemophilia A, Huntington disease).

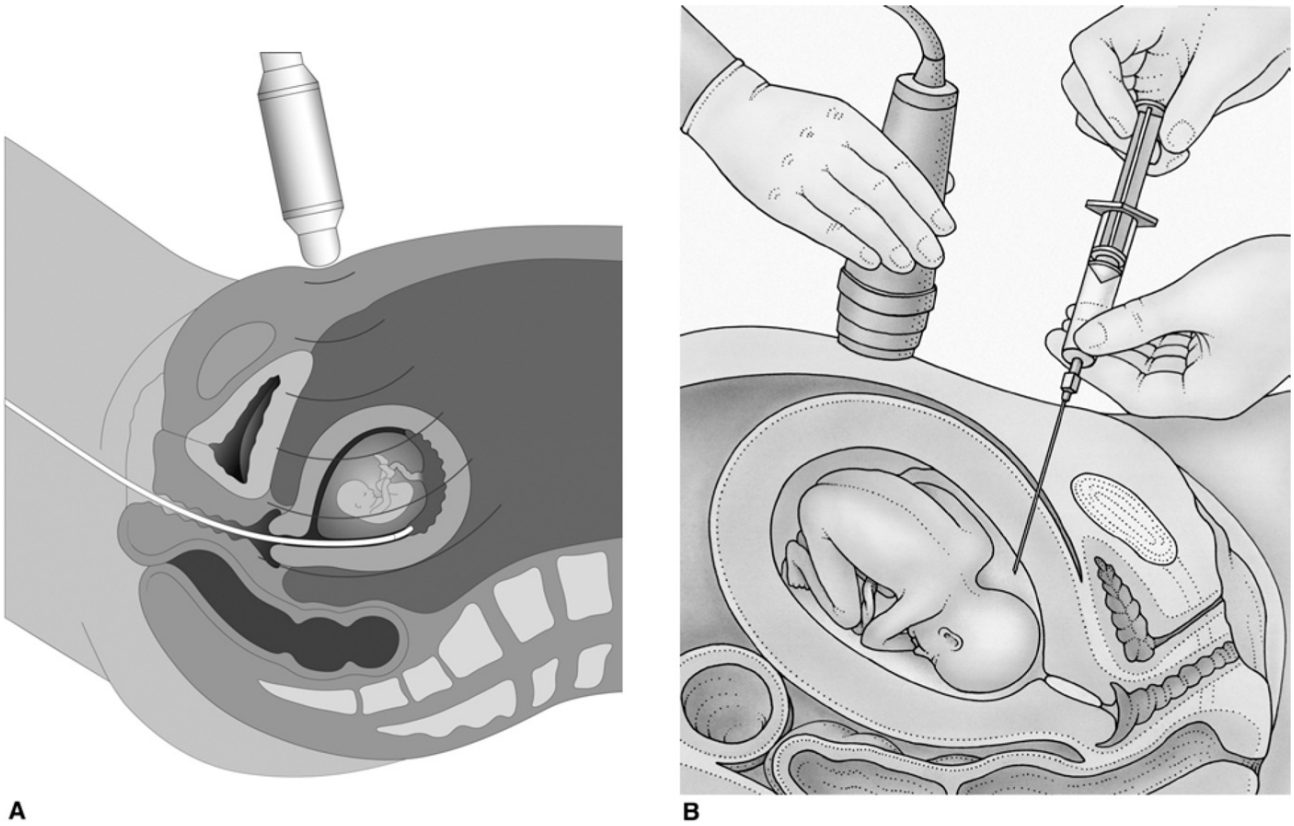

Figure 20-9 A. Transcervical chorionic villus sampling. **B.** Amniocentesis.

A. © Dorling Kindersley/Getty **B.** © Halli Verrinder/Getty

CVS is an invasive procedure that is associated with an additional 0.2% risk for miscarriage above the baseline risk of approximately 15% for an average pregnant woman at a similar gestation.[57] Furthermore, CVS is not performed prior to 10 weeks' gestation due to the documented risk of limb reduction birth defects among infants born to women who had CVS testing at an earlier gestational age. Transabdominal CVS is considered safer, technically less difficult, and more accurate than transcervical CVS.

Second-Trimester Diagnostic Testing

Diagnostic testing in the second trimester can be accomplished via amniocentesis, which entails inserting a fine needle through the woman's abdomen and into the uterus to collect a small sample of amniotic fluid (**Figure 20-9B**). Fetal cells are found in the fluid, separated, and usually grown in a culture medium until the chromosomes can be examined under a microscope. The final result is a fetal "G-banded" karyotype that is used to identify aneuploidies and other chromosomal derangements (**Figure 20-5A** provides an example of a

karyotype display.) As for CVS diagnostic testing, other technologies besides the G-banded karyotype may be required to detect smaller chromosomal abnormalities, such as microdeletions and translocations in the fetal cells obtained via amniocentesis.

Amniocentesis is usually performed at 16 to 18 gestational weeks of pregnancy and has an associated risk of pregnancy loss of approximately 1 in 1000 above the background risk for pregnancy loss less than 24 weeks' gestation.[57] Early amniocentesis (14–15 weeks' gestation) can be performed, but may be associated with a higher risk of pregnancy loss (approximately 1%).[58,59] Early amniocentesis may also be associated with a higher incidence of talipes (club foot) compared to CVS testing, although research has not confirmed this relationship. [58,59]

During a CVS or amniocentesis, direct DNA testing can be completed if warranted to identify genetic mutations in the fetus (e.g., Tay–Sachs disease, cystic fibrosis, hemophilia A, Huntington disease). If an individual chooses to have a diagnostic amniocentesis, an amniotic fluid AFP test can be completed at the same time to screen for NTDs.

Ultrasound

Ultrasound examination of the fetus during the second trimester is performed to establish gestational age and detect anatomic abnormalities such as NTDs and structural defects in the heart, kidneys, cranium/brain, and/or limbs. This examination is targeted to identify physical characteristics associated with aneuploidy phenotypes.[60,61] For example, ultrasound findings in a fetus that include an absent nasal bone, palmar creases, short femur, and echogenic bowel correspond to characteristics commonly found in the trisomy 21 phenotype.[60] Such findings would arouse suspicion for aneuploidy and prompt recommendations for further testing, such as diagnostic amniocentesis. Second-trimester anatomic ultrasounds are usually performed at approximately 20 weeks' gestation for best results.

Genetic Disorder Prevention and Risk Reduction

There are currently no cures for genetic disorders. However, there are some options and preventive approaches that can improve the outcomes for many women and their infants, of which midwives will want to be aware.

Excellent nutrition, including folic acid supplementation,[15] and avoidance of exposures to teratogens are two long-standing preventive strategies that are well known in most geographic areas of the world. Furthermore, many countries can offer genetic risk assessment and genetic testing to women and couples who are considering childbearing so that options can be considered before a pregnancy occurs. Indeed, some groups have taken it upon themselves to offer screening for carrier status of a genetic disorder specific to the population. For example, some Ashkenazi Jewish groups strongly encourage carrier status testing for Tay–Sachs disease prior to conception.

Unfortunately, many couples learn of hereditary disorders only after the birth of an affected child. In this situation, the midwife provides the family with accurate information and compassionate care. Preconception and postpartum testing for genetic disorders and carrier status can be obtained by families who have a child with a birth defect. This testing often provides answers to the questions most families have. Testing may be able to identify the specific disorder, as well as predict the risk for reoccurrence in subsequent children.

Moreover, options can be considered once a definitive answer is given. Options include the choice not to bear biological children, addition of future children via adoption, sperm and/or egg donation, and, in some countries, pre-implantation genetic testing. Pre-implantation testing involves in vitro fertilization (often with the sperm and/or egg from the prospective parents), genetic testing of a cell collected from the eight-cell blastocyst, followed by selection of only normal embryos for transfer into the uterus of the woman.[62] This method assures that only normal embryos without genetic disease mutations will be implanted. Some couples are delighted with this choice, whereas others are strongly opposed to this approach owing to religious or personal reasons; still others find the use of such technology too complex, too expensive, or too reminiscent of eugenics to consider it.[63]

When Genetic Disorders Are Identified

When genetic disorders are identified during pregnancy, parents have many questions and are in need of resources to help them deal with the situation. Helpful resources will vary depending on the setting and geographic area, and cultural, societal, family, and personal beliefs. Women may choose to enlist their families, religious leaders, or mental health counselors for direction and support, and may desire access to medical resources and options, where available. Midwives can be a valuable resource for women who need additional information and discussion of options, and for referrals to other healthcare providers such as geneticists and genetics counselors. If available, women may need and want additional information obtained from a referral to a maternal–fetal medicine physician or neonatologist. If the woman has an established relationship with a midwife, it may also be helpful for her to meet again with the midwife after she has met with and received input from other providers. Making decisions about how to proceed can be emotionally wrenching for women and their families.[45]

Pregnancy termination may be an option, depending on a woman's feelings, the gestational age, and local regulations and laws. Midwives can provide substantial assistance by offering nonjudgmental support and education about options and anticipatory planning.

Many women can continue with midwifery care during pregnancy and birth, in consultation or collaboration with other members of the healthcare team. Frequently, affected newborns will need immediate attention after birth, and arrangements for this care will need to be made in advance, including the site for the birth. Many proponents of prenatal testing believe that the biggest value in testing lies in the ability for parents to access resources and make arrangements for the care of a special-needs child well in advance of the birth. In addition, many support networks exist to help families who have a child with a specific genetic disorder or birth defect, such as the National Down Syndrome Society. Whatever final decision is made, the midwife can be instrumental in supporting a woman and directing her and her family to the best resources.

Financial, Ethical, Legal, and Social Issues in Genetics

Along with the rapid increase in genetic knowledge and technology came the need to address a myriad of financial, ethical, legal, and social issues, collectively referred to as FELSI. The World Health Organization (WHO) has proposed international guidelines regarding ethics in genetic testing, including in developed countries.[64] These guidelines include respect for the autonomy of individuals, beneficence, nonmalfeasance, and justice in provision of genetics-related services. The WHO guidelines are clear that genetic testing can have a profound impact on women and their families. Thus, confidentiality and privacy, the right for persons to receive sufficient information about testing and treatment, and individual autonomy to make decisions about testing and treatment, regardless of geographic area, socioeconomic status, ethnic background, religion, or belief system, are emphasized. Midwives have an obligation to understand and act on the principles related to FELSI, including a duty to fully inform women, offer appropriate testing when available, and refer women and families to additional resources such as genetic counselors or geneticists when their own professional or personal limitations have been reached. Some of the more common FELSI concerns and questions are listed in **Table 20-14**.[65]

Table 20-14 Common Financial, Ethical, Legal, and Social Concerns in Genetic Testing

Disparities in access to genetic resources due to lack of health insurance coverage, inability to pay, low-income economy, other competing priorities in healthcare needs, or geographic location
Distributive injustice (some populations benefit but not others)
Religious and cultural beliefs and perceptions about genetic risk, decision making, health and disease, family, privacy, authority, invasive procedures, childbearing, influence over life events, and use of alternatives to Western medicine
Racial and ethnic discrimination
Cultural factors that may impact accuracy or interpretation of family history information
Privacy and confidentiality
Discrimination or stigmatization by others based on genetic information
Judgment about family genetic history (Is it good or bad?)
Sensitive issues encountered, such as previously undisclosed adoption, rape, incest, misattributed paternity, substance abuse, mental illness, and ethnic origins
Stigma and legality of consanguinity
When or if relatives (who may not want to know) should be informed about an individual's genetic testing results
Implications of family history information and genetic testing results
The negative impact of false-positive test results
The ethical question of testing for disorders that have no cure or treatment
Eugenics
Pregnancy termination
Cost-effectiveness: the high cost of genetic testing versus the possibility of improved health outcomes
Denial of health insurance or employment based on genetic test results[a]

[a] The Genetic Information Nondiscrimination Act of 2008 (GINA) is a federal law that prohibits discrimination in health coverage and employment on the basis of genetic information including genetic test results.

Based on The New York – Mid-Atlantic Guide for Patients and Health Professionals. Ethical, legal, and social issues. In: *Understanding Genetics: A New York, Mid-Atlantic Guide for Patients and Health Professionals.* Washington, DC: Genetic Alliance; July 8, 2009. Available at: https://www.ncbi.nlm.nih.gov/books/NBK115574/. Accessed February 21, 2017.[65]

Future Trends in Genetic Testing

Expanded carrier testing is an approach that can identify a greater number of diseases, and is applied across all ethnic groups, regardless of risk status.[66,67] The availability of expanded carrier testing is rapidly expanding, with such testing increasingly being offered to women and couples in the preconception and early pregnancy periods. Testing for more than 100 autosomal recessive disorders is now readily available in the United States. Nevertheless, expanded carrier screening is not yet recommended for all women.

Direct-to-consumer (DTC) genetic testing is also widely available.[68] The harms and benefits of DTC genetic tests are the subject of debate. Proponents argue that provision of such testing options empowers people by increasing their knowledge about their own health and the genetic basis of their health. Others are concerned that many people have low health literacy, particularly regarding genetic information, and may not be able to interpret or emotionally process these tests without the assistance of trained healthcare personnel.[56] Although some countries and locations have adopted an over-the-counter approach in making the tests freely available, others have banned DTC genetic testing.[69-71]

Where available, individuals can purchase noninvasive DTC tests, including expanded carrier testing from commercial enterprises if they would like to determine, for example, the presence of genetic mutations for heritable disorders, including those that indicate carrier status and susceptibility to multifactorial diseases. Some tests are targeted to pregnant women and couples who would like to determine carrier status for specific genetic and chromosomal disorders, paternity, or the sex of the fetus prenatally. Samples (usually saliva/cheek swab or blood spot via finger stick) are collected in the privacy of one's home and returned to the commercial testing facility. This step may not require the services of a healthcare intermediary, such as the midwife, obstetrician, or family practice provider, although some tests do. One advantage of DTC testing is that it enables potential parents to test for carrier status prior to making the decision to attempt pregnancy. This approach raises the prospect of increasing use of preventive options for couples who want to avoid having a child with specific heritable disorders.[70,71]

Conclusion

In 1990, a collaborative project was begun among several public and private entities in the United States as well as governments and research centers in Europe and Japan with the goal of exploring genetics in more detail. The Human Genome Project focused on sequencing the DNA and mapping the more than 25,000 genes found in the entire genome of *Homo sapiens*. Although the Human Genome Project was completed in the early twenty-first century, applications of its findings and further investigation will continue for the foreseeable future.

In addition to knowledge being gleaned from the Human Genome Project, the body of information about non-Mendelian inheritance patterns has been growing for several years. For the midwife receiving a report of a CVS, amniocentesis, or direct DNA testing, the results usually are phrased in Mendelian terms (e.g., "autosomal recessive"). However, non-Mendelian inheritance patterns are emerging as potential important etiologies for some human genetic diseases. Among these are mitochondrial inheritance, which is a pattern exclusively from the maternal line; mosaicism, in which cells within the same person have different genetic makeup; and genomic imprinting, which occurs when a child receives only one "working" copy from one parent (instead of both) due to gene "silencing" by epigenetic mechanisms. Research continues into the variety of inheritance patterns because they may be of significant clinical relevance in the future.

This chapter has provided a foundation in genetics for midwives and has included several approaches for the provision of genetics-related healthcare services to women and families. The intention is to increase the confidence that midwives have when addressing prenatal genetic risk assessment, testing options, and decision making. Although genetics is considered a high-tech science, midwives have a talent for using low-tech tools to communicate potential risk, and screening and test results, to assist women and their families in shared decision making. Although most genetic disorders do not have a cure, prenatal genetic risk assessment, counseling, screening, and diagnosis have many potential benefits for individuals, including the ability to consider options, make well-informed decisions, access valuable resources, prepare for outcomes in advance, and ultimately optimize the health of women and newborns. Well-informed midwives can make valuable contributions to applications of genetic science to women's health care.

There are many excellent resources that can assist midwives and individuals for whom they care in obtaining additional information related to genetics. A selected list is included in the Resources section.

Resources

Organization	Description	Webpage
Genetics Competencies for Midwives		
Genetic Alliance	A nonprofit health advocacy organization. The website has multiple resources. Includes current recommended genomics competencies for nurses, genetic counselors, and physicians.	http://www.geneticalliance.org
	Understanding Genetics: A New York, Mid-Atlantic Guide for Patients and Health Professionals. This e-book includes a basic review of genetic disorders and tests. The appendix lists the National Coalition for Health Professional Education in Genetics (NCHPEG)'s Core Competencies in Genetics for Health Professionals.	https://www.ncbi.nlm.nih.gov/pubmed/23304754

APPENDIX

20A

Steps in Constructing a Three-Generation Pedigree

GWEN A. LATENDRESSE

© hakkiarslan/iStock/Getty Images Plus/Getty

1. Use standard symbols and notation for building the pedigree (**Figure 20A-1**).

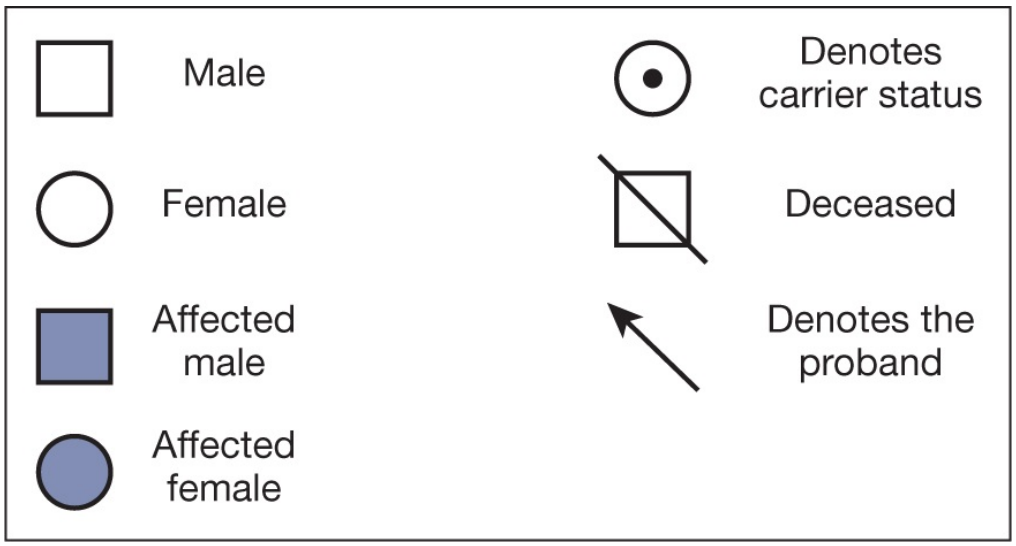

Figure 20A-1 Symbols used in constructing a three-generation pedigree.

2. Computer-generated pedigrees can be constructed, but a simple piece of paper works well.
3. For greater convenience, women can complete a genetic checklist or questionnaire or fill out a computer-generated (i.e., online) pedigree prior to the prenatal visit.
4. Collect information about the individual woman (often called the "proband") and her family members, including grandparents, parents, aunts and uncles, brothers and sisters, and any previous offspring.
5. Collect information about the father of the baby and his family members, including

grandparents, parents, aunts and uncles, brothers and sisters, and any previous offspring.

6. Identify any genetic "red flags" and mark affected relatives (i.e., use shading of symbols as appropriate).
7. List any health or medical conditions, or cause of death (if known), for each relative, along with the current age or age at time of death (if known) next to each corresponding relative on the pedigree.

An example of a three-generation pedigree is shown in **Figure 20A-2**. In this example, the 34-year-old woman is the proband. She has a 2-year-old daughter. Both she and her partner, who is the father of her daughter, are healthy. She has a sister who is healthy, one brother who has type 2 diabetes, and one brother who has a congenital heart defect. Her aunt died of cystic fibrosis at the age of 12.

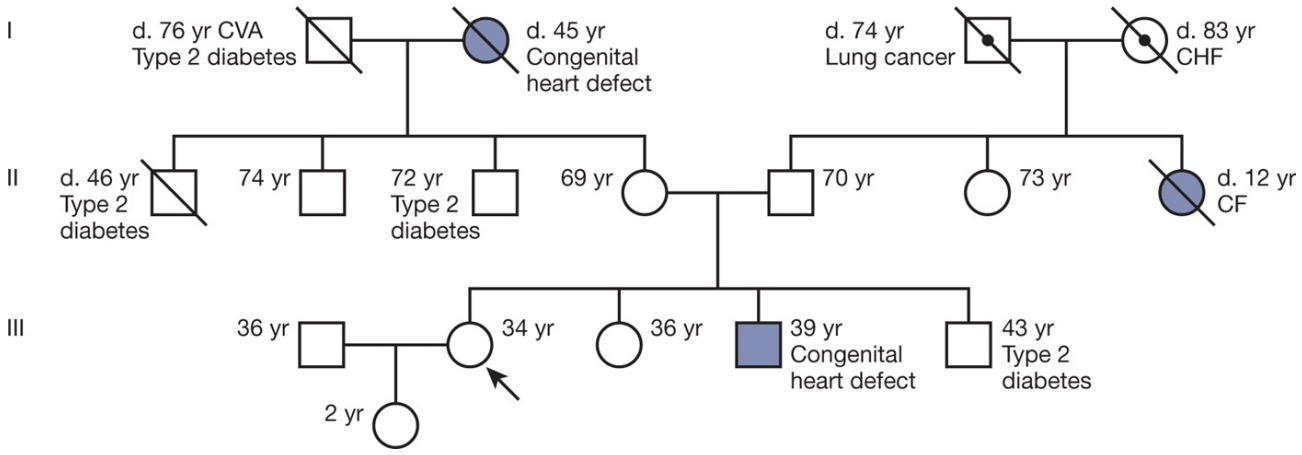

Figure 20A-2 Example of a three-generation pedigree.

Abbreviations: CF, cystic fibrosis; CHF, congestive heart failure; CVA, cardiovascular accident.

Introduction

Pregnancy is a time of role transition and identity change. Many aspects of primary care are integrated into prenatal care, along with evaluation of social support and referral to resources when needed. Guiding a person through the childbearing year with care that is safe, individualized, and ultimately empowering is one of the great joys of midwifery practice.

The goal of prenatal care is to optimize the health of the woman and developing fetus. The five basic components of prenatal visits, as established in a 1989 report by the U.S. Public Health Service, are (1) early and accurate identification of gestational age; (2) identification of the woman at risk for complications and ongoing risk assessment; (3) ongoing assessment of growth and well-being of the embryo/fetus; (4) health promotion in the form of counseling, education, and provision of resources; and (5) interventions and follow-up for existing physical and/or psychosocial illness and/or consultation with specialized providers as needed.[1]

This chapter reviews the essential components of routine prenatal care for women who have not been diagnosed with medical or pregnancy-related complications. The chapter is divided into six sections. The first section provides an overview of prenatal care, women's experiences of pregnancy, midwifery provision of prenatal care, and definitions of terms used. The second and third sections review the components of the first and return prenatal visits, including diagnosis and dating of pregnancy, prenatal history, physical examination, routine laboratory tests, and ultrasound evaluations. The fourth section discusses nutrition during pregnancy. The fifth section focuses on risk reduction topics that are covered over the course of prenatal care. The final section reviews preparation for birth. Detailed information about genetic counseling and screening tests can be found in the *Genetics* chapter. Management of the common discomforts of pregnancy and obstetric complications are reviewed in the *Pregnancy-Related Conditions* chapter. Medical complications of pregnancy are reviewed in the *Medical Complications in Pregnancy* chapter.

Overview of Prenatal Care

Organized prenatal care in the United States was introduced in the early twentieth century, initially as home visits conducted by public health nurses. The purpose of these visits, which occurred when the woman was 7 to 8 months pregnant, was to detect and prevent eclampsia using the newly invented sphygmometer.[2] By the 1960s, prenatal care had become a ritualized series of 9 to 12 individual visits conducted over the course of the pregnancy. Nevertheless, evidence of effectiveness for the individual components of prenatal care had not been established.

In 1989 and 2005, a U.S. Public Health Service Expert Panel conducted an analysis of the structure and content of prenatal care for the first time.[1,3] These reports recommended a total of 8 visits for nulliparous women and 6 visits for multiparous women, with an additional visit at 41 weeks' gestation for women with post-dates pregnancies. More recently, a 2015 Cochrane review of seven randomized controlled trials (RCTs) of more than 60,000 women evaluated standard prenatal care schedules versus a reduced number of visits and found that maternal and neonatal clinical outcomes were not different for selected low-risk populations, with the exception of a higher rate of perinatal mortality in women with a reduced visit schedule in low-resource countries.[4]

Most prenatal care providers in the United States have not adopted a decreased visit schedule, and most models of prenatal care include between 6 and 12 individual or group visits, depending on the timing of a woman's entry into prenatal care. A woman who is progressing normally through her pregnancy is typically seen every 4 weeks until 28 weeks' gestation, then every 2 weeks until 36 weeks' gestation, and then weekly until she gives birth.[5] When planning a schedule of care for an individual woman, her specific risk factors and her needs and concerns are the first consideration.

Effectiveness and Quality Measures in Prenatal Care

While prenatal care participation is medically and culturally accepted as important, limited evidence supports the effectiveness of prenatal care in the United States. Although women who access prenatal care have lower rates of preterm and low-birth-weight infants, it is not clear if prenatal care is responsible for these outcomes or whether healthier women are more likely to participate in prenatal care. This conundrum has haunted the research on the effectiveness of prenatal care, and the question remains unresolved. Despite significant expansion of prenatal care content over the last several decades, rates of negative birth outcomes such as low birth weight and preterm birth have remained elevated—especially among African American women.[6,7] Nonetheless, some authors argue that prenatal care should not be judged on the basis of specific birth outcomes per se, as longitudinal contact with the healthcare system provides the opportunity for numerous primary and secondary prevention strategies to be initiated. The body of prenatal care research has generally found that early entry into care and higher numbers of prenatal visits are positively correlated with better perinatal outcomes.[8] Furthermore, some medical interventions—in particular, those for preterm birth prevention and the detection of fetal anomalies—cannot be offered to women who first access prenatal care

after the first trimester. Racial and ethnic disparities with regard to the percentage of women who access prenatal care in the first trimester mirrors health disparities in maternal and neonatal outcomes.[7]

In summary, research to determine the effectiveness of individual components of prenatal care is lacking.[1,9] Innovations in the structure and content of prenatal care have been slow to emerge, although research related to nontraditional models of prenatal care—for example, group prenatal care, home visits, telemedicine, and reduced numbers of visits for low-risk women—suggests that these approaches hold promise to improve outcomes.

A Woman's Experience of Pregnancy

Pregnancy is a time of both biologic and social transformation. Just as each individual is different, so is each pregnancy. Prior to offering health education specific to pregnancy, it is important to understand the concerns identified by the woman. Most of the factors that influence the health and outcome of a woman's pregnancy are found outside the hospital or clinic walls. This section highlights a few of these factors that affect an individual's experience of pregnancy.

Social Determinants of Health

Social factors affecting pregnancy include housing, unemployment, food insecurity, exposure to environmental toxins, as well as racism, poverty, and discrimination of all kinds. The term *social determinants of health* (SDOH) refers the growing body of knowledge about how structural conditions in the places where people live and work affect health risks and health outcomes.[10] SDOH theory is increasingly being used in public health to help identify and reduce health disparities. It is also an excellent framework for exploring an individual's concerns in preparation for prenatal care education, counseling, and anticipatory guidance.

The Effects of Stress

The precise influence of stress on fetal development and pregnancy duration is poorly understood, although theories have linked chronic stress to poor health outcomes including preterm birth.[11,12] For example, African American adolescents and persons with a low income are at the greatest risk for poor perinatal outcomes; in addition, these individuals may experience a number of other conditions that independently adversely affect perinatal outcomes.[13-15] Moreover, an increasing body of evidence suggests that epigenetic mechanisms increasingly may mediate changes in fetal developmental programming through the hypothalamic–pituitary–adrenal axis, which controls the body's response to both acute and chronic stress.[14]

Stress during pregnancy may also exacerbate preexisting mental health conditions. The strongest risk factor for postpartum depression or postpartum mood disorder is a history of anxiety, depression, post-traumatic stress disorder, or other psychological illness during pregnancy.[15] Identification of prenatal mood disorders or severe acute or chronic stress during

prenatal care, followed by referral to mental health and social work resources as appropriate, is an important component of mental health support.

Individual Factors That May Adversely Affect Pregnancy Outcomes

Both younger maternal age and older maternal age affect the course of pregnancy. Young women, for example, are more likely have lower levels of education, finances, and social support. They are at higher risk for living in poverty, having depression, and being exposed to intimate-partner violence (IPV) than their peers who defer childbearing. Although adolescent pregnancy is associated with an increased risk for preterm birth and low birth weight, it is difficult to ascertain whether these outcomes occur secondary to a biologic age effect, socioeconomic status, or a combination of factors.[16]

Pregnancy can also be a more complicated and stressful experience for older women. As women age, fertility declines and the incidence of chronic illnesses increases. In addition, some chromosomal abnormalities are more likely to occur at the time of fertilization when a woman's eggs are older.

Prenatal care is unique with regard to the periodic pelvic examinations performed and the frequent reference to topics that impinge on sexual and gender identity. Women who have experienced sexual abuse or assault are at particular risk for feelings of vulnerability, stress, and loss of control during pregnancy.[17] Lesbian and bisexual women, transgender men, and gender-diverse individuals may all experience exacerbations of gender dysphoria during the physical changes of pregnancy or simply experience pregnancy in ways that are unique to that individual.[18],[19] To date, however, little research has been published regarding parental identity formation in transgender men and gender-diverse individuals.

Midwifery Provision of Prenatal Care

Midwifery has a long history and central role in the provision of prenatal care in the United States. Although studies have not demonstrated the effectiveness of prenatal care overall, several seminal studies have documented the effectiveness of midwifery-led prenatal care for specific populations.[20],[21] Midwifery care has shown demonstrable benefits in improving several pregnancy outcomes, including lower rates of preterm labor, decreased rates of low-birth-weight infants, increased access to care, and lower rates of morbidity and mortality.[20,21]

The benefits of midwifery care have been demonstrated internationally as well. For instance, in a review of 11 studies in four developed nations, which sought to compare midwife-led care with physician-led and shared care models of prenatal care, midwife-led care for low-risk women showed benefits in outcomes such as decreased prenatal hospitalization, decreased need for analgesia/anesthesia in labor, decreased number of operative deliveries, fewer episiotomies, and more breastfeeding initiation.[21] Midwifery care in underdeveloped nations has a well-recognized essential role in preventing adverse pregnancy outcomes.

Definitions

The prenatal period includes the time period that extends from the first day of the last normal menstrual period to the start of true labor, which marks the beginning of the intrapartum period. **Table 21-1** summarizes the nomenclature used to describe how many pregnancies (*gravida*, from the Latin word *gravidus*, which means "pregnant") and births (*para*, from the Latin word *parous*, which means "bringing forth or producing") a woman has experienced. It is important that the terms are used correctly with an accepted set of definitions.[22,23] The definitions listed in this chapter are those recommended in most texts. Because parity does not reflect all the possible outcomes of birth, a four-digit system, which encompasses term/premature/abortion/living (TPAL) outcomes, is used to better describe a woman's birth history.

Table 21-1 Nomenclature for Gravida and Para

Term	Definitions
Gravida	The total number of times a woman has been pregnant, regardless of whether the pregnancy resulted in a termination or if multiple infants were born from a pregnancy. A current pregnancy is included in the gravida count.
Nulligravida	A woman who has never been pregnant.
Primigravida	A woman who is pregnant for the first time.
Secundigravida	A woman who is pregnant for the second time.
Multigravida	A woman who has been pregnant more than twice.
Para	The number of times a woman has given birth to a fetus of at least 20 weeks' gestation (viable or not viable), counting multiple births as one birth "event."
Nullipara	A woman who has not remained pregnant beyond 20 weeks' gestation.
Primipara	A woman who has had one pregnancy in which the fetus or fetuses reached 20 weeks' gestation. This woman has given birth once.
Multipara	A woman who has had two or more pregnancies in which the fetus or fetuses reached 20 weeks' gestation. This woman has given birth more than once (counting multiple births as one birth "event").
Gravida/para 2-digit nomenclature	Notation of gravida and para status is essential to describe a woman's reproductive history and status. G2P0: A woman who has been pregnant twice and no births. She may have had abortions or miscarriages. G2P1: A woman who is currently pregnant. She has had one prior pregnancy that resulted in an infant born at 38 weeks' gestation.
Gravida/para TPAL 4-digit nomenclature	**Term (T):** The number of term births the woman has experienced. Term refers to any gestation of 37 completed weeks or more. **Preterm (P):** The number of preterm births the woman has experienced. Premature in this system refers to any infant born between 20 and 37 completed weeks' gestation. **Abortions (A):** The number of pregnancies ending in abortion (either spontaneous or induced). Abortion refers to any fetus delivered before 20 weeks' gestation. **Living (L):** The number of children currently living. Examples: G3 P2002: A woman who is currently pregnant with her third pregnancy. She gave birth to a full-term baby with each prior pregnancy, both of whom are living. G2 P0101: A woman who is currently pregnant. She gave birth to one preterm infant and has

one live child.

G3 P1103: A woman who is currently pregnant with her third pregnancy. She gave birth to one full-term infant and preterm twins. All three offspring are alive.

Gestational Age Versus Embryonic Age

Fertilization takes place during or shortly after ovulation, which is usually about 14 days before the next menstrual period, assuming a 28-day menstrual cycle. Therefore, gestation is approximately 266 days—that is, 38 weeks—in length after fertilization.[24] Women are not usually aware of the date of fertilization, but they typically do know the date their last menstrual period started. Thus, historically, a woman's due date has been calculated as 40 weeks (280 days) after the first day of her last menstrual period. The terms "gestational age" and "weeks' gestation" are used to refer to the number of weeks subsequent to the last menstrual period. The mean gestational age (i.e., menstrual age) for spontaneous labor in primigravid women is 41 weeks from the last menstrual period (287 days), or 40 weeks 3 days (283 days) for the multiparous woman.[24] Estimates based on pooled data are consistent with this finding and suggest that the mean menstrual age for pregnancy is 283 to 284 days.[24]

The study of embryology prefers language referring to "embryonic age," "postconceptional age," or "ovulation age," which more precisely reflects the age of the embryo or fetus. A postconceptional age differs from a gestational age by 2 weeks. When reviewing information about embryonic development or exposure to teratogenic agents, the type of calendar weeks being used—gestational or postconceptional—needs to be confirmed to avoid confusion.

Trimesters

The prenatal period is divided into three trimesters that each consist of 12–13 weeks or 3 calendar months. In practice, the first trimester is considered to be weeks 1 to 12 (12 weeks) because organogenesis is completed at the end of 12 weeks and the risk for spontaneous abortion is significantly reduced at this time. Historically, the second trimester was considered to be weeks 13 to 28 because prior to the introduction of modern neonatal intensive care techniques, 28 weeks' gestation was the limit of viability. The third trimester extends from weeks 28 to 40. The term "post dates" or "post term" is typically used to describe a pregnancy that continues beyond 40 weeks.[24]

Estimated Due Date

For many years, the expected date of the end of pregnancy by birth of a full-term newborn was called the estimated date of confinement (EDC). While this term is still used in many settings, a number of healthcare professionals have changed it to estimated date of delivery or estimated due date (EDD). This change was introduced because of the perception that the word "confinement" connotes illness, limitation, and a passive role based on an archaic practice of isolating women in late pregnancy, rather than recognizing pregnancy as a normal event, a healthy process, with active participation. Although there is no national consensus regarding

the use of EDC versus EDD, the term EDD is used throughout this text.

Initial Prenatal Visit

The primary goal for an initial prenatal visit is to establish the diagnosis of pregnancy and gestational age. If a pregnancy is confirmed, the next step is to determine the woman's goals. Approximately half of all pregnancies are unintended, and a woman may present for prenatal care prior to making a decision about the pregnancy. A pregnant women has three possible choices: (1) to continue the pregnancy and parent the child, (2) to continue the pregnancy and give the infant to an adoptive family, or (3) to terminate the pregnancy, provided that the gestational age is within an allowable time frame for an abortion procedure to be performed.

A good starting point during any initial prenatal visit is to ask the woman open-ended questions to ascertain her own questions, concerns, and plans for the current pregnancy, and to listen carefully to the responses. Options counseling is reviewed in detail in the *Family Planning* chapter. If the woman is planning an ongoing pregnancy, the focus of an initial prenatal visit shifts to establishing the viability of the pregnancy, determining the gestational age of the fetus, detecting significant maternal conditions that could adversely affect the pregnancy, and planning the course of care.

Diagnosis of Pregnancy and Calculation of Gestational Age

The evaluation of pregnancy has three components: (1) confirm that the woman is pregnant, (2) establish a gestational age, and (3) determine whether the pregnancy is viable. Signs and symptoms of pregnancy have historically been categorized into presumptive, probable, and positive signs (**Table 21-2**). While differentiation between these categories is not typically clinically significant today, the importance of these categories remains conceptually important because presumptive and probable signs of pregnancy can be manifestations of other conditions. The two positive signs of pregnancy are ultrasound visualization of a pregnancy and auscultation of fetal heart tones.

Table 21-2	Signs and Symptoms of Pregnancy
Presumptive Signs of Pregnancy (Reported by a Woman in the History)	
Amenorrhea in a woman who previously experienced regular cycles	
Breast or nipple tingling, tenderness, and/or enlargement	
Fatigue	
Nausea and vomiting	
Quickening (perception of fetal movement)	
Pigmentation changes (e.g., chloasma, linea nigra)	
Sustained elevated basal body temperature (in the absence of infection)	
Urinary frequency	
Probable Signs of Pregnancy (Detected by Physical Examination or Laboratory Testing)	
Breast changes (e.g., expression of colostrum, enlargement of breasts and nipples)	
Enlargement of the abdomen	
Enlargement of the uterus	

Changes noted on the pelvic examination:
Ballottement: detection of the fetus bouncing against the uterine wall after the midwife sharply pushes on the uterus with an examining hand in the vagina; palpation technique for detecting a floating object in the body
Chadwick's sign: bluish discoloration of cervix, vagina, and labia due to vascularization
Goodell's sign: softening of the cervix
Hegar's sign: softening of the lower uterine segment
Piskacek's sign: asymmetric lateral bulge in the uterus
Palpable fetal outline or fetal movement
Palpation of uterine contractions
Positive pregnancy test
Positive Signs of Pregnancy (Confirms Pregnancy)
Sonographic evidence of pregnancy
Audible fetal heart tones

Hormonal Pregnancy Tests

Hormonal pregnancy tests are based on the presence of the beta subunit of human chorionic gonadotropin (beta-hCG) in serum or in urine. Beta-hCG is produced by the placenta in increasing amounts in early pregnancy. Levels of this hormone are higher in serum than in urine, so a serum test performed very early in pregnancy may detect a pregnancy when the urine test is still negative.

Urine Pregnancy Tests

Different commercially available urine pregnancy tests have varying sensitivity thresholds, but are usually intended to test positive when the beta-hCG level is approximately 20 to 50 mIU/L. This corresponds to approximately the date of the missed menses, at which time beta-hCG is detectable in urine. A great deal of discrepancy exists in the actual detection rates for specific commercial products.[25] Furthermore, the concentration of beta-hCG in urine can vary within the same woman throughout the day depending on fluctuations in urine concentration. For some women, the first urine of the day tests positive while subsequent voids will test negative.

Although there is little difference between commercially available home urine pregnancy tests and those performed in the clinical setting, there is considerable room for user error. As a consequence, the theoretical accuracy of home pregnancy tests is superior to the accuracy found in typical-use testing. Some reports indicate the typical-use sensitivity is as low as 75%. False-negative results are more likely if the test is performed prior to the first day of the expected menstrual period.[26] As many as 10% of viable pregnancies are not implanted in the uterus by the first day of the missed menstrual period and, therefore, would register as a false-negative pregnancy test if testing is done at that time.[26]

A positive pregnancy test does not confirm the viability of a pregnancy. The percentage of pregnancies that are detected very early and result in a spontaneous abortion has been found to range between 20% and 62%.[27] Women who carefully track their menses and use highly sensitive home pregnancy tests may detect very early "chemical pregnancies" that otherwise

would be noted as a late or missed menses.

Serum Pregnancy Tests

Serum pregnancy tests can detect the presence of beta-hCG either qualitatively or quantitatively. However, as reviewed in the *Anatomy and Physiology of Pregnancy* chapter, individual blood values at specific gestational ages are highly variable, such that a single quantitative serum beta-hCG value does not provide reliable information about the gestational age or viability of the pregnancy. Instead, the clinical utility of quantitative beta-hCG measurement is based on following trends in these measurements in early pregnancy. When the serum beta-hCG is at least 1500 to 2000 mIU/L, the value is within the clinical "discriminatory zone." Approximately 91% of women with a beta-hCG level higher than this range will have an intrauterine gestational sac visible if transvaginal ultrasound is performed. Once the beta-hCG level reaches 3500 mIU/L, 99% of pregnancies are visible on ultrasound.[28]

Serum values of beta-hCG increase exponentially in early pregnancy, doubling approximately every 1.5 to 3 days in the first 5 to 6 weeks, then doubling every 3 to 3.5 days in weeks 7 to 8, peaking at about 8 to 10 weeks' gestation, and then plateauing (**Table 21-3**).[29,30] However, there is a great deal of inter-individual variability in the rate at which hCG rises in maternal plasma. In viable embryos, the minimal rise over 2 days can as little as 53% rather than doubling.[31]

Table 21-3 **Discriminatory Levels of Human Chorionic Gonadotropin Levels and Ultrasound Findings by Gestational Age**[a]

Gestational Age in Weeks from Last Menstrual Period	Approximate beta-hCG Level (mIU/mL)	Ultrasound Findings
3–4 weeks	150–1000	Decidual thickening
4–5 weeks	> 1000–2000	Gestational sac visible with TVUS when beta-hCG is approximately 1000 mIU/mL, and detectable on abdominal ultrasound when beta-hCG is approximately 1800 mIU/mL
5–6 weeks	1000–7200	Yolk sac present when gestational sac is > 10 mm
		Embryo present when gestational sac is > 18 mm
		Cardiac activity present when crown–rump length is > 5 mm
6–7 weeks	> 10,800	Crown–rump length is 4–9 mm

Abbreviations: beta-hCG, beta subunit of human chorionic gonadotropin; TVUS, transvaginal ultrasound.

[a] Beta-hCG values are approximate. Each ultrasound department will have institutionally specific values that can be used to guide management.

Modified with permission from Snell BJ. Assessment and management of bleeding in the first trimester of pregnancy. *J Midwifery Womens Health.* 2009;54:483-491.[30] © 2009, with permission from Wiley.

Serial measurements of quantitative serum beta-hCG values repeated every 48 to 72 hours are often used in conjunction with an early ultrasound and other clinical data to help determine the presence and viability of an intrauterine pregnancy, rule out ectopic pregnancy, or follow

the decline when a spontaneous abortion has occurred. The *Pregnancy-Related Conditions* chapter reviews management of first-trimester spontaneous abortion, ectopic pregnancy, and *pregnancy of unknown origin* (the diagnostic term for the clinical scenario in which the serum beta-hCG is positive but the ultrasound does not detect a pregnancy in the uterus).

Establishing Gestational Age and Estimated Due Date

Accurate assessment of gestational age is one of the most important aspects of caring for a pregnant woman. Gestational age at the time for birth is the single most valuable predictor of newborn health. An accurate calculation of gestational age is necessary to appropriately select interventions for threatened preterm labor, to determine the adequacy of fetal growth, and to time the initiation of fetal surveillance or induction of labor. Conversely, incorrect estimation of the gestational age can lead to inappropriate timing for screening, misinterpretation of data, unnecessary intervention, or a failure to intervene when indicated. The opportunity for accurate assessment of gestational age decreases as the pregnancy progresses, and estimated due dates should not be recalculated after the second trimester. Several methods can be used to calculate the EDD, all of which have some variability.

Estimated Due Date by Last Menstrual Period

The date of the first day of the last menstrual period (LMP) is used as the baseline for an initial determination of gestational age and the EDD. However, use of LMP to determine gestational age has several limitations. The normal menstrual cycle is 21 to 35 days, with the mean being 28.4 days. Many women with longer or shorter cycles, however, may not ovulate 14 days after their last menstrual period. Similarly, there is variation in the timing of implantation of the embryo, which can occur 5 to 14 days after the estimated time of ovulation.[32]

While many women can accurately recall the date of LMP within 1 to 2 days,[29] the reported LMP can also be inaccurate. Some women do not keep a record of their menstrual periods, and others have a history of irregular cycles or amenorrhea despite having an ovulatory cycle. In addition, various medications, recent changes in weight, breastfeeding, and shift work are examples of factors that can change menses frequency and timing of ovulation.

Many women experience spotting in early pregnancy that may be perceived as a menstrual period. It is theorized that this bleeding, or spotting at the time of implantation of the blastocyst, is a result of the invasive activity of the chorionic villi in the endometrial lining.[33] Some recent studies, however, suggest that bleeding that occurs near the time of the expected menses is common but not directly connected to implantation.[34] In one large study, 27% of pregnant women experienced bleeding in the first trimester, typically between 5 and 8 weeks' gestation, which corresponded to the shift from luteal to placental hormonal dominance.[35]

Given the inexact nature of menstrual frequency, it can help to establish the date of the last *normal* menstrual period (LNMP) before estimating gestational age. The woman's description of her last menstrual period is compared to her description of her regular menstrual periods with regard to timing, duration, and flow. Supplemental information that can be used in conjunction with LNMP to improve the accuracy of the estimated due date includes coital

timing (inclusion or exclusion dates for exposure to conception), use (or not) of contraception (i.e., type, timing, consistency), and date(s), type, and result(s) of any home ovulation timing or pregnancy test that the woman has done prior to seeking prenatal care.

Naegele's Rule

Traditionally the EDD is initially calculated using Naegele's rule, which is based on the assumption of a 28-day menstrual cycle. Franz Karl Naegele, a German physician, authored a text in 1812 that contained the advice to estimate that a pregnancy would terminate approximately 40 weeks (280 days) after the first day of the last menstrual period.[36] Although this theory is not based on any modern concept of research and its accuracy has been questioned,[37,38] it remains widely used today and is the basis of many pregnancy calculators.

To use Naegele's rule, 7 days are added to the LMP and then 3 months are subtracted to obtain the EDD. For LMPs that occur after the first 3 months of the year, an additional year is added. Thus, the formula is the first day of LMP + 7 days – 3 months = EDD.

Use the actual number of days in the month of the LMP if adding 7 days crosses over to the next month. This is illustrated in the following example of calculating the EDD by Naegele's rule: If the LMP is May 28, then 5/28 + 7 days = 6/4 (May has 31 days) – 3 months = EDD is March 4 of the next year. Note that Naegele's rule does not account for the additional day in a leap year.

Estimated Due Date by Pregnancy Wheels and Apps

The pocket gestational wheel, which is traditionally used to calculate EDD and determine gestational age, calculates an EDD based on 280 days for the duration of gestation. Such gestational wheels are easy to use, but their calculated EDDs vary by 1 to 7 days.[38]

In many settings, the pocket wheel has largely been replaced by computer-based software. Most electronic health record systems used for prenatal care and obstetric ultrasonography include dating calculators, which allow the automatic calculation of an EDD. The electronic calculators that can be found on the Internet or as an app remove most of the margin of error associated with pregnancy wheels and arithmetic calculations.[38]

Artificial Reproductive Technology

When a pregnancy is conceived through artificial reproductive technology (ART), the date of insemination or embryo transfer is used instead of the LMP. A precise due date can be calculated using the date of insemination or and the date of embryo transfer.

First-Trimester Ultrasound

Calculation of gestational age and EDD based on ultrasound performed before 13 6/7 weeks is the most accurate method for dating pregnancy.[39] In maternity care, an ultrasound may be requested to provide a general or targeted assessment. The usual application of ultrasound in pregnancy is classified as one of three types of evaluation as described in **Table 21-4**.

Table 21-4 Ultrasound in Pregnancy

Type of Ultrasound	Description
Standard ultrasound	Often referred to as an anatomy ultrasound, this examination provides fetal biometry needed to confirm gestational age and is simultaneously able to detect most major morphologic malformations prior to the time that the fetus would be viable if born. A standard ultrasound identifies gestational age, fetal number, fetal biometry, amniotic fluid volume, cardiac activity, placental position, placental localization, and complete assessment of fetal anatomy. Maternal adnexa and cervix including cervical length are usually included. Cervical length may be an included component of the standard examination. The standard ultrasound is offered to all pregnant women between 18 and 20 weeks' gestation.
Limited ultrasound	Performed for a specific indication and is not considered a replacement for the routine standard ultrasound. Components of a limited examination may include assessment of gestational age, embryonic or fetal viability, confirmation of fetal heart activity, identification of number of fetuses, confirmation of fetal presentation and position, determination of placental location, determination of amniotic fluid volume, fetal well-being and cervical length. A limited ultrasound may be done in any trimester and may be done in the office setting. Midwives may acquire advanced skills in performing limited ultrasounds in accordance with American College of Nurse-Midwives guidelines.
Specialized or targeted ultrasound	A specialized ultrasound is ordered when an anomaly is suspected based on a woman's history, laboratory results, or abnormal findings on a standard ultrasound. Additional technology can be utilized for specific purposes. For example, fetal echocardiogram can be used to accurately diagnose cardiac malformations. Fetal Doppler velocimetry is used to evaluate maternal-fetal blood flow particularly in cases of fetal growth restriction, multifetal gestations, severe maternal hypertension and placental abnormalities. A specialized ultrasound is performed/reviewed by physicians trained in the technology—typically maternal fetal medicine or specialist radiologists.

First-trimester ultrasound is used to confirm LMP dating or to establish the gestational age for pregnant women without a known LMP. The most accurate first trimester ultrasound measurement for determining gestational age is the crown–rump length measurement. This dating method can reduce the number of inductions of labor for post-dates pregnancies and has been shown to be cost-effective in most developed nations.[39,40] If the difference between the ultrasonographic and LMP due dates is more than 5 to 7 days, the ultrasound-calculated EDD will be used. The recommendations for changing due dates based on LMP and ultrasound dating discrepancies are presented in **Table 21-5**.

Table 21-5 Guidelines for Establishing Estimated Due Date Based on Last Menstrual Period and Ultrasound Discrepancies

Gestational Age Range Based on LMP	Ultrasound Measurements Obtained	Number of Days Difference Between LMP and Ultrasound Dates That Supports Use of Ultrasound Dating
≤ 8 6/7	CRL	> 5 days

9 0/7 to 13 6/7	CRL	> 7 days
14 0/7 to 15 6/7	BPD, HC, AC, FL	> 7 days
16 0/7 to 21 6/7	BPD, HC, AC, FL	> 10 days
22 0/7 to 27 6/7	BPD, HC, AC, FL	> 14 days
28 0/7 and beyond	BPD, HC, AC, FL	> 21 days

Abbreviations: AC, abdominal circumference; BPD, biparietal diameter; CRL, crown–rump length; FL, femur length; HC, head circumference; LMP, last menstrual period.

Modified with permission from American College of Obstetricians and Gynecologists. Committee Opinion No. 700: methods for estimating the due date. *Obstet Gynecol*. 2017;129:e150-e154.[37]

Second-Trimester Ultrasound

Second-trimester ultrasound estimates of fetal age are based on composite measurements of the fetal head circumference, biparietal diameter, and femur length, as well as the woman's abdominal circumference.[37] These estimates are slightly less accurate than first-trimester ultrasound gestational age determinations because there is more individual variation in fetal growth and development as pregnancy progresses.

Less Reliable Methods of Dating Pregnancy

Although uterine size correlates positively with gestational age, fundal measurement is a less reliable predictor of EDD than the LMP.[41,42] Clinical assessment of uterine size may be affected by distension of the bladder (up to 7 cm), maternal adipose deposition,[41] retroversion or retroflexion of the uterus, presence of fibroids, uterine anomaly, position and presentation of the fetus, amniotic fluid volume, and clinician experience.[42] Measurement of the uterine fundal height above the symphysis to monitor fetal growth is a standard component of prenatal care. The use of fundal height measurements is reviewed in detail in **Appendix 21A**.

Other indicators such as the onset of quickening, along with the clinician's notation of first detection of fetal heart tones by ultrasound or fetoscope or the client's signs and symptoms of pregnancy, are poor predictors of gestational age but may be supportive data if reliable dating is not available. In women in whom the fetal heart tones have been detectable via a Pinard stethoscope for at least 21 weeks, approximately 90% will be at least 38 weeks' gestation. Similarly, when fetal movement has been detected for at least 25 weeks, it is 90% certain that the woman is at least 38 weeks' gestation. Although these measures are helpful in predicting the presence of fetal maturity, they are not helpful in ruling out post-maturity. Nonetheless, these observations may be of value in low-resource or disaster settings, and it is traditional to record the initial detection of the fetal heart tones and fetal movement in the woman's health record.

Prenatal History

After the pregnancy is diagnosed and the woman's choice to pursue prenatal care has been confirmed, a complete history is obtained. This includes past medical and surgical history,

along with family, genetic, social, menstrual, obstetric, gynecologic, sexual, and contraceptive history. All current medications and allergies are noted. The components of the woman's health history that may adversely affect the course of pregnancy are detailed in **Table 21-6**.

Table 21-6 Components of the Medical History That May Affect the Course of Pregnancy

History Element	Clinical Implications
Present pregnancy	Signs of pregnancy complications such as cramping, bleeding, or excessive vomiting in the first trimester; signs of preterm labor or preeclampsia in the late second and early third trimesters
	Signs of medical complications such as fever, dysuria, or rash
	Extreme discomforts of pregnancy
	Exposures to teratogens such as drugs or medications, street drugs, alcohol, tobacco, X rays, environmental exposures, or occupational exposures
Oral health	Periodontal disease is common among pregnant women and has in some studies been associated with preterm birth. Women with poor oral health can transmit the bacteria that cause dental caries to their newborn and studies have shown that their children are more likely to develop dental caries. Dental care during pregnancy can prevent this transmission. It is recommended that the woman be asked about bleeding gums or tooth pain and when she last had dental care.
Medical history	Medical conditions that are associated with increased risks for adverse maternal or fetal outcomes, such as diabetes or hypertension; they indicate a need for consultation, collaboration, co-management, or referral to a physician
Surgical history	Uterine surgery such as cesarean section or myomectomy, which may indicate a need for a physician consultation to evaluate the ability of the uterine scar to withstand a subsequent labor
	Significant surgeries on vital organs such as the heart, lungs, or kidneys
Family history	Evidence of genetic disorders such as hemophilia, cystic fibrosis, or intellectual disability, which may suggest the need for specific genetic counseling or tests
Social history	Risks that indicate a possible need for additional visits, social services, psychology consultation, or referral:
	Living situation: barriers to accessing care such as transportation, work schedule, unemployment, homelessness, food insecurity
	Adolescent pregnancy
	History of substance use, alcohol use disorder
	Personal stressors: history of sexual or physical abuse, or emotional abuse
Menstrual history	Irregular or regular cycles
	Cycle length
	Number of days between menses
Reproductive history	Gravidity, parity (TPAL)
	Dates of previous births, as well as weights of newborns
	Pregnancy complications such as mid-trimester loss, gestational diabetes, preterm labor, preterm premature rupture of membranes, fetal growth restriction, or preeclampsia[a]
	Induction or augmentation of labor, prolonged stages of labor
	Previous birth complications: mode of birth, shoulder dystocia, vaginal lacerations, or episiotomies
	Postpartum complications
	Newborn complications such as injury, infection, or congenital defects
Gynecologic history	Past or current STIs, especially herpes simplex virus and HIV
	Diagnosed malformations of the reproductive tract

	History of female genital cutting or female circumcision
	Procedures for treatment of abnormal cervical cytology
	Vulvovaginal disorders
Sexual history	Sexual activity: number of current partners and number of partners in the last year; gender of partners (male, female, or both)
	Risks for STIs and use of barrier methods for prevention of STIs
Contraceptive history	What was the last form of contraception used and when was it discontinued?
Current medications	Current medications, dose, and duration of treatment
	Vitamins, supplements, or herbal remedies
Allergies	Allergies to medications
	Allergies to foods or environmental exposures

Abbreviations: HIV, human immunodeficiency virus; STI, sexually transmitted infection; TPAL, term birth, premature birth, abortion, living children.

[a] Each of these conditions is an indication for physician consultation or referral: (1) History of midtrimester loss: may indicate a need for referral and consideration for cerclage placement; (2) prior gestational diabetes: early pregnancy screening for glucose intolerance is recommended; (3) history of preterm birth or preterm premature rupture of membranes: physician consultation to consider or plan intramuscular progesterone beginning in the second trimester; and (4) previous preeclampsia: treatment with low-dose aspirin (81 mg) is recommended for women with a history of early-onset preeclampsia and preterm delivery at < 34 0/7 weeks' gestation or women who had preeclampsia in more than one prior pregnancy.

While extra time is typically allotted for the initial prenatal visit, the content of the visit may need to be divided between multiple visits. The scope of questions asked at the initial prenatal visit may seem intrusive. Sensitive subjects such as intimate-partner violence, sexual abuse history, and substance use can be readdressed at subsequent visits when a trusting relationship has been established.

Physical Examination

A complete physical examination, including weight, height, and vital signs, is usually performed during the initial prenatal visit. Oral health is particularly important during pregnancy and the physical examination should include assessment of the gingiva. The other aspect of the physical examination specific for pregnancy includes the abdominal examination with auscultation for fetal heart tones (if gestational age permits) and a pelvic examination with clinical pelvimetry. The techniques for the abdominal examination and clinical pelvimetry are presented in Appendix 21A and **Appendix 21B**.

Undressing and exposure of genitals may be a trigger for women who have a history of abuse or those experiencing ongoing abuse. Some women may decline to have a pelvic examination for personal or cultural reasons. Under no circumstances should an individual be coerced to undergo a pelvic examination. The midwife may explain the benefits of doing the examination and the information that can be obtained from the pelvic examination, but the woman is entitled to decline or to defer the examination to another time.

Laboratory Tests, Genetic Tests, and Carrier Screening

Laboratory tests recommended or offered to women at the first prenatal visit fall into one of the following four categories:

- Routine laboratory tests that detect maternal infection or immunity to infections known to have adverse perinatal effects, which are recommended for all pregnant women (**Table 21-7**).[5,43-45]
- Laboratory tests that detect disorders or infections in women who have an increased risk (**Table 21-8**).[5,43-45]
- Tests to screen or diagnose detect fetal aneuploidy are offered to all pregnant women via a shared decision-making process. These tests are reviewed in detail in the *Genetics* chapter. An algorithm for recommending these tests during prenatal care is presented in **Figure 21-1**.[46]
- Carrier screening of either biological parent to detect carrier status for inheritable autosomal disorders can be offered using an ethnic-specific, panethnic, or expanded carrier screening strategy.[47] Carrier screening can be performed for anyone at any age. The available carrier screening tests and controversy regarding ethnic-specific versus expanded carrier screening strategies are reviewed in detail in the *Genetics* chapter.

Table 21-7 Laboratory Tests Recommended for All Pregnant Women at Initial Prenatal Visit[a]

Laboratory Test[a]	Recommendation and Follow-Up
Blood Tests	
Blood type, Rhesus type, antibody screen	Rh (D)-negative women who do not have alloantibodies are offered prophylactic anti-D immune globulin at 28 weeks or to prevent alloimmunization. If Rh alloantibodies are present, the baseline titre will be used to monitor the condition.
Hemoglobin, hematocrit, MCV, platelets: usually ordered as a CBC	A complete blood count will detect anemia. The MCV will determine whether anemia is microcytic, normocytic, or macrocytic, with this information then being used to identify appropriate tests for further evaluation of anemia.
HBsAg	Recommended for all women at an initial examination and then again in the third trimester for women who were not already screened prenatally, those who engage in behaviors that put them at *high risk* for infection, and those with signs or symptoms of hepatitis at the time of admission to the hospital for delivery. Risk factors: Having had more than one sex partner in the previous six months Evaluation or treatment for an STI Recent or current injection-drug use An HBsAg-positive sex partner
HIV	Opt-out approach for all women Recommended for all women at an initial examination and then again in the third trimester for women at high risk for acquiring HIV
Rubella titer	Women who are not immune to rubella are counseled to avoid exposure to the disease during pregnancy and vaccinated postpartum.
Syphilis	Recommended for all women at an initial examination and then again in the third trimester for

(VDRL/RPR)	women with continued or new risk for STIs: Uninsured, living in poverty, sex worker, or use of illicit drugs Diagnosed with another STI Living in high-prevalence areas Not previously tested in pregnancy Had a positive test in the initial prenatal screen
Blood Tests	
Varicella immunity	Obtain laboratory test for women who do not have a history of infection or vaccination and women who are not immune to varicella are counseled to avoid exposure to the disease during pregnancy and vaccinated postpartum
Urine Tests	
Urinalysis	Urinalysis for protein is performed to establish a baseline for comparison if renal function needs to be assessed later in pregnancy
Urine culture	Untreated bacteriuria increases the risk a woman will develop pyelonephritis; treatment of bacteriuria is per standard guidelines
Endocervical Culture	
Chlamydia[b]	Chlamydia screening strategy may be universal or selective. If selective, the indications are: All women < 25 years Women > 25 years who have a risk for STIs: Women who have a new sex partner More than one sex partner A sex partner with concurrent partners A sex partner who has an STI Third trimester: Rescreen women < 25 years and women > 25 years who have risks for STIs If the culture is positive, a test of cure is recommended 3 weeks after treatment and rescreen 3 months after treatment
Gonorrhea	Gonorrhea screening strategy may be universal or selective. If selective, the indications are: All women < 25 years Women > 25 years who have a risk for STIs: Living in a high-morbidity area Previous or coexisting STI New or multiple sex partners Inconsistent condom use among persons not in mutually monogamous relationships Exchanging sex for money or drugs Third trimester: Rescreen all women who have continued high risks for STIs If the culture is positive, rescreen 3 months after treatment

Abbreviations: CBC, complete blood count; HBsAg, hepatitis B surface antigen; HIV, human immunodeficiency virus; MCV; mean corpuscular volume; RPR, rapid plasma reagin; STI, sexually transmitted infection; VDRL, Venereal Disease Research Laboratory.

[a] If these tests were performed preconceptionally, repetition is not necessary.

[b] Chlamydia can be detected via endocervical culture or via nucleic acid amplification (NAAT) of urine. Culture is preferred but not mandatory.

Table 21-8 Laboratory Tests Recommended for Selected Indications During Pregnancy

Condition (Test)	Recommendation and Follow-Up
Cervical cancer screening (Pap test)	Pregnancy does not change the recommended interval for cervical cancer screening
Type 2 diabetes (fasting blood glucose, HbA1c)	Risk factors for type 2 diabetes are BMI ≥ 25 kg/m^2 (23 kg/m^2 for Asian populations) and one of the following: Clinical condition associated with insulin resistance First-degree relative with diabetes Gestational diabetes mellitus in a previous pregnancy HbA1c ≥ 5.7% (39 mmol/mol) Impaired glucose tolerance or impaired fasting glucose on previous testing HDL cholesterol level < 35 mg/dL (0.90 mmol/L) and/or a triglyceride level > 250 mg/dL (2.82 mmol/L) High-risk race/ethnicity (e.g., African American, Latina, Native American, Asian American, Pacific Islander) History of cardiovascular disease Hypertension (≥140/90 mm Hg or on therapy for hypertension) Physical inactivity Polycystic ovary syndrome
Hepatitis C	Screen all pregnant women at increased risk Risk factors: Past or current injection-drug use Having received a blood transfusion before July 1992 Receipt of an unregulated tattoo Long-term dialysis Known exposure to hepatitis C
Thyroid function (TSH)	Women with signs or symptoms of thyroid disease and women using thyroid medications
Trichomoniasis (wet prep for microscopic visualization)	Screen women who are HIV-positive
Tuberculosis (tuberculin skin test)	Women at increased risk for latent tuberculosis infection: Those who were born or lived in countries with high prevalence rates Those who live in high-risk settings (e.g., homeless shelters, correctional facilities) Those with HIV Those in close contact with other persons known or suspected to have tuberculosis, and those who work in longterm care facilities, nursing homes, or correctional facilities

Abbreviations: BMI, body mass index; HbA1c, hemoglobin A1c or glycosylated hemoglobin; HDL, high-density

lipoprotein; HIV, human immunodeficiency virus; TSH, thyroid-stimulating hormone.

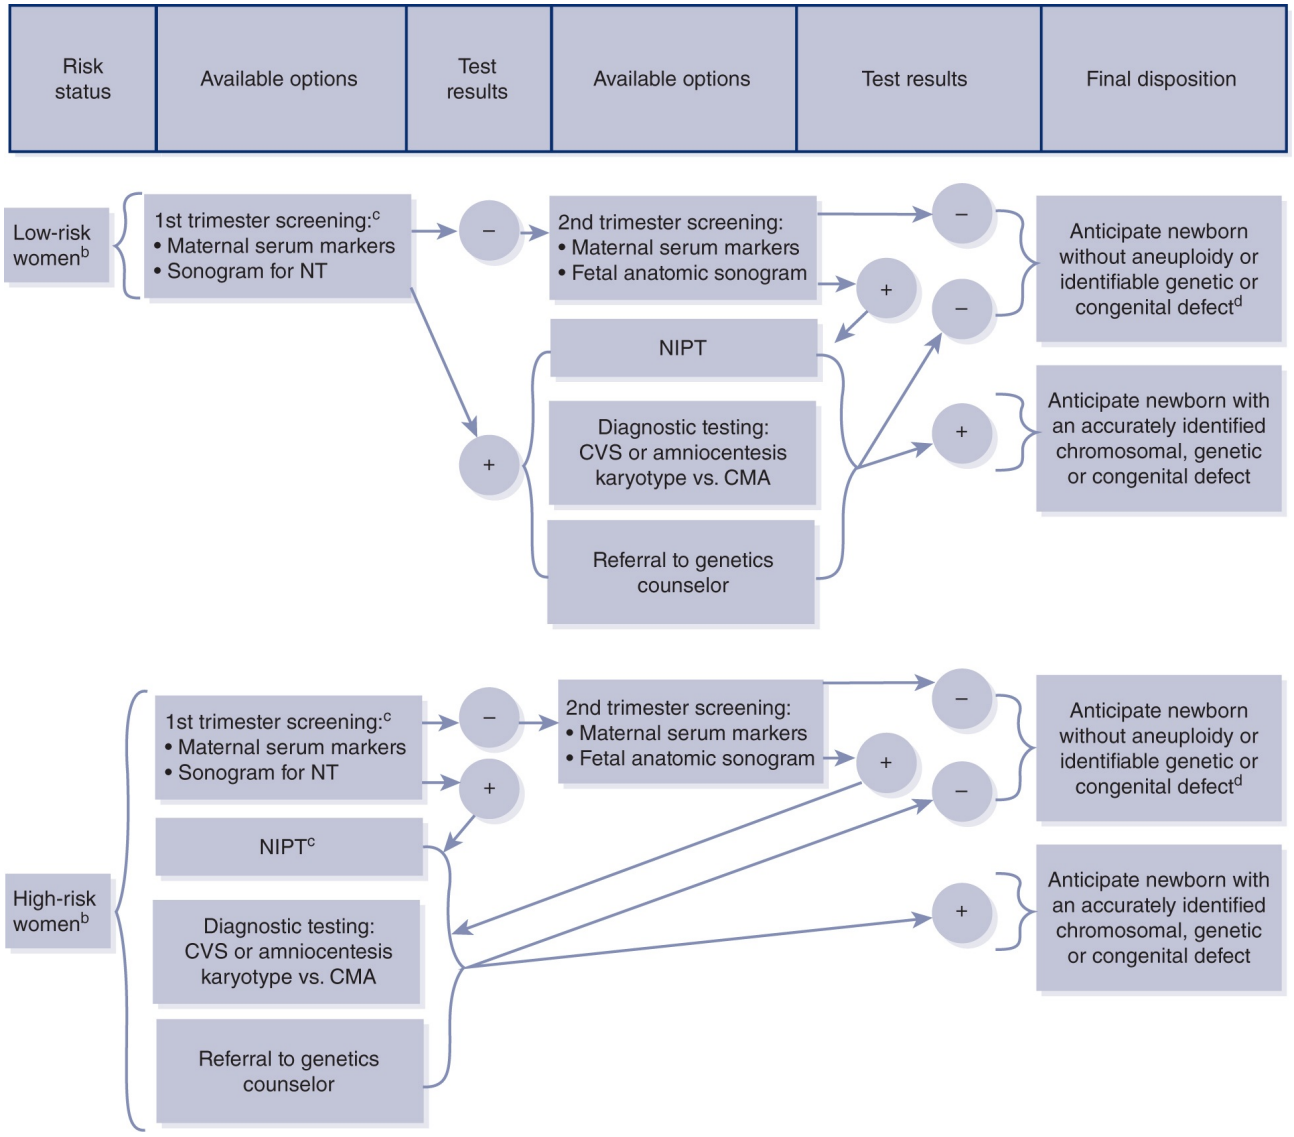

Figure 21-1 Algorithm for offering prenatal testing options.[a]

Abbreviations: CMA, chromosomal microarray analysis; CVS, chorionic villus sampling; NIPT, noninvasive prenatal testing; NT, nuchal translucency/thickness; ONTD, open neural tube defect.

[a] Based predominantly on Level A recommendations (good and consistent scientific evidence).

[b] In the absence of risk factors, women are considered “low risk.” Women are considered “high risk” when specific risk factors apply: advanced maternal age (age 35 years or older); high-risk ethnic/racial heritage (i.e., Ashkenazi Jewish, Mediterranean, African American); consanguinity (blood relationship of parents); family history (mother’s and father’s) of a known or suspected genetic condition; multiple affected family members with the same or related disorders; any major malformations (i.e., heart,

kidney, brain) or other birth defects occurring in the mother, father, grandparents, offspring, or close relatives (brothers/sisters); congenital blindness or deafness in family members; extremely tall or short stature of mother, father, or their relatives; developmental delays or mental retardation occurring in the mother, father, offspring, or close relatives; recurrent pregnancy losses (two or more) for the mother; environmental exposure to known or suspected teratogens; and infertility or premature ovarian failure.

[c] First-trimester screening for aneuploidy will not detect risk for ONTD. If a woman does not have second-trimester screening or amniocentesis, she should be informed that ONTD-specific screening is available (i.e., second-trimester ultrasound alone or in combination with maternal serum alpha-fetoprotein serum protein [MSAFP]).

[d] Negative screening tests are not a 100% guarantee that a fetus does not have aneuploidy or ONTD. Diagnostic testing has limitations—for example, it does not detect all possible genetic or congenital abnormalities.

Tests for Fetal Aneuploidy

Screening and diagnostic tests for fetal aneuploidy are offered to all pregnant women. Screening or diagnostic tests can be performed in the first or second trimester. First-trimester screening tests include a combination of ultrasound and blood tests that detect maternal biochemical markers for aneuploidy. Diagnostic procedures include chorionic villus sampling, which is performed in the first trimester; amniocentesis, which is performed in the second trimester; and maternal cell-free DNA, which can be performed at any time during pregnancy. Each test has different capabilities and limitations that are reviewed in the *Genetics* chapter. For example, cell-free DNA testing detects trisomies 21, 18, and 13, but does not detect other chromosomal abnormalities that are identified by the tests used to examine placental tissue or amniotic fluid obtained via chorionic villus sampling (CVS) or amniocentesis. Because CVS and amniocentesis have procedure-related risks, many women chose a sequential approach whereby they first obtain a screening test and then undergo diagnostic testing only if the screening test reveals a high risk.[43]

Carrier Screening

Carrier screening tests are reviewed in the *Genetics* chapter. In brief, all pregnant women are offered carrier testing for cystic fibrosis, hemoglobinopathies, and spinal muscular atrophy if these tests have not been performed previously.[47] The chosen strategy for selected carrier screening depends on factors including background population prevalence and the woman's race, ethnicity, and family history.[47]

First-Trimester Ultrasound

In the United States, one routine standard ultrasound in the first or early second trimester is recommended for all pregnant women.[49,50] In practice many women receive a first trimester limited ultrasound to confirm a viable pregnancy and establish gestational age and a standard ultrasound at 18–20 weeks for the purpose of evaluating fetal anatomy. Midwives may perform a first-trimester ultrasound if trained and certified or privileged to do so.[51] The standard ultrasound that occurs at 18 to 20 weeks is performed by a clinician who is trained and credentialed to conduct this examination. Prior to scheduling or performing an ultrasound, the midwife must review the indications, benefits, and risks with the woman.

Counseling and Anticipatory Guidance

Anticipatory guidance and instruction at the end of an initial prenatal visit can encompass many health education topics, but always includes the following components:

- Instruction about signs that may indicate a complication requiring medical evaluation (**Table 21-10**)
- Practices for health maintenance during pregnancy, including counseling about alcohol,

smoking, and substance abuse
- An orientation to the plan of care and timing of return visits
- Information about how to contact the midwife and the roles of all members of the healthcare team
- Expected costs to the patient of prenatal care and birth

Table 21-10	Signs of Pregnancy Complications
Contractions or uterine cramping or sudden, sharp, or continuing abdominal cramping or pain	
Decreased fetal movement	
Dysuria, hematuria, or inability to void	
Facial edema, edema of the hands, or unilateral lower-extremity edema	
Fever or chills	
Headache that is persistent or severe, and that is unrelieved by over-the-counter pain relievers	
Leaking of fluid or abnormal vaginal discharge	
Nausea and vomiting, unable to keep fluids down or to void	
Visual changes (e.g., blurring of vision, dizziness, spots before eyes)	
Vaginal bleeding	

All pregnant women should be screened for intimate-partner violence and mental health conditions during an early prenatal visit, but the timing for these screens should be individualized.

Diagnosis and Plan

The primary assessment at the end of the initial prenatal examination is a pregnancy diagnosis. Examples include “pregnancy of unknown location,” “viable intrauterine pregnancy,” or “threatened spontaneous abortion.” The assessment should include the estimated gestational age and dating criteria used.

Other assessments following the first prenatal visit include those related to the woman’s prepregnant health that may confer risk to the current pregnancy. The woman’s health record should also list any common discomforts of pregnancy for which a management plan was required. Finally, all tests ordered are recorded in the health record. Critical components of the assessments to be documented following the first prenatal visit are listed in **Table 21-11**.

Table 21-11	Critical Elements of Documentation Following the First Prenatal Visit
Obstetric Review of Systems	
First trimester:	
Vaginal bleeding	
Severe cramping or pelvic pain	
Excessive nausea and vomiting	
Headache	

Dysuria

Fever

Second/third trimesters:

The presence of expected fetal movement appropriate for gestational age

Signs and symptoms of preterm labor: uterine cramping or contractions, leaking of fluid, or vaginal bleeding

Maternal Vital Signs

Blood pressure should always be documented. If blood pressure is elevated, documentation will include the subjective symptoms of preeclampsia (headache, visual changes, and epigastric pain).

Other vital signs, including temperature, respiratory rate, and oxygen saturation, should be reported in the presence of maternal constitutional symptoms.

Fetal Well-Being

Detection of fetal heart tones: Documented at every prenatal visit after 12 weeks' gestation

Assessment of fetal growth relative to that expected for gestational age

Determination of fetal presentation > 36 weeks' gestation.

Management Plan

Diagnostic and therapeutic plans for each problem identified

Follow-up plan

Consultation (if indicated), including the name of the provider consulted, the information discussed with the consultant, and any recommendations provided

Interval Prenatal Visits

Before seeing a woman for an interval prenatal care visit, the midwife reviews the woman's record to determine the gestational age of the fetus; the woman's EDD; any significant problems that have been noted on a problem list; medications, treatments, and dietary interventions; results of laboratory tests or ultrasound assessments; and need for follow-up testing. The essential components of an interval prenatal visit are presented in **Table 21-12** and the skills for performing the physical examination are reviewed in Appendix 21A.

Table 21-12 **Essential Components of Routine Interval Prenatal Visits**

History
Obstetric review of systems:
Fetal movement: Appropriate for gestational age?
Vaginal bleeding or leaking of fluid
Uterine contractions (frequency, regularity, strength)
Interval medical history:
New bodily changes, symptoms, or concerns
Status of previous problems and response to treatment
Interval social history:
Social support or concerns
Safety at home
Preparation for labor and baby
Medications, including vitamins and OTC products
Physical Examination
Weight and interval weight gain
Blood pressure
Urine dipstick to test for proteinuria, specific gravity, or leucocytes if indicated
Obstetric abdominal examination:
Fundal height in centimeters
Fetal heart tones
Fetal presentation after 36 weeks' gestation
Third trimester: Assess for inverted nipples
Health Screening
Intimate-partner violence screening at least once every trimester
Depression screening
Alcohol and drug use
Laboratory Assessments
16–20 weeks' gestation: Second-trimester Down syndrome screening test (triple or quad screen) offered
24–28 weeks' gestation:
Gestational diabetes screen
Antibody screen if Rh negative and subsequent RhoGAM therapy for Rh-negative women
35–37 weeks' gestation:

Group B *Streptococcus* screening culture
Repeat STI screening (gonorrhea, chlamydia, syphilis, HIV, hepatitis B) if indicated
Ultrasound Assessments
18–20 weeks' gestation: Fetal anatomy survey
≥ 36 weeks' gestation: Confirm fetal presentation, if uncertain

Abbreviations: HIV, human immunodeficiency virus; OTC, over-the-counter; STI, sexually transmitted infection.

Schedule for Interval Prenatal Visits

Schedules for subsequent prenatal visits vary between practices, and based on the individual woman's needs or risks that develop during her pregnancy. Traditionally, interval prenatal visits have been scheduled monthly in the first and second trimesters, every 2 weeks between 28 to 36 weeks' gestation, and weekly thereafter.

Group Prenatal Care

In the last decade, alternatives to individual one-on-one prenatal visits have been developed, including group prenatal care. The best-studied group prenatal care model is CenteringPregnancy, which has been widely adopted. CenteringPregnancy differs from the traditional individual care model in that it combines the typical elements of a prenatal visit risk assessment with childbirth education and peer support.

CenteringPregnancy utilizes a standardized approach and group process that focuses on the creation of a self-empowering environment.[52] Groups of 8 to 12 women or couples at approximately the same gestational age, usually starting at 12 to 16 weeks' gestation, are formed. The group meets monthly for 4 months, and then biweekly, and once in the early postpartum period, for a total of ten 90-minute sessions. Additional individual examination room visits are scheduled as needed.

The effectiveness of group prenatal care has generally been investigated through observational, small studies, with varied results. Overall, group prenatal care—and in particular CenteringPregnancy—is associated with high rates of patient satisfaction.[52,53] Data on the effects of this model on perinatal outcomes are still emerging. Some studies have found lower rates of adverse outcomes such as preterm birth, low birth weight, and neonatal intensive care unit admissions, along with higher rates of breastfeeding initiation, later cervical dilation on admission, and improved pregnancy-weight management.[54-61] Nevertheless, these findings have not been replicated in all studies.[62-64] Notably, larger systematic reviews, which did not account for possible a priori risks within the population of women included in the studies, have not confirmed the links between group prenatal care and improved maternal or newborn health outcomes.[65-68]

Although more study is needed to determine the effectiveness of CenteringPregnancy in different populations, this prenatal care model is clearly as good as individual care. In some populations, it may even have significant advantages—especially in at-risk populations such as women who experience racial/ethnic disparities and adolescents.[54-60] For example, although

outcomes have not been published, the Akwesasne Mohawk Nation has integrated traditional Mohawk coming-of-age ceremonies and traditions into CenteringPregnancy prenatal care in the United States and Canada to reinforce social connections, customs, and values consistent with Mohawk traditions.

Interval History

The initial conversation and review of interval history is designed to address any questions, discomforts, or complications that the woman may have experienced since the last visit. In addition to the standard components of the interval prenatal examination, the physical examination may include a targeted examination to assess specific symptoms. For example, a speculum examination might be performed to assess a vaginal discharge or determine whether membranes have ruptured. A bimanual examination might be performed to evaluate cervical ripening or to perform membrane sweeping after 37 weeks' gestation.

Interval Physical Examination

The interval physical examination includes maternal weight, blood pressure, and abdominal examination, as detailed in Appendix 21A.

Screening, Laboratory Tests, and Adjunctive Studies

In many practices, a voided urine specimen is obtained at each prenatal visit to detect proteinuria, glucosuria, or signs of asymptomatic bacteriuria. However, the urine dipstick test —especially in the absence of symptoms or risk factors such as hypertension—is not a reliable means of detecting asymptomatic bacteriuria[69] or preeclampsia,[69,70] and is of questionable benefit in early detection of gestational diabetes. Most authors have advocated for discontinuation of such testing as a part of regular prenatal care.

Diabetes Screening

Gestational diabetes mellitus (GDM) is a condition of carbohydrate intolerance that develops during pregnancy. Traditionally, any woman who was found to have glucose intolerance during pregnancy was given the diagnosis of GDM. In recent years, however, the increasing rates of obesity in the general population have resulted in more women of childbearing age who have type 2 diabetes. Some women may be initially diagnosed with this condition during pregnancy. Because the prevalence of type 2 diabetes in pregnancy has increased, recommendations for screening and diagnosis have recently changed: Women who are diagnosed with diabetes in the first trimester are now considered to have type 2 diabetes, whereas women who are first diagnosed in the second or third trimester are classified as having GDM.[71]

Overall, approximately 6% to 9% of pregnant women have diabetes during pregnancy, with an estimated 90% of these women having GDM.[71] The prevalence of GDM is higher among Hispanic, African American, Native American, Asian, and Pacific Islander women.[72] GDM is subcategorized as either A1 GDM, in which alterations in diet result in euglycemia, or A2

GDM, in which medication is needed to maintain euglycemia.

Women who have GDM have an increased risk for developing preeclampsia, developing polyhydramnios, and having a cesarean section; their infants have an increased risk for macrosomia, shoulder dystocia, hypoglycemia, and hyperbilirubinemia. These risks increase in a dose–response manner as maternal blood glucose values increase. Importantly, GDM is a significant risk factor for developing type 2 diabetes later in life. Approximately 70% of women with GDM will develop type 2 diabetes within 22 to 28 years after the index pregnancy.[73] Among Latina women, approximately 60% will develop type 2 diabetes within 5 years of the index pregnancy.[74]

There are two time frames for screening for diabetes in pregnancy: early (first trimester or at entrance to care) and second trimester (24–28 weeks). Early screening is primarily done to identify women with undiagnosed pregestational diabetes or prediabetes.[75] Second-trimester screening is used to identify women with GDM.[75,76] **Figure 21-2** presents an algorithm for diabetes screening in pregnancy.[75,77]

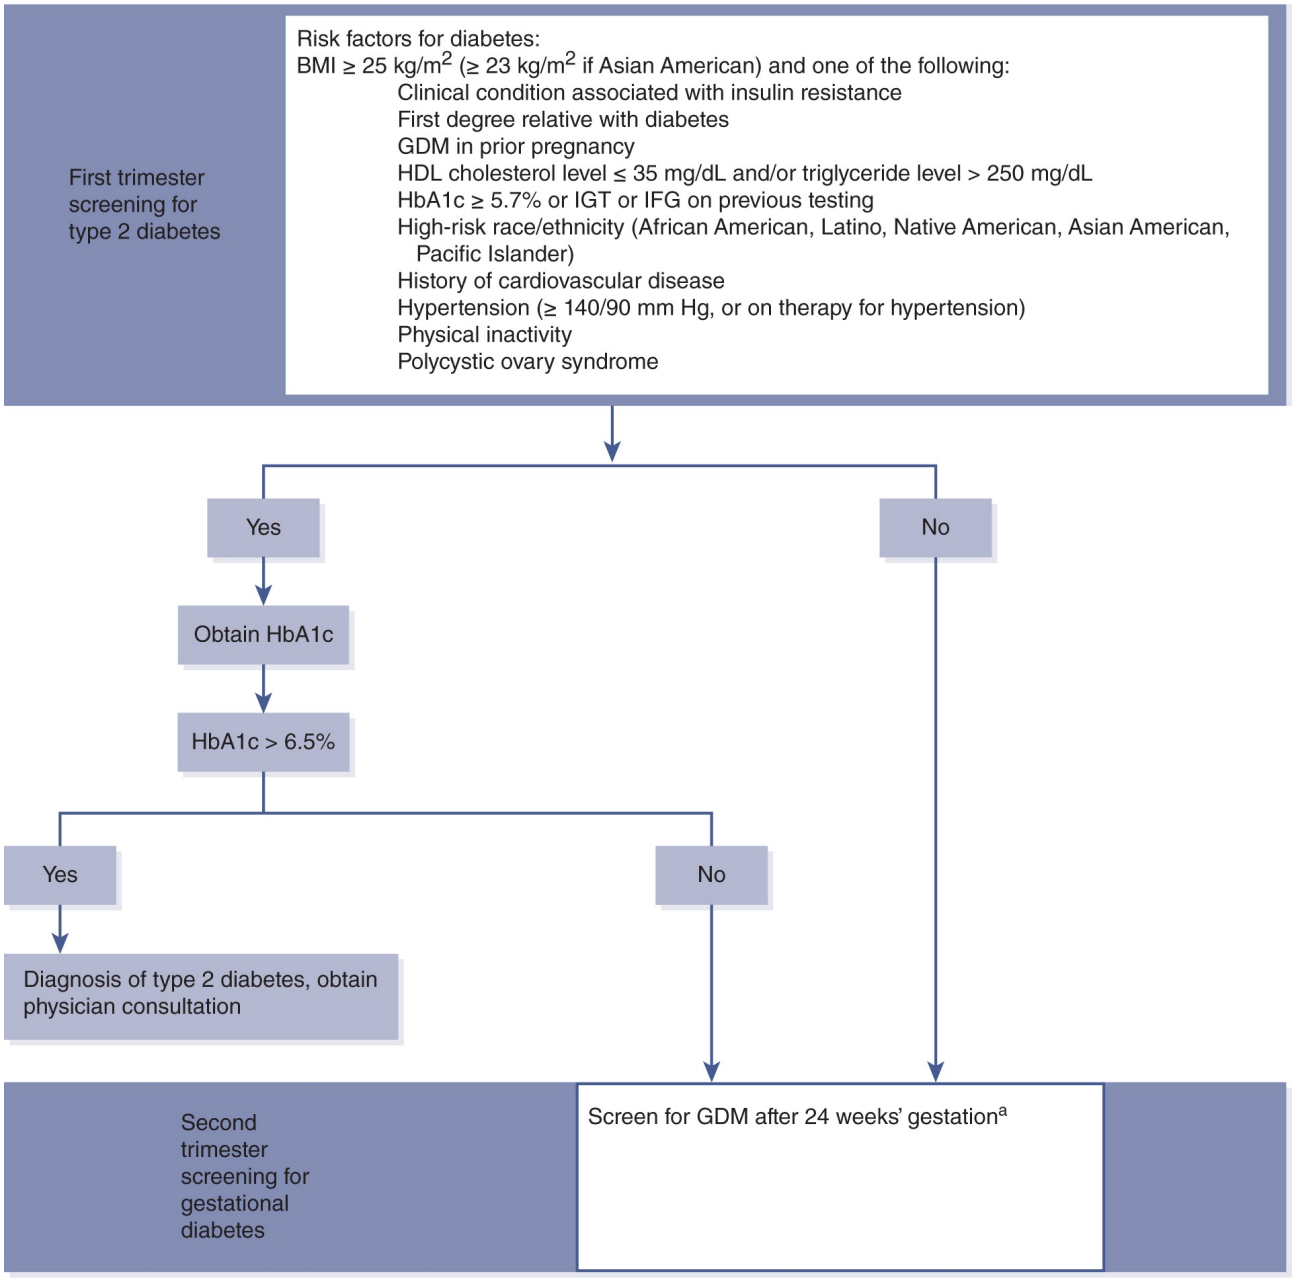

Figure 21-2 Screening and diagnosis of diabetes during pregnancy.

Abbreviations: BMI, body mass index; GDM, gestational diabetes mellitus; HbA1c, hemoglobin A1c; HDL, high-density lipoprotein; IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

[a] Screening can be done via one of the following:

1. One-step 75-g glucose load with blood glucose obtained 2 hours later, or via 2-step process that includes an initial 50-g glucose load with blood glucose obtained 1 hour later.

2. A 3-hour glucose tolerance test is obtained if the blood glucose following the 50-g load is > 130 or 140 mg/dL.

Based on American Diabetes Association. 2. Classification and diagnosis of diabetes. *Diab Care*. 2016;39(suppl 1):S13-S22[75]; Committee on Practice Bulletins—Obstetrics. Practice Bulletin No. 137: gestational diabetes mellitus. *Obstet Gynecol*. 2013;122(2 pt 1):406-416.[77]

Early Screening for Undetected Type 2 Diabetes. Early screening for diabetes is recommended by the American Diabetes Association (ADA) and American College of Obstetricians and Gynecologists (ACOG) for women with risk factors for diabetes, as noted in **Figure 21-2**. The ADA recommends testing women with obesity who have two additional risk factors.[76] The ACOG criteria suggest early screening based on one risk factor.[77] The diagnosis of type 2 diabetes is based on the hemoglobin A1c (HbA1c) value obtained.

Second-Trimester Screening for Gestational Diabetes Mellitus. All professional associations recommend screening for GDM after 24 weeks' gestation, but their recommendations sometimes differ with regard to (1) who should be screened (risk based versus universal) and (2) which test to use. The first consideration is the indication—that is, screening on the basis of risk or universal screening for all pregnant women. The problem with risk factor screening is that 90% of the general population has one or more risk factors. Thus, the overwhelming majority of women would meet the criteria for early screening, which is why the U.S. Preventive Services Task Force (USPSTF) and ACOG recommend universal screening.[77],[78] Nonetheless, it is important to remember that women who do not have risk factors for GDM and who want to decline screening should be counseled that their choice is a safe one. Characteristics of women who are at low risk for GDM are listed in **Table 21-13**.

Table 21-13	**Women Who Are at Low Risk for Gestational Diabetes**
Younger than 25 years	
Not a member of one of the following racial or ethnic groups:	
African American	
South or East Asian	
Hispanic	
Native American	
Pacific Islands descent	
No known diabetes in a first-degree relative	
Body mass index of 25 kg/m^2 or less	
No history of glucose intolerance	
No history of adverse obstetric outcomes associated with gestational diabetes (e.g., stillbirth, macrosomia)	

Modified with permission from Moyer VA; U.S. Preventive Services Task Force. Screening for gestational diabetes mellitus: U.S. Preventive Services Task Force recommendation statement. *Ann Intern Med*. 2014;160:414.[78]

The best testing procedure for screening and diagnosis of GDM is also a continuing controversy. All strategies involve an oral glucose test. The strategy recommended by ACOG and the National Institutes of Health is a two-step process that initially involves a 50-gram, 1-hour glucose challenge. With this test, the woman ingests 50 grams of glucose and a blood glucose level is obtained 1 hour later.[77],[79] If this blood glucose level is elevated above 130 mg/dL or 140 mg/dL, a 3-hour glucose tolerance test (GTT) is performed, in which glucose levels are obtained before (fasting) and at 1, 2, and 3 hours after ingesting 100 grams of glucose. The results of the 3-hour glucose test determine the diagnosis.

The International Association of Diabetes and Pregnancy Study Groups (IADPSG) recommends a universal, single, one-step strategy using a 75-gram dose of glucose with a blood glucose level obtained 2 hours later. This testing strategy results in a significant increase in the number of women diagnosed with GDM.[80] As yet, there is no international consensus on which strategy to use. A concern with any of these approaches is the lack of evidence showing the benefit of the increased diagnoses.

Some women may prefer to eat a natural meal or food instead of ingesting the glucose drink. Two studies have evaluated glucose loading in the form of a prespecified number of jelly beans and found that this approach had similar sensitivity, specificity, and positive predictive value as that using the 50-gram glucose drink.[81,82] The primary reason that "confectionary screening" is not recommended is that jelly beans are metabolized into circulating glucose at differential rates, and it is unknown exactly how that glucose load affects blood glucose levels exactly 1 hour later.

Rh Alloimmunization Prevention

The treatment of Rh alloimmunization is a success story of the twentieth century. The Rhesus factor was first identified in the late 1930s, and Rh incompatibility was identified shortly thereafter as the etiology for large numbers of fetal deaths and stillbirths. In the late 1960s, an anti-D serum was approved.

Red blood cells have many different proteins on the cell membrane surface that are antigenic. Some of these proteins are controlled by a single gene locus. To date, more than 30 blood group system genes have been identified, along with their corresponding red cell surface proteins. They have been assigned a variety of names mostly based on when they were discovered and who discovered them. Because these blood groups are polymorphic, there are approximately 200 genetic variations. The polymorphic subtypes are designated with a second letter (e.g., RhD, RhC, or RhE). The A, B, O, and Rh red blood cell antigens are the most important clinically because they are highly immunogenic. An individual who is Rh (D) positive has the Rh (D) antigen on the membrane of his or her red blood cells. Conversely, a person who is Rh (D) negative does not have the Rh (D) antigen on his or her red blood cell membranes and, therefore, may create antibodies to Rh (D)-positive cells when exposed to Rh (D)-positive blood—a phenomenon called *alloimmunization.*

Fetal blood has several opportunities to mix with maternal blood during pregnancy and birth, although such mixing is not common during the prenatal period. During the third stage of labor, fetal blood commonly escapes into the maternal circulation as the placenta separates from the decidua. For a woman who is Rh (D) negative and pregnant with a Rh (D)-positive fetus, physiologic events that expose her circulation to fetal blood can cause her to develop immunoglobulin G (IgG) antibodies to the Rh (D) antigen. It is estimated that approximately 17% of women will become alloimmunized secondary to some fetomaternal blood transfer during birth.[83] The anti-Rh (D) IgG–type antibodies produced are small in size. During subsequent pregnancies, they can easily cross the placenta and attach themselves to any antigens found on Rh (D)-positive red blood cells of a fetus, causing hemolysis, erythroblastosis fetalis, and stillbirth.

The ABO blood groups can also be different between the mother and the fetus, although ABO antibodies are not likely to damage fetal red blood cells if the mother has a previous exposure to a different blood type and has created antibodies to the A, B, or AB blood groups. The A, B, and AB blood group proteins are not expressed on red blood cells as profusely as are Rh proteins, and are not well developed at birth compared to the Rh antigen. Antibodies to A, B, and AB are usually of the immunoglobulin M (IgM) class; they are larger in size compared to the anti-D IgG antibodies, so they are not able to cross the placenta. Furthermore, because many other cell types express the A, B, and AB proteins, antibodies to them are less likely to specifically attack red blood cells in enough numbers to cause harm.

Today Rh alloimmunization in pregnant women and hemolytic disease of the fetus or newborn are rarely seen, primarily because women who are Rh (D) negative are given anti-D immune globulin prophylaxis in the third trimester of pregnancy and after birth if the newborn is Rh (D) positive. Anti-D immune globulin (RhoGAM) is extracted from the plasma of individuals who have high titers of anti-D immune globulin antibodies. Since 1985, all plasma used for anti-D immune globulin production has been tested for viruses that can cause infection.[83] The anti-D immune globulin has a unique mechanism of action. A small amount of anti-D IgG attaches to any fetal cells that are present in maternal circulation and masks them, thereby preventing the maternal immune system from developing permanent antibodies. The amount of anti-D immune globulin is small enough that it does not induce a maternal antibody response and is removed from maternal circulation in approximately 12 weeks. Thus, every subsequent pregnancy becomes a “first pregnancy” in terms of Rh (D) antibody development.

Today, women are screened for Rh (D) status at the initial prenatal visit. If a woman is found to be RH negative, an antibody titer is usually ordered in the second trimester to ascertain whether she has become alloimmunized. If this titer is negative, she is given anti-D immune globulin at 28 weeks’ gestation.[83] Supportive data are limited, but some sources recommend a second prenatal dose of anti-D immune globulin if more than 12 weeks elapses between the second-trimester dose and the onset of labor (although this is not common practice).[83] The most likely time for alloimmunization to occur is following birth, however, and women who are Rh (D) negative should receive another dose of the agent within 72 hours after giving birth if the newborn is Rh positive. Anti-D immune globulin is also given after a first- or second-trimester pregnancy loss or termination to prevent alloimmunization.[83]

Special situations warranting additional administration of anti-D immune globulin and other antigens that can cause hemolytic disease in the fetus or newborn are discussed in the *Pregnancy-Related Conditions* chapter.

Group B Streptococcus Colonization

Group B *Streptococcus* is a gram-positive coccus that normally inhabits the gastrointestinal system and genital tract of approximately 15% to 40% of pregnant women. Colonization with GBS is generally asymptomatic and not pathogenic in women. In contrast, newborns colonized with GBS can develop severe sepsis. The newborn is most likely to become colonized at birth during passage through the vagina. Although rare in absolute numbers (0.25 case per 1000 live births), GBS is the leading cause of early-onset newborn sepsis in the United States.[84,85]

The Centers for Disease Control and Prevention (CDC) recommends universal screening for maternal carrier status performed between 35 and 37 weeks' gestation, followed by intrapartum prophylaxis for women who have a vaginal/rectal culture that is positive for GBS. Vaginal colonization can be intermittent or persistent, so women are screened during each pregnancy. A woman who was GBS positive in a prior pregnancy may have no vaginal colonization with this organism in a subsequent pregnancy. If GBS is identified in a urine culture at any time during a pregnancy, it is a sign of heavy colonization. Such women are offered intrapartum prophylaxis, without performing a confirming culture, at 35 to 37 weeks' gestation.[85]

The collection of a culture for GBS testing is a simple procedure, and a speculum is not needed. The woman can collect the specimen herself if desired. The vaginal introitus is swabbed, and then the swab is inserted into the anus.[85] Swabbing just within the external third of the vagina (not the cervix) and then the rectum is necessary to swab the areas most likely to have a large inoculum. Group B *Streptococcus* is not easy to culture, and cultures are more reliable if a large inoculum is obtained. If the GBS culture is positive, the midwife provides the woman with information about intravenous penicillin prophylaxis in active labor or after rupture of membranes. Birth centers and home birth midwives are equipped to administer intravenous GBS prophylaxis in those sites.

Second-Trimester Ultrasound Examination

A standard fetal anatomy survey, typically performed between 18 and 20 weeks' gestation, is recommended for all pregnant women. This survey is intended to identify fetal and placental structural abnormalities and confirm gestational age (if a first-trimester ultrasound was not performed). By 18 weeks' gestation, fetal organs are formed and large enough that ultrasound can detect anatomic abnormalities, particularly in the heart and brain. This ultrasound examination is generally performed prior to the gestational limit for termination of pregnancy, in the event that anomalies are detected. Abnormal ultrasound findings are reviewed in the *Pregnancy-Related Conditions* chapter.

Gestational Weight Gain and Nutrition

Individuals who have a healthy diet before becoming pregnant need only subtle changes to optimize nutrition in pregnancy. Energy requirements increase by approximately 200, 300, and 400 calories per day in the first, second, and third trimesters, respectively[86]—an increase that is equivalent to the addition of one healthy snack per day. In light of emerging epigenetic research findings that relate in utero nutrient exposure to health outcomes later in life, specific, accurate nutrition counseling during pregnancy is more important now than ever.[87]

Weight Gain

Gestational weight gain is just one aspect of a woman's nutritional status. Indeed, routine weight measurements during pregnancy are not the standard of care in all developed nations.[86] The United States is one of the few developed nations in which weight gain is routinely tracked over the course of pregnancy.

A relationship exists between both insufficient and excess gestational weight gain and adverse outcomes for both the woman and the fetus. Pregestational weight and subsequent gestational weight gain affect offspring weight gain and adiposity. In turn, birth adiposity affects adult weight and long-term health.[88] Inadequate weight gain is associated with low birth weight, small for gestational age infants, preterm birth, increased perinatal mortality, and failure to establish breastfeeding.[86,89] Conversely, infants of women who gain excessive weight are at increased risk of being large for gestational age, hypoglycemia, polycythemia, low Apgar scores, seizures, and birth trauma associated with difficult birth.[86] For women, excessive gestational weight gain is associated with cesarean section and postpartum weight retention. Long-term outcomes associated with excessive gestational weight gain may include metabolic syndrome, type 2 diabetes, and cardiovascular disorders.[86]

Guidelines for gestational weight gain in pregnancy have changed over the years. In 1990, the Institute of Medicine (IOM) issued pregnancy weight gain guidelines aimed at ensuring adequate weight gain to prevent low birth weight. At the time, the weight gain recommended by IOM was higher than the 12-pound weight gain typically recommended in clinical practice. Since then, obesity and excessive weight gain in pregnancy have become public health concerns in the United States. In 2009, IOM revisited its recommendations in light of the evidence accumulated since the early 1990s, with a particular focus on the role of retention of gestational weight gain in the development of long-term obesity in women, and issued revised gestational weight gain guidelines (**Table 21-14**).[88]

Table 21-14	Recommended Gestational Weight Gain for Women with a Singleton Pregnancy[a]	
Pregestational Weight Category: BMI (kg/m^2)	**Recommended Total Weight Gain: Pounds (kg)**	**Second- and Third-Trimester Rate of Weight Gain: Mean (Range)**
Underweight: < 18.5	28–40 (12.5–18)	1 (1–1.3) lb/wk 0.51(0.44–0.58) kg/wk

Normal weight: 18.5–24.9	25–35 (11.5–16)	1 (0.8–1) lb/wk 0.42(0.35–0.50) kg/wk
Overweight: 25.0–29.9	15–25 (7–11.5)	0.6(0.5–0.7) lb/wk 0.28(0.23–0.33) kg/wk
Obese: ≥ 30.0	11–20 (5–9)	0.5(0.4–0.6) lb/wk 0.22(0.17–0.22) kg/wk

Abbreviation: BMI, body mass index.

[a] Calculations assume a mean first-trimester weight gain of 2 kg (range: 1–3 kg) for women who are underweight, normal weight, and overweight. The assumed first-trimester weight gain for women who are obese is 1.5 kg (range: 0.5–2 kg).

Modified with permission from Rasmussen KM, Yaktine AL, eds. *Weight Gain During Pregnancy: Reexamining the Guidelines.* Washington, DC: National Academies Press; 2009. Available at: http://www.ncbi.nlm.nih.gov/books/NBK32815. Accessed October 9, 2017.[88]

The recommended gestational weight gain for women differs based on pregestational body mass index (BMI).[90] The IOM recommendations are for the general population in the United States; subpopulations—such as adolescents, women who smoke, and women with chronic illness—may require individualized weight gain targets.[91,92] The pattern of gestational weight gain is also different by race and ethnicity. For example, Hispanic, black, and Asian normal-weight women are more likely to experience inadequate gestational weight gain compared to white women.[86,93-95]

Persons are provided with information about their BMI category and target prenatal weight gain using the IOM recommendations at the first prenatal visit. Weight gain is then assessed and nutrition counseling reviewed at subsequent prenatal visits. Charting weight gain on a graph gives both the woman and the prenatal care providers a pictorial representation for easy visualization. Although a composite weight gain graph is often available in prenatal charts, weight gain graphs that show the mean and range specific for each BMI category are available.[90] (See the Resources section at the end of this chapter for weight chart sources.) Encouraging the pregnant woman to complete forms such as the "Starting the Conversation" or REAP questionnaires (reviewed in the *Nutrition* chapter), and assessing their results, can be a rapid method to gain valuable information about the woman's current dietary patterns.

Nutrition

The recommended Daily Reference Intakes for macronutrients and micronutrients for women during pregnancy are summarized in the *Nutrition* chapter. Diet can play a powerful role in maintaining a healthy pregnancy, and prenatal care is an ideal time to start the conversation about a healthy dietary pattern.[96] An increasing body of evidence supports the Barker hypothesis, which states that a woman's diet during pregnancy has effects on the fetus that are important postnatally and throughout her child's entire life, including genetic predispositions for some chronic diseases.[97]

Frequency of meals also plays a role during pregnancy. A substantial body of research supports the recommendation that pregnant women eat three meals a day and at least two snacks. Some pregnant women will want to observe their religion's periods of fasting, even

though Catholicism, Judaism, and Islam all customarily exempt a pregnant woman from any obligation to fast. As part of prenatal care, the midwife elicits this information and provides teaching as required. **Table 21-15** summarizes dietary recommendations during pregnancy.[96,98]

Table 21-15 Summary of Dietary Advice for All Pregnant Women

Supplements
Take folic acid in a multivitamin at least 1 month prior to conception and for the first 3 months after conception to prevent neural tube defects.
Diet
Gain the recommended weight for BMI by eating the following:
Three meals a day and two snacks to avoid prolonged periods of fasting
Five servings of fruits and vegetables, at minimum, per day
Whole-grain carbohydrates; limit food with high sugar content like desserts, juices, and sodas
Adequate amounts of protein, choosing more plant-based sources such as nuts and beans
At least two servings of best-choices fish weekly or one serving of good-choices fish:
Examples of best choices: catfish, clam, crab, flounder, pollock, salmon, sardines, shrimp, sole, trout, whitefish
Examples of good choices: bluefish, carp, Chilean sea bass, halibut, snapper, tuna (albacore, white tuna, canned and fresh or frozen, yellowfin)
Limit canned tuna to twice a week
Drink 8–10 glasses of water per day.
Limit caffeine to 200 mg/day (2 cups of coffee or 4 cups of black tea)
Avoid all alcoholic drinks
Limit sweetened drinks
Ensure adequate intake of these micronutrients:
Vitamin A as beta-carotene; limit food sources with preformed vitamin A such as liver (< 4 oz/week) or cod liver oil
Vitamin D from exposure to sunlight (amount will vary by geography, BMI, and skin pigmentation); if not feasible, consider supplementation with vitamin D_3 (1000–4000 IU depending on intake of vitamin D–fortified dairy products and vitamin D serum levels)
Folic acid through a multivitamin supplement
Women adhering to strict vegan diets: Take vitamin B_{12} supplements or consume vitamin B_{12}–fortified products
Iodine through diet (dairy and fish) or a multivitamin with iodide (preferably as potassium iodide)
Iron through diet, multivitamin, or additional low-dose supplement if anemic
Calcium through diet, with supplementation suggested for women at risk for preeclampsia
Choline-rich food sources such as meat, poultry, and eggs, since this nutrient is not typically included in prenatal vitamins
Foods to Avoid
Soft cheeses unless they clearly state they are made from pasteurized milk, including brie, feta, camembert, blue-veined cheeses, and Mexican-style cheeses such as queso blanco, queso fresco, and queso panela
Uncooked meats or refrigerated pâtés or meat spreads
Raw eggs, cookie dough
Raw fish
Mercury-concentrating fish: king mackerel, marlin, orange roughy, shark, swordfish, tilefish (Gulf of Mexico), tuna (bigeye)

Deli meat salads or smoked seafood
Raw sprouts
Raw unpasteurized fruit juice, raw milk, or unpasteurized dairy products
Refrigerated perishable foods that have not been consumed in 2–3 days
Food Handling
Wash cutting boards and equipment used to cut raw meat with hot soap and water
Wash and peel raw fruits and vegetables before eating
Wash hands after handling hot dogs, luncheon meats, or deli meats
Food Processing
Cook all deli meats, hot dogs, smoked meats, pâtés, and luncheon meats to steaming hot before eating
Cook meat and eggs to 71.1°C (160°F)
Cook seafood to 62.8°C (145°F)

Abbreviation: BMI, body mass index.

Vitamin and Mineral Supplementation

Prenatal vitamins are multivitamin supplements formulated to provide the vitamins and minerals needed most by pregnant women. Although prenatal vitamins are one of the hallmarks of prenatal care, the actual value of vitamin and micronutrient supplements for pregnant women is more nuanced and complex. First, a balanced diet generally provides all the nutrients needed for health during pregnancy. Unfortunately, a majority of the women in the United States do not consume a diet that provides all the vitamins and micronutrients needed during pregnancy. The specific vitamins and micronutrients that have documented adverse effects on fetal development if present in insufficient amounts in the diet are folic acid, iron, and iodine.[96]

Folic Acid. Supplemental folic acid is recommended for all pregnant women.[99] Supplemental folic acid started in the preconception period and taken through the first trimester lowers the risk of neural tube defects (NTDs) by approximately 30% to 70% (odds ratio [OR], 0.67; 95% confidence interval [CI], 0.58–0.77), with the amount of decrease depending on the study conducted and the amount of folic acid used by study participants.[100] The neural tube closes between 4 and 6 weeks after the LMP; consequently, women are advised to start supplements in the preconception period if possible, and at the first prenatal visit if not already taking a prenatal supplement. The recommended dose is 400 micrograms per day for women who do not have an a priori risk for neural tube defects. Women who had a previous pregnancy complicated by an NTD are advised to take 4 milligrams of folic acid per day starting 1 month prior to conception and through the first 4 months of pregnancy.

Iron. Iron is the single most difficult nutrient to obtain via the diet during pregnancy, and iron

intake needs are approximately doubled during pregnancy.[101-103] However, unlike folic acid supplementation, routine iron supplementation is controversial. The CDC recommends routine iron supplementation, but other organizations suggest that supplementation should be started only for women who do not have normal hemoglobin values.[101-103] Iron supplementation increases plasma hemoglobin levels but does not affect overall maternal and neonatal outcomes unless iron is used specifically to treat anemia during pregnancy. Moreover, iron supplements frequently cause gastrointestinal distress.

Two types of iron exist: heme iron, which is found in meat, and non-heme iron, which is found in plants and, to a smaller extent, dairy products. Iron is absorbed via the mucosal cells in the jejunum. Approximately 20% to 30% of heme iron is absorbed without being affected by other dietary factors. Non-heme iron is more difficult to absorb; only approximately 2% to 10% is absorbed, and an acidic environment in the gastrointestinal tract is necessary to reduce the ferric iron to ferrous iron for absorption. Tannins found in tea, caffeine, and whole grains can adversely affect non-heme iron absorption. Absorption increases substantially in pregnancy, when more iron is used and iron stores are low.

The absorption of iron in prenatal vitamins can depend on the amount of calcium in the vitamin. For example, more iron may be absorbed from a vitamin with a lower iron content without calcium than from a vitamin containing both calcium and iron. The absorption of iron in supplements depends on the amount of elemental iron in the formulation, whether it is a quick-release or extended-release formulation, and whether the iron is in the ferric, ferrous, or iron polymaltose complex form.[104] Doses and side effects of various iron supplements are detailed in the *Nutrition* chapter.

Because iron absorption increases in pregnancy, some authors have proposed that intermittent iron supplementation may be preferable to daily iron supplementation. Exposure of the intestinal mucosal cells to iron supplements on an intermittent basis may improve iron absorption because these cells might absorb iron better if not exposed continuously. Randomized controlled trials of intermittent iron supplementation rather than daily iron supplementation demonstrated equally positive pregnancy outcomes when iron supplements were taken one to three times per week rather than daily.[102]

Iodine. Iodine deficiency can cause significant intellectual impairment but is rare in the United States, given that table salt and many common foods are routinely fortified with iodine. Nevertheless, many multivitamins contain iodine. Iodine supplementation during pregnancy is recommended by the American Thyroid Association.[105]

Vitamin D. Data on the effects of vitamin D supplementation are conflicting. Some studies have shown that vitamin D supplementation reduces the incidence of preeclampsia and preterm birth, but these data are preliminary and more research is needed.[106]

Prenatal Multivitamins. Prenatal multivitamins generally contain sufficient amounts of the vitamins and minerals that may be needed by a pregnant woman and, therefore, are a convenient vehicle for delivering those micronutrients. Prenatal multivitamins are specifically

recommended for women who are in one of the following categories: nutritionally inadequate diet, multiple pregnancy, cigarette smoker, addictive drug or alcohol use, adolescent, vegetarian, history of bariatric surgery, eating disorder, or lactase deficiency.

The amounts of specific vitamins and minerals in commercially marketed prenatal vitamins vary greatly, and there is no known advantage for one combination over another. With the addition of extra calcium and the omega-3 long-chain polyunsaturated fats (docosahexaenoic acid [DHA] and eicosapentaenoic acid [EPA]), many prenatal vitamins become difficult to swallow. Some manufacturers provide chewable vitamins, whereas others recommend twice-daily dosing. If calcium, iron, and omega-3 supplementation are needed, midwives might consider separate tablets for each nutrient needed.

Prenatal multivitamins can cause increased gastrointestinal distress and constipation in some women. These symptoms presumably arise secondary to the iron content in the vitamin. For women with nausea and vomiting, discontinuing iron-containing pills does appear to improve nausea symptoms.[107] When a prenatal vitamin is discontinued, even if temporarily, it should be replaced with a folic acid supplement.

Vitamins are not always beneficial. For example, vitamin A in large doses can be a teratogen. Initially the threshold for adverse effects was thought to be more than 25,000 IU of vitamin A daily, but studies have since shown that cranial neural crest anomalies may occur with as little as 10,000 IU daily. Routine supplementation of vitamin A is unnecessary, and, if supplementation is used, it should not exceed 5000 IU daily. Typical prenatal multivitamins contain at least 800 IU of vitamin A. Women should be cautioned not to double or triple their intake of multivitamins in an attempt to get additional folic acid or calcium. Increasing intake of a multivitamin increases intake of all of that product's constituents, including vitamin A.

Special Nutritional Needs

Vegetarians

The term *vegetarian* can encompass a number of subpopulations: women whose diets include dairy (lacto-vegetarians); those who eat eggs (ovo-vegetarians); and those who eat both dairy and eggs (lacto-ovo vegetarians). Individuals who strictly eat only foods from plant sources and do not use animal products such as leather can be called *vegans*. Women who eat any of the vegetarian diets can meet all their nutritional needs in pregnancy and have healthy birth outcomes,[108] although some modifications may be needed. In particular, a vegetarian diet during pregnancy may not provide the recommended daily amounts of iron, vitamin D, vitamin E, and choline.[109] Vitamin B_{12} intake can be adequate among women who consume eggs, dairy products, and fortified foods; without a regular source of vitamin B_{12}, however, vegan diets tend to have low levels of this vitamin, and possibly low levels of calcium. Women consuming a vegan diet need to be certain that they are receiving vitamin B_{12} from either fortified soy and rice beverages, fortified foods, or nutritional yeast supplements. Fermented soy products are not a source of vitamin B_{12}.

Iron from plant sources is non-heme iron; thus, it is less easily absorbed and more foods can inhibit its absorption than is the case with heme iron. Nevertheless, iron can be obtained in a vegetarian diet. Nonanimal sources of zinc include nuts and beans. Similar to what happens

with iron, phytates can bind zinc, thereby preventing absorption of this micronutrient. Another source of zinc is fortified cereals.

If no dairy products are consumed, pregnant women may not have adequate vitamin D levels and, in the absence of sufficient sunlight exposure, may need vitamin D supplements. Iodine, which comes from fish or sea vegetables and dairy, will be low if these foods or iodized salt are not part of the diet.

Studies have shown that vegetarian diets, and especially vegan diets, are lower in the omega-3 long-chain polyunsaturated fats, DHA and EPA, compared to an omnivorous diet. These fatty acids are essential for development of the retina and central nervous system. It is generally assumed that they must be obtained from diet, although the exact amounts needed per day and the adverse effects of deficiencies have not been determined.[110,111] Women who eat eggs can increase their DHA by consuming DHA-fortified eggs from hens fed microalgae; otherwise, women can consume microalgae-derived DHA supplements to obtain sufficient amounts of these fatty acids.

Women with Medical Conditions

Medical conditions that adversely impact nutrition during pregnancy include eating disorders,[91] a history of bariatric surgery,[92] conditions associated with malabsorption, or a need for medications that affect folic acid metabolism. The most likely nutritional deficiencies in women with medical conditions that diminish their ability to absorb nutrients have been identified. Midwives caring for these women will want to consult with a nutritionist to individualize their care.

Midwives are increasingly providing care for women after bariatric surgery. Two types of bariatric surgery procedures are commonly performed: (1) restrictive (laparoscopic gastric banding or Lap-Band) and (2) restrictive/malabsorptive (Roux-en-Y gastric bypass [RYGB]). Lap-Band slippage and movement can occur during pregnancy and result in severe vomiting. Some advocate for deflating the band prior to pregnancy to allow for adequate nutrition, though there are no national guidelines. Current recommendations advise women to wait 12 to 18 months after bariatric surgery before starting a pregnancy, so that weight loss is stabilized.[112]

Knowing the type of bariatric procedure done allows the midwife to provide appropriate nutritional advice and risk screening. Gestational weight gain recommendations are based on pregravid BMI even after bariatric surgery. Any type of malabsorptive surgery will reduce food, micronutrient, and medication absorption. In turn, deficiencies in iron, vitamin B_{12}, folate, vitamin D, calcium, and protein can be common after such surgery.

Baseline vitamin and mineral status of the pregnant woman post bariatric surgery is evaluated at the first prenatal visit, with supplements recommended as needed. A complete blood count and measurement of vitamin B_{12}, iron, ferritin, calcium, and vitamin D levels every trimester should also be considered.[112] The midwife providing prenatal care for a woman following bariatric surgery must effectively coordinate care among a network of clinicians, including maternal–fetal medicine physicians, nutritionists, and ultrasonographers. Such team-based care optimizes a woman's chance for a safe and satisfying birth.

Women who take anticonvulsant medications (e.g., valproate [Depakote, Depakene],

carbamazepine [Tegretol]) should take 4 milligrams of folic acid per day starting 1 month prior to conception and continue that regimen throughout the pregnancy, as these medications have an antifolate effect.

Multifetal Gestation

There are no national guidelines for the increases in other nutritional requirements for women with multiple pregnancies, but extrapolations have been made from singleton to twin pregnancies. It is generally recommended that women with multiple fetuses take two prenatal vitamin supplements beginning in the second trimester to obtain the additional iron, folate, calcium, magnesium and zinc that is needed.[113] This recommendation is safe as long as the vitamin A in the supplements is not retinol; if it is retinol, then the dose needs to remain less than 10,000 IU.

Pica

Pica is the term applied to the unusual condition in which an individual purposefully ingests nonfood items. Pica is more common in pregnant women than in women who are not pregnant. The prevalence of pica varies by geographic region and culture, but has been noted to affect as many as 50% of women in some settings.[114] The most common substances eaten are earth, clay, or dirt; raw starches such as cornstarch; and ice and freezer frost. The etiology of pica is unknown, although several theories exist. There is a clear association between ice-ingestion pica and iron-deficiency anemia, but it is not clear whether pica causes anemia or whether anemia triggers pica. Pica can cause lead poisoning and may be associated with other micronutrient deficiencies. Management consists of diagnosis and treatment of nutritional deficiencies, assessment of hunger or eating disorders, and health education.

Women with Limited Resources

Women with low incomes are at increased risk for dietary deficiencies. The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC)—an income-based, supplemental food program from the U.S. Department of Agriculture (USDA)—provides food resources and cultural-based nutrition education for pregnant women, breastfeeding women, infants, and children younger than the age of 5. WIC policy changes from 2009 aimed at consumption of healthier foods and access to farmers markets have improved access to fresh fruits and vegetables and improved dietary intakes among this program's participants. The program is also able to connect women with other important community resources to help improve their pregnancy outcomes. WIC is not an entitlement program, but rather a grant program that requires reallocation of funding annually. Therefore, changes may occur at any time based on federal and state funding.

Psychosocial Risk Screening and Counseling

Many nonbiologic factors affect mental and physical well-being during pregnancy. Screening for perinatal mental health disorders, substance abuse, and intimate-partner violence is sensitive and should be done in private. Screening should be performed early in pregnancy and repeated if there are indications the woman's situation has changed. Screening should be offered to all pregnant women regardless of race, ethnicity, or socioeconomic background.

Depression Screening

Depression is common among reproductive-age women. Untreated depression has been associated with adverse perinatal outcomes, impaired maternal–infant attachment, and disordered family relationships.[115] Screening for depression and anxiety is recommended for all pregnant women. Screening tools are reviewed in the *Mental Health Conditions* chapter.

Intimate-Partner Violence Screening

Screening for intimate-partner violence (IPV) deserves special note, because violence may begin during pregnancy, it may increase in severity, and women may need time to consider whether they want to reveal the violence during prenatal care.[116] Violence may take the form of threatened or actual physical, sexual, verbal, or psychologic abuse, and is more likely to escalate during pregnancy. Persons may be more vulnerable to the effects of violence while pregnant, due to their physical condition or their financial and emotional dependence. When a woman is exposed to violence, child abuse is also more likely to occur. Any individual can be the victim of violence, irrespective of her race, ethnicity, socioeconomic status, profession, sexual orientation, or gender identity.

It is recommended that women be assessed for the risk of intimate-partner violence at least once per trimester.[116] There are no reliable indicators of IPV, but women who are exposed to violence are more likely to have the following characteristics: late entry to prenatal care or missed appointments, nonmedical or excessive use of substances, sexually transmitted infections, poor weight gain and nutrition, multiple somatic complaints or hospital visits, and undesired pregnancy.

A variety of screening tools for IPV can be used, though all such screening should be conducted in private.[117] There is no single screening method or tool that has demonstrated consistently high sensitivity and specificity in screening for IPV, especially in outpatient settings with diverse populations. Midwives may choose to screen for IPV in a face-to-face interview, using a self-administered questionnaire, or using a computer-assisted self-interview.[118]

The midwife's primary role in working with a woman who is a victim of IPV is to assess her safety, to help her make a plan for safety if needed, and to accurately document her condition and refer her to appropriate resources. IPV is a very dangerous environment; when it is revealed, the midwife has an ethical responsibility to provide the woman with needed resources and to follow up as indicated. Midwives also need to be aware of legal reporting

requirements. In particular, child abuse is reportable in all jurisdictions in the United States.

Substance Use Screening

Screening for drug use, alcohol use, and smoking is often included while obtaining a general health history. Use of illicit drugs or illicit use of prescription drugs may cause fear of legal ramifications for the woman and her unborn child and delay presentation for care.

Smoking Cessation

Despite known adverse health effects associated with smoking, approximately 13.6% of women in the United States smoke.[119] Pregnancy is an ideal time to address smoking cessation. As many as 45% of women smokers do stop smoking during prenatal care, although the metabolism of nicotine during pregnancy is faster, which can make smoking cessation more difficult.

Smoking cessation interventions have been shown to lower the incidence of low-birth-weight infants and preterm birth.[119] Smoking cessation counseling via use of the 5 A's prenatal smoking cessation approach can be effective. A pilot study in West Virginia demonstrated a clear reduction in pregnant women's smoking after midwives were trained to use the 5 A's program.[120]

Behavioral interventions alone are not sufficient for the majority of women who try smoking cessation during pregnancy. Research on the effects of smoking cessation medications used during pregnancy is limited,[121] and the USPSTF has stated that the safety and efficacy of nicotine replacement products has not been sufficiently reviewed for use by pregnant women. Nonetheless, given the import of smoking cessation, the "window of opportunity" presented during prenatal care, and research evidence showing that nicotine replacement therapies can be effective during pregnancy, many providers offer nicotine replacement therapy. A summary of the therapies available and their pharmacologic effects can be found in recent reviews.[119,121,122]

At-Risk Alcohol Use

Fetal damage caused by maternal alcohol use ranges from mild to severe; thus, a general category known as fetal alcohol spectrum disorder has been described that encompasses the various forms of damage. Within this continuum, fetal alcohol syndrome is characterized by growth restriction, facial abnormalities, and central nervous system dysfunction. Fetal alcohol syndrome is one of the most common preventable causes of mental disability in the United States.

National guidelines in the United States and many other developed nations recommend that women do not consume alcohol during pregnancy. This recommendation reflects the fact that the dose–response relationship between alcohol intake and fetal effects is unknown. Alcohol freely crosses the placenta, and its elimination from both maternal and fetal systems is dependent upon maternal metabolism.

Surveys conducted by the CDC have found that 7.6% of pregnant women report using alcohol and 1.4% report binge drinking.[123] For women, at-risk drinking is defined as drinking more than three standard drinks on any day or exceeding seven standard drinks per week. A standard drink constitutes 5 ounces of wine (12% alcohol content), 12 ounces of beer (5% alcohol content), or 1.5 ounces of distilled liquor (40% alcohol content). No level of alcohol use is considered safe during pregnancy. All women should be screened for at-risk alcohol use; if a woman is identified to be at risk, the midwife should pursue her openness to intervention by using motivational interviewing techniques.[124]

Illicit Drugs

The complexity of individual motivations, the various physical reactions to drugs and their interactions, and the widespread tendency toward polypharmacy all contribute to the difficulty in assessing for substance abuse. Although many drugs can be used inappropriately, opioid use is a growing source of concern: The incidence of opioid dependency among pregnant women increased from 1.19 to 5.77 per 1000 hospital live births per year between 2000 and 2009 in the United States.[125]

Screening for substance use is recommended for all women early in pregnancy.[126] Several validated tools for substance use screening are available, as reviewed in the *Health Promotion Across the Lifespan* chapter. The care of a woman struggling with substance use requires collaboration with professionals in multidisciplinary programs who have skills in treating chemical abuse and addictions.

The factors that motivate recovery in a person who has been abusing drugs or alcohol are varied and unpredictable. Sometimes concern about a fetus during pregnancy may be the catalyst to begin the cycle of recovery. By providing ongoing care and support while recognizing the recovery/relapse pattern, the midwife can work to minimize maternal and fetal complications, encourage decreased substance use, and support the woman appropriately depending on where she is in the cycle of recovery.

Marijuana

Women’s reports of marijuana or cannabis product use during pregnancy may place the midwife in an awkward position. Marijuana is a legal medicinal and recreational product in a growing number of states, but remains illegal in others. Data indicating safety or harm to the fetus from maternal marijuana use during pregnancy are limited, which may lead women to believe marijuana is safe. Cannabinoids cross the placenta and have not been linked with fetal malformations, but a growing evidence base indicates that in utero exposure to marijuana may cause harm to the fetus.[127,128] ACOG advises cessation of cannabis use in pregnancy and lactation, even if prescribed for medicinal purposes.[129]

Health Education During Pregnancy

Health education about health promotion and health maintenance strategies is a core component of midwifery care for all women of all ages, as reviewed in the *Health Promotion Across the Lifespan* chapter. Nevertheless, many women do not access primary healthcare services until they are pregnant, and certain health promotion strategies are particularly important for fetal health. Therefore, prenatal care is considered one of the most opportune periods to address these health education topics. Health maintenance topics that are frequently of import to pregnant women are summarized in **Table 21-16**.[130-135]

Table 21-16 Health Maintenance During Pregnancy

Topic	Recommendations
Air travel	Air travel is not associated with known risks for healthy women. Flying increases the risk for venous thromboembolism; pregnant women are encouraged to wear support hose and/or move frequently if traveling a long distance.[130] Women with conditions that increase the risk for hypoxia, such as cardiac disease or fetal growth restriction, may need supplemental oxygen or should avoid flying.[130] It is safe to fly until 36 weeks' gestation, when the risk of spontaneous labor increases.[130]
Exercise and physical activity	Regular exercise is associated with cardiovascular fitness, prevention of low back pain, reduced symptoms of depression, and lower weight gain. Thirty minutes or more of moderate exercise per day is recommended for pregnant women. Avoid activities that increase the risk for falls or abdominal injury. Scuba diving and sky diving are not recommended.
Hair treatments	No data support a relationship between hair dye and teratogenic effects.
Hot tubs and saunas	Maternal fever or increased core temperature (> 102°F/38°C) is associated with an increased risk of neural tube defects (OR: 1.62; 95% CI: 1.10–2.17).[131] It takes approximately 10 minutes to raise the core temperature to > 40°C (104°F) in water of 40°C (104°F) and 15 minutes if the water temperature is 39°C (102°F).[132] Hot tubs should be avoided in the first trimester.
Medication use	Although only a few medications are known teratogens, the safety of most medications for use in pregnancy has not been proven. Women are counseled to check with a midwife or other healthcare provider before using medications or over-the-counter treatments.
Oral health	Pregnancy-associated changes increase a woman's risk of dental caries. Pregnancy-associated gingivitis increases the risk of developing periodontal disease. Women should be encouraged to see a dentist if it has been > 6 months since their last dental examination, or if they are experiencing any dental problems.[133] Dental X rays are safe if the abdomen and thyroid are shielded which is standard procedure. Treatment for most dental disorders can be performed during pregnancy.
Seat belts	Three-point seat belts are recommended. The lap belt is placed across the hips and below the uterus. The shoulder belt is placed between the breasts and lateral to the uterus.[134]
Sex during pregnancy	Sexual intercourse is not associated with adverse pregnancy outcomes. Sexual intercourse is contraindicated for women with a placenta previa, preterm labor, or ruptured membranes.[135]

Employment During Pregnancy and Maternity Leave

Working during pregnancy is generally quite safe. Information about the most common workplace hazards (e.g., anesthetic gases, formaldehyde, heat, night shifts or long work hours)

is available from the CDC.[136] Clinical guidelines for occupational lifting have been published and are shown in **Figure 21-3**.[136-138] Women who work in high-risk occupations and women who have medically complicated pregnancies can obtain work accommodations to assure safety.[139] The Pregnancy Discrimination Act of 1964 protects pregnant women from being fired secondary to being pregnant. It is also illegal to ban a woman from a particular job if she might become pregnant. Complaints about pregnancy discrimination are filed with the U.S. Equal Employment Opportunity Commission.

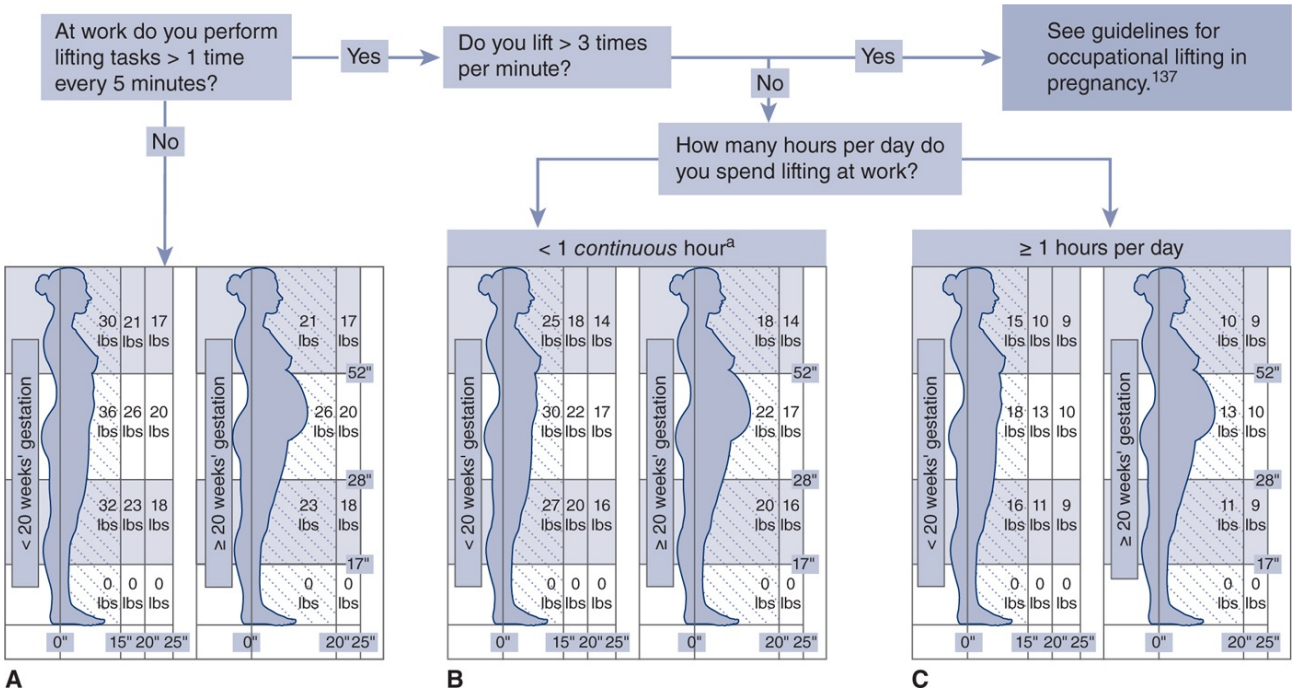

Figure 21-3 Provisional recommended weight limits for lifting at work during pregnancy. A. Infrequent lifting. B. Repetitive short duration lifting. C. Repetitive long duration lifting.

[a] Repetitive short duration lifting can encompass multiple hours of lifting per day; however, each continuous lifting period should be < 1 hour and followed by a minimum of 1 hour of nonlifting activity before the next continuous lifting period is initiated.

Reproduced with permission from MacDonald LA, Waters TR, Napolitano PG, et al. Clinical guidelines for occupational lifting in pregnancy: evidence summary and provision recommendations. *Am J Obstet Gynecol.* 2013;209(2):80-88.[137]

Laws and eligibility requirements governing pregnancy-related disability for childbirth vary by state. Maternity leave benefits are usually a combination of short-term disability, sick leave, vacation, and unpaid leave. Not all jobs offer maternity leave benefits. Although the federal Family Medical Leave Act (FMLA) mandates that individuals receive 12 weeks of unpaid leave for childrearing in a 12-month period, many women are not eligible for FMLA benefits. A current list of state laws and regulations regarding maternity leave benefits is included in the Resources section at the end of this chapter.

Environmental Exposures

The primary environmental exposures of concern in pregnancy are lead, mercury, ionizing and

non-ionizing radiation, and endocrine disruptors such as phthalates. A thorough review of environmental toxins and teratogens is presented in the *Preconception Care Visit* appendix in in the *Health Promotion Across the Lifespan* chapter. **Table 21-17** summarizes the environmental exposures for which there is the most evidence of adverse pregnancy effects.[140-146]

Table 21-17 Environmental Exposures with Adverse Pregnancy Effects

Exposure	Fetal Effects
Endocrine disrupters	Endocrine disrupters are chemicals that mimic or disrupt the effects of hormones such as estrogen, androgen, and thyroid in a way that results in adverse effects on development, reproduction, neurologic function, or immunity. The primary endocrine disrupters of concern for pregnant women are bisphenol A (BPA) and phthalates. Current evidence suggests that BPA and phthalates might potentially have adverse effects on a fetus, based on animal studies and effects on wildlife. To avoid these risks, women are counseled to use BPA-free baby bottles, avoid microwaving plastic containers, avoid use of plastic containers with the number 3 or 7 on the container, and limit intake of foods packaged in cans.[140] Phthalates are used to make soft plastics such as cling wrap, some baby toys, many cosmetics, and polyvinyl tubing. The most common phthalate, di(2-ethylhexyl) phthalate (DEHP), is currently voluntarily being removed by some manufacturers from baby toys.
Ionizing radiation (X ray)	X rays used in flat-plate imaging and computed tomography (CT) scans expose women to ionizing radiation that can damage DNA. High levels of exposure to ionizing radiation during organogenesis can cause congenital anomalies, and exposure to high doses up to 25 weeks' gestation can cause fetal growth restriction, mental retardation, and—at very high doses—death or stillbirth. Fetal effects are dose dependent, but are not noticeable when the exposure is < 0.05 Gy (5 rads).[141] Routine X rays expose the fetus to very low doses of ionizing radiation, with a chest X ray providing approximately 0.00007 rad.[142] Exposure in the first 2 weeks after conception is an "all or nothing" phenomenon: It either is fatal or has no adverse effects. Therefore, women can be assured that accidental exposure to one diagnostic X ray will not cause fetal harm.[143] If X-ray exposure has occurred, the woman can be referred to a radiologist who will calculate the exact dose and counsel her appropriately. Ultrasound and magnetic resonance imaging (MRI) are the imaging modalities of choice for imaging during pregnancy, but X rays and CT scans may be recommended if indicated and necessary for medical management.[143]
Lead exposure	Potential lead exposure from contaminated water supplies, outdated lead water pipes, and post-industrial soil contamination is widespread in the United States, and other countries.[144] Elevated lead levels are associated with miscarriage, gestational hypertension, low birth weight, and impaired neurodevelopment in offspring. Both chronic and acute lead poisoning can be dangerous during pregnancy, because lead is stored in bone and pregnancy is a time of increased bone turnover.[145] Although routine screening for lead exposure is not indicated, women who have risk factors for lead exposure are offered screening. Risk factors include drinking contaminated water; using water from outdated water pipes; dust exposure from home renovation or old, chipping paint; pica; gardening in soil contaminated by former industry; folk medications made outside of the United States; and use of unglazed pottery. Maternal venous lead levels of < 5 mcg/dL do not require any further follow-up. Women whose levels are between 10 mcg/dL and 45 mcg/dL should have the source of lead identified and be retested within a month, then within 1 month to 3 months, following the schedule recommended by the CDC.[145] Women whose lead level is > 45 mcg/dL are referred to a clinician who specializes in caring for individuals with lead toxicity.
Mercury exposure	Mercury exists naturally in the environment but is also a pollutant resulting from industrial processes. Excess mercury can impair neurologic development in a fetus. The primary source of mercury today is the methylmercury that accumulates in large fish. Pregnant

	women are counseled to avoid consumption of king mackerel, marlin, orange roughy, shark, swordfish, tilefish (Gulf of Mexico), and tuna (bigeye). In addition, women are advised to avoid fish caught by family and friends, unless local advisories have been reviewed. A former source of mercury was the thimerosal in vaccines. All vaccines offered to pregnant women and infants are now thimerosal free.
Non-ionizing radiation	Ultrasound, microwaves, electric blankets, computers, cell phones, and airport screening devices for metal all emit non-ionizing radiation. Exposure to non-ionizing radiation has not been shown to cause fetal harm.[146]

Infection and Disease Protection

Pregnant women, like all individuals, are exposed to infectious organisms. Some infections can harm a fetus or newborn, whereas others are more likely to cause serious or life-threatening illnesses in a woman during pregnancy if she becomes infected.

- Infections that can harm the fetus include listeriosis, parvovirus, rubella, syphilis, varicella, cytomegalovirus, and toxoplasmosis. Herpes and group B *Streptococcus* infection can be harmful to the newborn if infected at the time of vaginal birth. Zika virus, noted in late 2015 to be associated with congenital microcephaly, is an example of an emerging viral teratogen.[147]
- Influenza and varicella can become severe illnesses in pregnant women and are associated with an increased risk of maternal death.

Health education related to infection precautions is described in **Table 21-18**.[148-154] Additional information about management of exposure to these infections in nonimmune individuals is discussed in the *Medical Complications in Pregnancy* chapter.

Table 21-18 Prevention of Infection During Pregnancy

Disease-Causing Agent	Prevention Measures
Cytomegalovirus	Wash hands after changing a diaper or handling body fluids of an infant or toddler.
Herpes	Avoid sexual contact with persons who have active herpes lesions.
Listeriosis	Wash all raw vegetables before eating. Do not consume unpasteurized milk or soft cheeses made with unpasteurized milk. All meat, including precooked deli meats, should be properly heated before eating. Avoid smoked seafood and salads made in stores, such as ham and chicken salads, as *Listeria* can grow slowly at refrigerator temperatures.
Parvovirus B19 (fifth disease or slap-cheek disease)	Teachers, childcare workers, and others who work with children are at risk. Avoid contact with a child who has this illness.
Pertussis (whooping cough)	Teachers, childcare workers, and others who work with children are at risk. Avoid contact with a child who has this illness unless immunity is known. Vaccination during each pregnancy is recommended.
Rubella	Avoid contact with a child who has this illness unless immunity is known.
Toxoplasmosis	Avoid cleaning cat litter boxes. If this task cannot be avoided, wear gloves. Wash hands after

	cleaning and working in dirt or soil unless gloves are worn. Do not eat raw or uncooked meat.
Varicella (chickenpox)	Avoid contact with a child who has this illness unless immunity is known.
Zika virus	Avoid travel to areas where the *Aedes* mosquito is epidemic.

Based on Meaney-Delman D, Rasmussen SA, Staples JE, et al. Zika virus and pregnancy: what obstetric health care providers need to know. *Obstet Gynecol*. 2016;124(4):642-648[150]; Madjunkoy M, Chaudhry S, Ito S. Listeriosis during pregnancy. *Arch Gynecol Obstet.* 2017;296(2):143-152[151]; Sugishita Y, Akiba T, Sumitomo M, et al. Shedding of rubella virus among infants with congenital rubella syndrome born in Tokyo, Japan, 2013–2014. *Jpn J Infect Dis.* 2016;69(5):418-423[152]; Neu N, Duchon J, Zachariah P. TORCH infections. *Clin Perinatol.* 2015; 42(1):77-103[153]; Feldman DM, Keller R, Borgida AF. Toxoplasmosis, parvovirus and cytomegalovirus in pregnancy. *Clin Lab Med.* 2016;36(2):407-419.[154]

Immunizations

Maternal immune antibodies of the IgG class cross the placenta and generally confer passive immunity to the fetus. Vaccines that are composed of inactive antigen ingredients or toxoid are safe for use in pregnancy, whereas live-attenuated vaccines have a small risk of causing disease and are not recommended for use by pregnant women. Vaccines that are recommended and those that are contraindicated during pregnancy are listed in **Table 21-19**.[155]

Table 21-19 **Immunizations That Are Recommended or Contraindicated During Pregnancy**

Vaccine	Recommended in Pregnancy	Type of Vaccine
Hepatitis A	If at risk[a]	Inactivated
Hepatitis B	If at risk[b]	Inactivated
Human papillomavirus (HPV)	No[c]	Inactivated
Influenza, trivalent inactivated vaccine (TIV)	Recommended for all women during pregnancy	Inactivated
Influenza, live attenuated vaccine (LAIV)	Contraindicated	Live
Measles, mumps, rubella (MMR)	Contraindicated	Live
Meningococcal: polysaccharide or conjugate	If indicated	Inactivated
Pneumococcal polysaccharide	If indicated	Inactivated
Tetanus/diphtheria (Td)	Yes, but Tdap preferred if > 20 weeks' gestation	Toxoid
Tetanus/diphtheria/pertussis (Tdap), one dose only	Recommended for all women during each pregnancy, irrespective of having received the vaccine previously	Toxoid/inactivated
Varicella	Contraindicated	Live

[a] The hepatitis A vaccine is considered safe for pregnant women. It is recommended only if the woman has a high risk of exposure.

[b] Risk factors for hepatitis B include having more than one sex partner during the previous 6 months, having been

evaluated or treated for a sexually transmitted disease, recent or current injection drug use, or having had a hepatitis B surface antigen–positive sex partner.

[c] If a woman is in the middle of the HPV vaccine series and becomes pregnant, the rest of the series is delayed until after the pregnancy.

Based on Kim DK, Riley LE, Harriman KH, Hunter P, Bridges CB; ACIP Adult Immunization Work Group, Centers for Disease Control and Prevention. Advisory Committee on Immunization Practices recommended immunization schedule for adults aged 19 years and older—United States, 2017. *MMWR Surveill Summ.* 2017;66:5.[155]

All pregnant women and their immediate family members are offered vaccination for tetanus, diphtheria, and pertussis (Tdap) during pregnancy to protect the newborn from pertussis until infant vaccination is complete.[156] Annual influenza vaccines are offered during pregnancy in the fall before the spring influenza season. If women are in the middle of the hepatitis B series when they become pregnant, they are counseled to finish the series. In contrast, women who are in the middle of the human papillomavirus (HPV) vaccine series are counseled to wait until the pregnancy is over before finishing this series. Additional vaccines can be given during pregnancy if the woman is at increased risk for specific infections.

The topic of vaccine safety is important to the woman, her fetus, and her newborn. Controversies about purported associations between vaccines and methylmercury poisoning and between vaccines and autism have been reviewed extensively. Although thimerosal was not shown to be harmful in the amounts used in vaccines, it has been removed from all vaccines administered to pregnant women and children so vaccines no longer expose individuals to methylmercury.[157] The hypothesized relationship between vaccines and autism has been found to be spurious.[158]

Preparing for Birth

Health education topics specific to preparing for labor, birth, and parenting include discussions of where to give birth, what to expect during labor and birth, childbirth education classes, newborn feeding and newborn procedures such as circumcision, and preparing the home for the newborn (**Table 21-20**).

Table 21-20 Health Education Topics: Preparing for Birth

Topic	Recommendations
Birth place	Individual choice and prenatal risk screening can assist women in choosing a location for the birth: home, birth center, or hospital. Birth place arrangements are finalized in the third trimester.
Car seats	Car seats are required by state law in all states, for children up to specific age and weights. State laws vary. Infants should ride in a rear-facing seat until age 2 years. State laws for car seats can be found at http://www.iihs.org/iihs/topics/t/child-safety/topicoverview.
Circumcision	The American Academy of Pediatrics states that the health benefits of circumcision outweigh the risks of this procedure, but the benefits are not great enough to recommend routine circumcision of all male newborns. (See the *Neonatal Care* chapter.)
Newborn examinations and tests	Some examinations, tests, and immunizations such as eye prophylaxis, newborn hearing screening, and vitamin K administration are offered to newborns in the first few days after birth. A review of these tests and their purpose during prenatal visits can help women prepare and make informed choices about the tests.

Postpartum contraception	Some forms of contraception can be initiated in the immediate postpartum period. A discussion of options and timing for initiation is best started in the prenatal period.
Preparing for feeding the infant	Breastfeeding or chest-feeding is recommended unless medically contraindicated. Infants can thrive if not breastfed. It is important to respect personal choice and informed decision making.

Childbirth Preparation Classes

One could argue that childbirth education has existed forever in the form of information shared by women and midwives. Even today, pregnant women obtain the majority of the information they receive about birth from electronic media, books, or friends and family, rather than healthcare providers or childbirth educators.[159] Nevertheless, childbirth education classes, like prenatal vitamins, are generally recommended, albeit without strong evidence for their effectiveness.

In the United States, the first formal childbirth classes in the early 1900s focused on preparation for parenting, nutrition, and health care.[160] Formal childbirth preparation classes that addressed how to cope with labor first started in the United States in 1947, when the Maternity Center Association in New York sponsored Grantly Dick-Read's visit to the United States. Dick-Read's work served as the foundation for the different models of childbirth preparation taught today.[159] The focus of the childbirth preparation techniques was originally to teach women about the process of labor and to give them techniques for coping with labor pain, with the goal of having an unmedicated birth. Today, most childbirth classes also teach women about medical procedures that can occur during labor; the focus on having an unmedicated birth varies with the particular technique. **Table 21-21** briefly outlines the different types of childbirth education classes that are taught today.[160]

Table 21-21 Comparison of Childbirth Education Models and Organizations

Childbirth Education Model	Description
Lamaze Childbirth Education	Goal: increase confidence in giving birth by focusing on how to cope with labor pain Natural childbirth Breathing techniques used to enhance relaxation and decrease perception of pain Communication skills Evidence based Comfort measures Information about prenatal procedures Breastfeeding encouraged
Bradley Method (husband-coached childbirth)	Goal: facilitate natural birth via breathing techniques and partner support Natural childbirth Partner's active participation Avoidance of medications and medical procedures Nutrition and exercise

	Relaxation techniques, guided imagery, and coping mechanisms
	Immediate contact with newborn and immediate breastfeeding
	Six needs of laboring women: darkness and solitude; quiet; physical comfort during the first stage of labor; physical relaxation; controlled breathing; need to close eyes with the appearance of sleep
International Childbirth Education Association (ICEA)	Family-centered maternity care
	Freedom of choice
	Alternatives in childbirth
	Draws from other models
HypnoBirthing, Mongan Method	Calm, peaceful, natural childbirth
	Relaxation techniques and negate the fear–tension–pain cycle
	Education
	Evidence based
Mindfulness-Based Childbirth Preparation (MBCP)	Mindfulness techniques used to help individuals and their support persons cope with labor
	Meditation and yoga
	Stress reduction, awareness, and breathing
	Group dialogue
Birthing From Within	Natural childbirth goal
	Based on *primordial knowing* (knowledge of body) and *modern knowing* (knowledge of medical culture and how to give birth within this culture)
	Soulful and holistic approach
	Creative self-expression via artwork and journaling
	Instructor and couples co-create class together
	Coping with challenges
Hospital-based classes	Instructors can be certified in Lamaze, ICEA, or other childbirth education technique
	Philosophy of childbirth educators varies
	Increased focus on institutional policies and procedures with medical procedures information
	Breathing, relaxation, and massage technique

Modified with permission from Walker DS, Visger JM, Rossie D. Contemporary childbirth education models. *J Midwifery Womens Health.* 2009;54(6):469-471.[160] © 2009, with permission from Wiley.

The effectiveness of childbirth education has proved difficult to determine, as the goals of the programs are all somewhat different and there may exist differences between groups of women who seek classes and those who do not. Overall, formal childbirth education appears to improve knowledge, lower anxiety, and increase self-efficacy. The effect of childbirth education on perception of labor pain is modest at best.

Preparing for Breastfeeding

Breast milk is the optimal form of nutrition for newborns and infants. Prenatal breastfeeding education has multiple benefits that include higher rates of breastfeeding exclusivity and duration.[161] Although most women initiate breastfeeding in the immediate postpartum period, some individuals choose not to breastfeed. The discussion of infant feeding plans is a process of shared decision making.

Prenatal breastfeeding education has multiple components and is best done over several

visits. **Table 21-22** summarizes the topics included in the prenatal assessment. Through this assessment, the midwife can identify contraindications to breastfeeding, the woman's goals for infant feeding, and any previous experience with breastfeeding. Further discussion can then be tailored to the individual and the midwife can help the woman develop a plan for addressing problems that may be anticipated.

Table 21-22 Prenatal Assessment for Breastfeeding

Medical, Surgical, and Psychosocial History
Past medical history of PCOS, diabetes, or condition that requires medications which might affect breastfeeding.
Contraindications to breastfeeding (maternal infectious disease such as HIV or untreated TB, or required medications that are contraindicated during breastfeeding such as statins)
History of breast surgery including augmentation or reduction
Breast cancer: mastectomy or lumpectomy
History of physical, sexual, or psychological abuse
Breastfeeding History
Plan regarding breastfeeding
Prior unsuccessful breastfeeding
Family or support persons attitudes toward breastfeeding
Physical Examination
Breast size, symmetry, and shape; any scars or abnormalities
Nipple type, texture, and extensibility

Abbreviations: HIV, human immunodeficiency virus; PCOS, polycystic ovary syndrome; TB, tuberculosis.

Any history of sexual trauma or abuse should be discussed with regard to the plan for breastfeeding once a therapeutic relationship has been established because it may trigger underlying stressors that could affect the breastfeeding relationship.

Colostrum discharge may be noted after about 16 weeks' gestation. Colostrum may be clear, yellowish, or milky, and signals normal changes consistent with preparation for lactation. However, inability to express colostrum prenatally should not be interpreted as a sign of pending lactation failure.

Significant breast asymmetry or a wide space between breasts may be a marker for marginal or inadequate functional tissue. Wide variations exist in nipple configuration, size and shape. Preparation of the nipple tissue is unnecessary and has not been proven to be beneficial. Likewise, the prenatal use of breast shields for women who have inverted nipples does not improve breastfeeding outcomes and are not recommended. A postpartum consultation with a lactation consultant may be of benefit for women with unusual breast configurations or inverted nipples.

Postpartum Contraception

The initial conversation about postpartum contraception begins prenatally. Women often think about their family size during the third trimester. Intentions about future pregnancies can be

explored, and the recommendation reviewed that pregnancies be spaced by at least 18 months, or 2 years in the case of cesarean section.

Contraceptive choices may also depend on infant feeding choice. Some women assume that pregnancy cannot occur while they are breastfeeding and not menstruating. Women should be informed that they may have a return to fertility prior to the return of menses. Also, health education should note that breastfeeding does not reliably prevent pregnancy, even if it prevents return of regular menses, unless the requirements of the lactational amenorrheic method are met as outlined in the *Nonhormonal Contraception* chapter.

While postpartum contraception is traditionally initiated at the 6-week postpartum visit, progesterone-only methods can be initiated in the immediate postpartum period, including Depo-Provera and long-acting reversible contraception (LARC). Women unlikely to attend a postpartum visit can be offered immediate postpartum initiation to help them prevent an unintended pregnancy. A delay in the initiation of estrogen-containing contraceptives is recommended until 8 weeks postpartum to decrease the risk of thromboembolism. More information on contraceptive choices is included in the *Family Planning* chapter.

Preparation of the Home

Women often have questions about items needed for child care. Current American Academy of Pediatrics recommendations state that the infant should sleep on his or her back in a separate crib or bassinet with a firm sleep surface, preferably in the same room with the parent for the first year of life.[162] Many women, while aware of the recommendations for safe sleep, choose to co-sleep with their infant, which provides an opportunity for a discussion of safe sleep practices.

An infant car seat is required by law for all infants placed in cars, and checking for one is often a part of the discharge process after a hospital birth. Car seats and bassinets are sometimes available through health insurance companies or local programs for women with limited resources.

Conclusion

Although protocols and guidelines abound, prenatal care is more than a simple series of visits with scripted interventions. In reality, the complex nature of a pregnant person's experience requires flexible and knowledgeable midwifery care and a multifaceted approach. For the midwife, prenatal care requires an extensive knowledge of pregnancy, a broad understanding of common primary care topics, and recognition of the continuum of mental health states.

The midwife caring for a pregnant woman continually multitasks, holding several different perspectives at the same time, simultaneously offering support and health education, conducting ongoing risk assessment, and monitoring normal fetal development and pregnancy changes. Integrating these perspectives and helping women empower themselves, all in a short series of visits, is a unique and rewarding undertaking.

The components of the abdominal examination in pregnancy include (1) abdominal inspection and palpation; (2) measurement of fundal height; (3) Leopold's maneuvers for determining fetal lie, presentation, position, variety, and engagement; (4) estimation of fetal weight; and (5) detection of fetal heart tones.

While ultrasound can effectively be used to assess fetal growth and position—and should be used when discrepancies arise or assessment is challenging—being able to employ one's hands to gain information about the progress of a pregnancy is an invaluable skill. The standard descriptions in this appendix assume a woman of normal habitus and a singleton pregnancy. Maternal height and weight, uterine abnormalities, fetal growth pattern, and multiple pregnancies are all factors that can challenge interpretation of clinical findings and their effects are discussed.

Equipment

- Measuring tape with centimeter increments
- Pinard, Allen, DeLee, or Doppler fetoscope

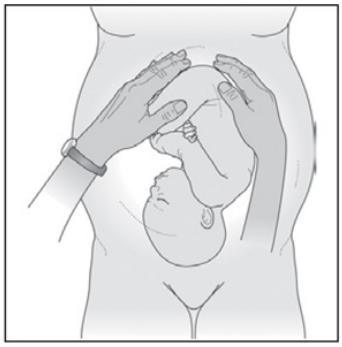
Abdominal Inspection

The following aspects of the abdomen are noted during inspection:

1. Surgical scars. The scar of a previous cesarean section is of particular importance; it may be either vertical or horizontal. It is useful to know if the woman has undergone an appendectomy so that appendicitis can be ruled out in the event of right-sided abdominal pain during the pregnancy.
2. Bruises or abrasions. Document a description and location of any bruises and discuss their origin with the woman, paying particular attention to the possibility of intimate-partner violence and abuse.
3. Linea nigra. This hyperpigmented vertical line on the lower abdomen may be visible by approximately 20 weeks' gestation, or it may be faintly present from a previous pregnancy and begin to darken in the first trimester. The linea nigra will fade during the first 6 months postpartum.
4. Striae gravidarum. Many women develop these pink or red streaks during pregnancy as the dermis is stretched. Silvery white streaks may be present from previous weight changes or previous pregnancy.
4. Abdominal contours give some initial indication of the fetal lie, presentation, position, and attitude, although none of the following observations is diagnostic:
    a. Uterine shape is a longitudinal ovoid: Fundal height in the expected range suggests a longitudinal lie.
    b. Uterine shape is a transverse ovoid: Fundal height lower than expected for gestational age may indicate a transverse lie, fetal growth restriction, or oligohydramnios.
    c. A long smooth curve prominent on one side of the abdomen suggests that the back of the fetus is on that side of the abdomen.
    d. A saucer-like depression appearing just below the umbilicus and a bulge like a full bladder appearing above the symphysis pubis suggests a possible occiput posterior position or maternal full bladder.
    e. Movement of fetal small parts seen all over the abdomen suggests an occiput posterior position.

Abdominal Palpation

The midwife may palpate these structures during physical examination:



1. Diastasis recti (midline separation of the rectus abdominus muscle) presence and width are palpated by placing one or two fingers parallel to the abdominal midline, just below the epigastric region, and feeling the separation of the rectus abdominis muscle after asking the woman to lift her head while lying supine. This examination is routinely performed at the postpartum visit but may also be useful at the first prenatal visit, especially for a multiparous woman, as she may have a persistent diastasis recti.
2. Umbilical hernia (intestinal protrusion through a separation in the abdominal muscles behind the umbilicus) can be detected on palpation at any time during pregnancy.
3. Uterine muscle tone (hard versus soft), contractions (palpable or not palpable), and

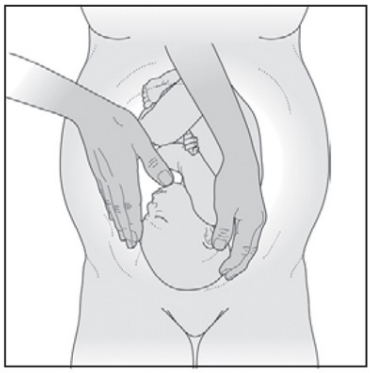
tenderness are evaluated to assess for signs of preterm labor in the second and third trimesters, for signs of labor after 37 weeks' gestation, and for signs of infection.

4. Amniotic fluid volume. When performing an abdominal examination, the midwife can estimate the quantity of amniotic fluid by placing one hand on each side of the uterus and gently pushing first on one side of the uterus, then the other. A fluid wave or thrill might be palpated depending on gestational age, size and position of the fetus, and amount of fluid present. If a woman has polyhydramnios, it will be difficult to palpate small parts of the fetus and may be difficult to determine fetal position. The opposite will be true if a woman has oligohydramnios.

Leopold's Maneuvers

The process of evaluating fetal lie, position, and presentation with Leopold's maneuvers also offers the opportunity to assess the abdomen for muscle tone, uterine tone and contractility, and palpable fetal movement, and to estimate fetal weight. The four Leopold's maneuvers and the combined Pawlik's grip are shown in **Figure 21A-1**.

First maneuver. Identify the part of the fetus that resides in the fundus. Curve fingers of both hands around the top of the fundus.



Second maneuver. Identify the location of the small parts and fetal back. Place both hands on the side of the uterus.

Third maneuver. Identify the presenting part. With the thumb and middle finger of one hand, press gently but deeply into the woman's abdomen immediately above the symphysis pubis and grasp the presenting part.

Fourth maneuver. Check whether the presenting part is engaged and the location of the cephalic prominence. Place both hands on the sides of the lower uterus, press deeply, and move the fingertips toward the pelvic inlet.

Combined Pawlik's grip. Combine Leopold's third maneuver with one hand and palpation of the fundus using the other hand. Compare the two poles for final determination of lie and presentation.

Figure 21A-1 The four Leopold's maneuvers and the combined Pawlik's grip.

Photos reproduced with permission from Jenifer Fahey.

Key Points

1. The woman's bladder should be empty.
2. The woman's abdomen is typically exposed from just below the breasts to the symphysis pubis. Provide privacy and consider cultural variations in comfort with exposure of skin. Ask the woman to move her clothing instead of doing it for her. This allows her to control the extent and amount of skin exposure.
3. Relaxation of the abdominal muscles can be facilitated by:
   a. Placing a pillow under the woman's head and upper shoulders
   b. Asking her to place her arms by her sides or across her chest

c. Having her bend her knees slightly

4. Before palpating, the midwife lightly rests her hand on the woman's abdomen (**Figure 21A-2**). This action gives the woman an opportunity to adjust to the sensation of the midwife's touch and allows any initial muscle-tightening reaction to dissipate.

Figure 21A-2 Midwife preparing to do an abdominal palpation.

Procedure for Leopold's Maneuvers

First Maneuver: Determine Fetal Lie and Presentation

Facing the woman's head, palpate the area of the uterine fundus, noting the shape of the fetal part in the fundus. A fetal part that feels round and hard, and that can be balloted between the midwife's fingers or hands, suggests a fetal head. The mobility arises from the head being able to move independently of the trunk. A fetal part that feels irregular, larger or bulkier, and less firm than a head, and that cannot be well delineated or readily moved or balloted, suggests the fetal breech. The breech cannot move independently of the trunk. In these cases the lie is longitudinal. If neither of the preceding conditions is felt in the fundus, a transverse lie may be present.

Second Maneuver: Determine Location of Fetal Back

1. Continue to face the woman's head. Place the hands on both sides of the uterus about midway between the symphysis pubis and the fundus.
2. Apply slight pressure with one stabilizing hand against the side of the uterus, thereby

pushing the fetus to the other side of the abdomen against the examining hand and stabilizing it there. Maintain this pressure while the examining hand palpates the side of the uterus to identify fetal parts.

3. Palpate the entire area with the examining hand, from the abdominal midline to the lateral side, and from the fundus to the symphysis. Use firm, smooth pressure and rotary movement.
4. Reverse the procedure to examine the other side of the uterus.
5. The flat palmar surfaces of the fingers are used for palpating—*not* the fingertips. Smooth, deep pressure is used—as firm as is necessary to obtain accurate findings without causing pain or discomfort.

A firm, convex, continuously smooth, and resistant mass extending from the breech to the neck indicates the fetal back. The location of the back in the anterior, lateral, or posterior portion of the abdomen helps to determine the variety (position). Small, knobby, irregular masses that might move when pressed on suggest the fetal small parts—hands, feet, knees, elbows. When palpating the uterus, the fetal small parts should be opposite the fetal back. If the back is difficult to feel and seems to be just out of reach in the posterior portion of the abdomen, and small parts are palpable all over the abdomen, a posterior position may be present.

Third Maneuver: Determine the Fetal Presentation and Engagement

The third maneuver is called *Pawlik's grip*. Clasp the lower abdomen immediately above the symphysis pubis between the thumb and middle finger of one hand with the thumb and middle finger spread so they start the procedure as far laterally into the inguinal area as possible. It will be necessary to press gently but firmly into the abdomen to feel the presenting part between the thumb and finger. Pawlik's grip can be uncomfortable and may be omitted as the fetal presentation can be determined with the fourth maneuver. A kicking motion palpated in the fundus during Pawlik's grip increases confidence that the presentation is cephalic.

If the fetal head is above the pelvic brim, it is readily movable and ballottable, as described for the first maneuver. A procedure that is sometimes added to this maneuver is called the combined Pawlik's grip, in which Pawlik's grip is utilized with one hand and the fundus is grasped in the same way with the other hand at the same time (**Figure 21A-3**). This combination enables the simultaneous comparison of what is in the two poles for final determination of the fetal lie and presentation.

Figure 21A-3 Combined Pawlik's grip.

Reproduced with permission from Jenifer Fahey.

Fourth Maneuver: Cephalic Prominence and Fetal Attitude

1. Turn and face the woman's feet.
2. Place both hands on the sides of the uterus with the palms just above the symphysis and iliac crest with the fingers directed toward the symphysis pubis.
3. Press with the fingertips into the lower abdomen slowly but firmly, and move them toward the pelvic inlet to determine the *cephalic prominence*; note if it is on the side of the fetal back or fetal front. If the cephalic prominence is on the same side as the fetal small parts, the fetal *attitude* is flexed and the fetal head is tucked toward the chin. If the presentation is vertex and the cephalic prominence is on the same side as the fetal back, the fetus is in a face or brow presentation.

At the conclusion of the four maneuvers, share the findings with the woman, and offer to help her feel and identify various parts of her fetus if she would like.

Estimation of Fetal Weight

Estimated fetal weight (EFW) is used during the prenatal period, particularly after 30 weeks' gestation, as one clinical measurement in the overall evaluation of gestational age and progressive fetal growth. During Leopold's maneuvers, the midwife can compare the palpated fetal size to known volumes such as a liter bag of IV fluid, a 5-pound bag of flour, or a gallon jug of milk to estimate size. Neither experienced hands nor an ultrasound is necessarily more

accurate than the other method when assessing fetal weight in a full-term fetus. The EFW is important in the intrapartum period, when this estimation is compared with the clinical evaluation of the pelvis to ascertain the adequacy of a woman's pelvis. Estimating fetal weights and comparing those estimations to ultrasound estimations or birth weights for feedback sharpens a midwife's skill in estimating fetal weight.

Auscultation of Fetal Heart

The sound of the fetal heart is transmitted best through the convex portion of the fetus closest to the anterior uterine wall, which is usually the fetal back. Thus, if the position of the fetus is known, fetal heart tones can be readily located, allowing for some variation depending on how far the fetus has descended into the pelvis (**Figure 21A-4**). Location of the fetal heart is an additional piece of data that either confirms or calls into question the diagnosis of fetal presentation and position.

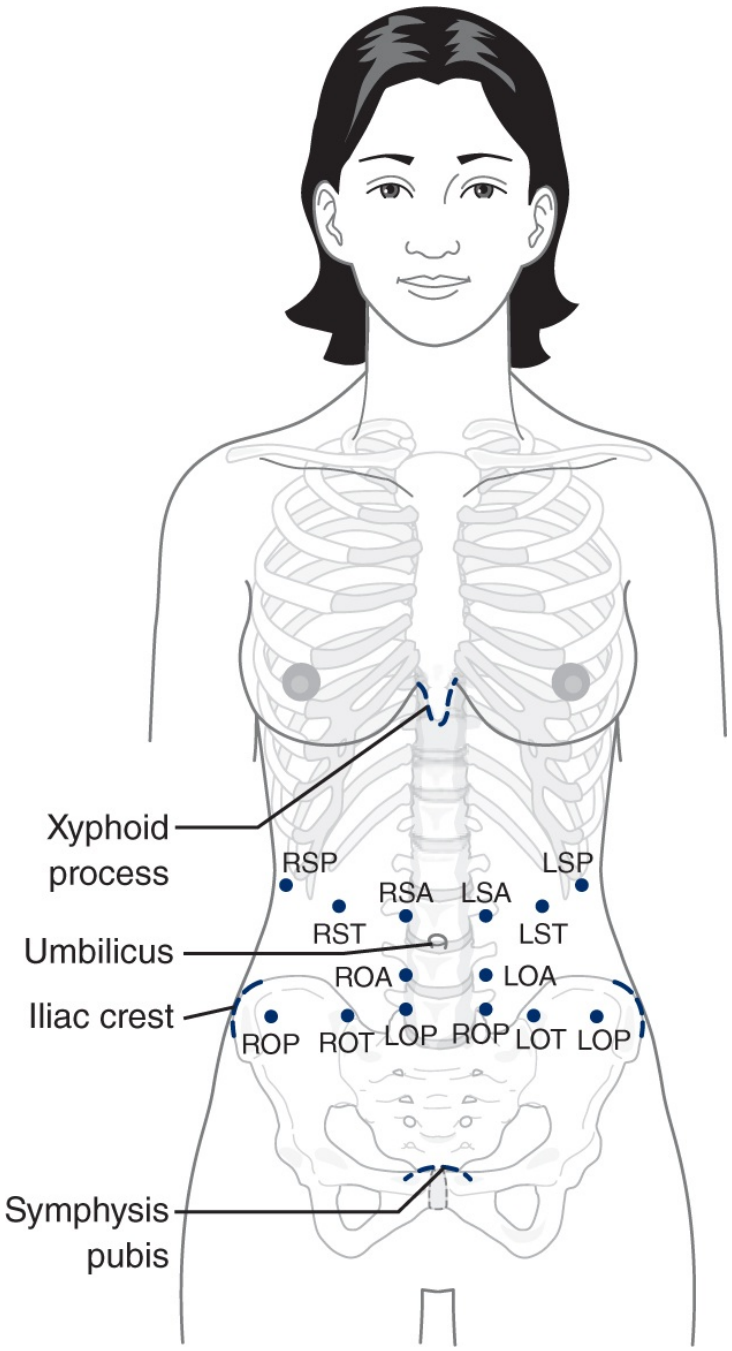

Figure 21A-4 Location of the point of maximum intensity of auscultation of the fetal heart tones for specific fetal presentations and positions.

Abbreviations: LOA, left occiput anterior; LOP, left occiput posterior; LOT, left occiput transverse; LSA, left sacrum anterior; LSP, left sacrum posterior; LST, left sacrum transverse; ROA, right occiput anterior; ROP, right occiput posterior, ROT, right occiput transverse; RSA, right sacrum anterior; RSP, right sacrum posterior; RST, right sacrum transverse.

Measuring Fundal Height

Fundal heights are measured at each prenatal visit. Serial fundal height measurements provide information about the enlargement of the uterus and, therefore, about the growth of the fetus.

The height of the fundus, measured in centimeters from the top of the symphysis pubis to the top of the fundus, is used to monitor fetal growth and can be a screening tool for detection of multifetal gestation, fetal growth restriction, polyhydramnios, oligohydramnios, and other complications of fetal growth. Fundal height is of greatest value when it is measured the same way by the same midwife at successive prenatal visits.

The fundal height (measured in centimeters) and gestational age (expressed in weeks from the last menstrual period [LMP]) is closely correlated between 20 and 32 weeks' gestation, when the number of weeks' gestation is close to the number of centimeters measured between the symphysis and the fundus.[1-6] However, the correlation between weeks' gestation and fundal heights depends on several factors, including maternal habitus and fetal lie. For example, a petite woman who is only 5 feet (1.5 meters) tall may have different fundal measurements than a taller woman of 6 feet (1.8 meters) in height at the same point in pregnancy. Similarly, women with large deposition of abdominal adipose tissue may have a fundal height measurement that is larger than expected. **Table 21A-1** lists the approximate expected location of the fundal height at different gestational ages for a woman with a normal body mass index (BMI) and singleton fetus in a longitudinal lie.

Table 21A-1 Approximate Expected Fundal Height at Specific Weeks' Gestation

Weeks' Gestation	Approximate Expected Fundal Height
12	Level of the symphysis pubis
16	Halfway between symphysis pubis and umbilicus
20	Within 1 fingerbreadth of umbilicus
24	2–4 fingerbreadths above umbilicus
28–30	One-third of the way between umbilicus and xiphoid process (3 fingerbreadths above umbilicus)
32	Two-thirds of the way between umbilicus and xiphoid process (3–4 fingerbreadths below xiphoid process)
36–38	1 fingerbreadth below xiphoid process
40	2–3 fingerbreadths below xiphoid process if lightening has occurred

In clinical practice, it is common to use a rule of gestational age plus or minus 2 centimeters to diagnose adequate fetal growth. That is, during 20–32 weeks' gestation, a woman should have a fundal measurement in centimeters that is within 2 cm of the number of weeks' gestation. No strong evidence supports this approach, most likely because of the maternal and fetal variations noted earlier. Despite a lack of evidence, deviation from the 2-cm rule of thumb can be used as an alert to carefully assess for size–dates discrepancy. Assessment of size–dates discrepancies first includes remeasurement when the woman has an empty bladder, as a full bladder can elevate the uterus. Ultrasound is used to diagnose the etiology of a size–dates discrepancy.

Key Points

1. Early in pregnancy, the uterus is contained within the pelvic girdle. The uterine fundus can be palpated abdominally by 10 to 12 weeks' gestation just at or above the symphysis pubis. Prior to 18 to 20 weeks' gestation, the uterine size is best described in relation to the level of the uterine fundus between the symphysis pubis and the umbilicus, using the midwife's fingerbreadth (fb) as the measuring tool (e.g., 1 fb above symphysis, 4 fb below umbilicus). (For more information, see the *Anatomy and Physiology of Pregnancy* chapter.)
2. Between 20 and 32 weeks' gestation, the measurement should be within 2 cm of the number of weeks' gestation.
3. In the last few weeks of pregnancy, as the fetal presenting part moves into the pelvis, more variation is seen between measurements, and the absolute fundal height may remain stable or decrease slightly.
4. Used alone, the fundal height measurement may be specific, but lacks sensitivity. When a measurement is not within the expected value for the woman's gestational age:
   a. First assess for confounding factors such as a full bladder or excess abdominal adipose tissue.
   b. Refer the woman for ultrasound evaluation if confounding factors do not sufficiently account for the size–dates discrepancy.

Procedure for Measuring Fundal Height

Fundal height can be measured in a number of different ways. For an extensive review of fundal height measurement, the interested reader is referred to the classic series of articles written by Engstrom et al.[1-7]

1. Assessment of the fundal height should take place with the woman in a supine or semi-recumbent position.
2. Some midwives advocate turning the tape measure to hide the centimeter markings, thereby minimizing inadvertent bias by the midwife. Alterations in maternal position, a full urinary bladder, multiple examiners, and provider awareness of the weeks' gestation all create bias that can lead to inaccurate measurements.
3. Before measuring, the symphysis pubis and uterine fundus are identified (**Figure 21A-5**).
   a. The woman may need to partially remove her clothing to allow access to the symphysis and fundus. The abdomen is exposed from the xiphoid process to the top of the pelvis.
   b. Assessment is done with a gentle, firm touch using the palmar surface of the fingers.
   c. Facing the woman's head as she lies in a semi-reclining position, the midwife's hands are placed on each lateral side of the uterus approximately midway between the symphysis and the fundus, with the fingers pointed vertically toward the woman's head.
   d. The uterine fundus is identified by walking one's hands up the sides of the uterus until they meet at the top. Smooth motions avoid the sensation of kneading or poking and will decrease uterine contractility during the examination.

e. Measuring “over the top” of the fundus is a common error that can be avoided by paying attention to the curve of the uterus, the location of the fetal part highest in the uterus, and any laxity of the maternal abdomen.

4. Two techniques are commonly employed:
   a. Place the zero line of the tape measure on the superior border of the symphysis and measure *upward* in a straight line, following the abdominal midline to the crest of the uterine fundus, and taking care not to cross over the top and begin to measure the posterior aspect of the uterus.
   b. After identifying the fundus, place the tape at that point and measure *downward* to the superior border of the symphysis.

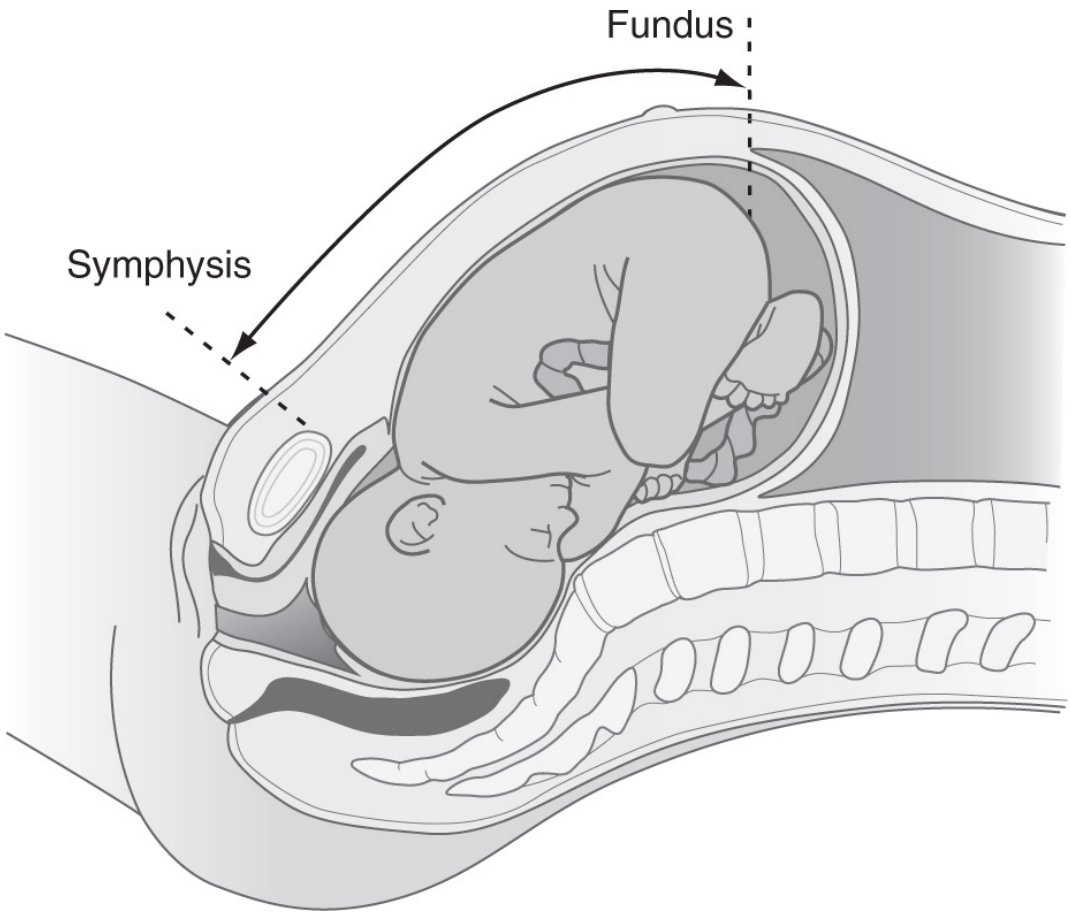

Figure 21A-5 Measurement of fundal height.

Clinical Pelvimetry

JENNIFER M. DEMMA, KAREN TRISTER GRACE, AND TEKOA L. KING

© hakkiarslan/iStock/Getty Images Plus/Getty

Pelvimetry comes from the Latin word *pelvis* (meaning "basin or bowl") and the Greek word *metron* (meaning "measure").[1] Thus, pelvimetry refers to measurement of diameters of the pelvis. It is possible to evaluate the general structure (size and shape) of the pelvis and measure some of the critical diameters of the pelvis during a vaginal examination. This assessment, which is referred to as "clinical pelvimetry," is classically done when an initial vaginal examination is performed during pregnancy and/or during the course of labor.

Pelvic diameters are most accurately measured by X ray or computerized tomographic (CT) X ray. However, X-ray pelvimetry is no longer used because of the potential hazards of exposing the fetus to radiation and lack of research supporting this method's accuracy. CT scans are reserved for prenatal assessment of the pelvis in women who plan a vaginal breech birth.

Historically, clinical pelvimetry was an essential piece of information that was used to guide clinical management. A woman whose pelvis was contracted in one or more dimensions was likely to have cephalopelvic disproportion (CPD) in labor and could be assisted with a cesarean section or use of high or mid-forceps.[2] The shape and size of the pelvis partly determined which method of birth would be safest. Because diseases such as rickets, scurvy, and polio were more common in the past, CPD was a more frequent occurrence and clinical dilemma.[3]

Today the diagnosis of CPD is not made until there is a failure of progress or descent in labor; thus, the predictive value of clinical pelvimetry is controversial.[4,5] Nevertheless, it is important that we do not "throw the baby out with the bath water": The results of clinical pelvimetry can help confirm cephalopelvic disproportion and, therefore, inform and help guide intrapartum management. In addition, clinical pelvimetry continues to have an important role in low-resource nations, wherein a contracted pelvis is more common.[3]

Key Points

1. The midwife should have an understanding of the four classic pelvic shapes and dimensions of the pelvic planes, as described in the *Anatomy and Physiology of the Female Reproductive System* chapter.
2. Before doing clinical pelvimetry, it is important that the midwife measure the lengths of the fingers as well as the width of the fist, as these lengths will used to determine specific measurements.
   a. The length of the reach of the examining fingers is measured from the tip of the longest finger to the juncture of the first finger (palm) and thumb.
   b. The fist is measured from the lateral (ulnar) aspect to the medial (radial) aspect of the tops of the knuckles of the fingers where they attach to the hand. If this does not measure at least 8 cm, then position the thumb in the way that it will be positioned each time and add the joint or knuckle of the thumb into the measurement.
3. Clinical pelvimetry is best performed with the thumb of the examining hand tucked into the palm. If the thumb is extended, it will come in contact with the clitoris or another part of the external vulva, which disallows use of the full length of the examining fingers in reaching for the sacrum or diagonal conjugate.
4. The procedure for performing clinical pelvimetry can be practiced using a bony pelvis model but must be performed consistently and methodically at the completion of a vaginal examination to truly understand the effects of soft tissue and movements that cause discomfort.
5. Some midwives believe that it is necessary to palpate and evaluate completely both sides of the bony pelvis. Others believe that it is sufficient to palpate only one side of the bony pelvis and assume both sides are equilateral, unless an obvious pelvic deformity is observed or the woman has a history of pelvic trauma. In such cases, both sides of the bony pelvis should be evaluated.
6. Clinical pelvimetry may be performed in several different ways. Some texts advocate assessing the diagonal conjugate first and moving from the back of the pelvis forward; others advocate the reverse order. Some texts do not include assessment of the retropubic arch or sidewalls. The order of maneuvers recommended in this text is designed to cause a woman the least discomfort.
7. Clinical pelvimetry uses measures of the length and shape of pelvic structures to indirectly assess the size of the three pelvic planes as well as the back and forepelvis. The pelvic planes cannot be measured directly. Thus, clinical pelvimetry is used to categorize the pelvis as adequate, borderline, or contracted for the birth of an average-size fetus by determining the shape and size of the pelvic inlet, midplane, and outlet.

Procedure for Performing Clinical Pelvimetry

The procedure for performing clinical pelvimetry is presented in **Table 21B-1**. The pelvis is palpated from the forepelvis posteriorly toward the sacrum, and the shape and length of the following structures are noted: symphysis pubis, ischial rami, sidewalls, ischial spines, interspinous diameter, sacrospinous ligament, coccyx, sacrum, and diagonal conjugate. The

pubic arch is measured as the midwife's hand is removed from the vagina, and the intertuberous diameter is measured externally at the end of the examination. **Figure 21B-1** and **Figure 21B-2** show the pelvic diameters and shape of the sacrum as described in **Table 21B-1**.

Table 21B-1 Procedure for Performing Clinical Pelvimetry

Step	Obstetric Plane	Area Measured	Technique	Description of Findings	Clinical Implications During Labor
1	Forepelvis and AP diameter of the pelvic inlet	Retropubic arch	Insert two fingers just inside the vagina; rotate so the palmar surface is up. Separate fingers gently to avoid trauma to the urethra, and gently palpate the posterior aspect of the symphysis pubis to determine the inclination.	*Parallel inclination*: The longitudinal axis of the symphysis pubis is parallel to the sacrum. *Anterior inclination*: The superior margin of the symphysis pubis is tilted toward the sacral promontory, and the inferior margin is tilted away from the sacrum. *Posterior inclination:* The inferior margin of the symphysis pubis is tilted toward the sacrum, and the superior margin is tilted away from the sacral promontory.	When the symphysis pubis is not at least approximately parallel to the sacrum, the anteroposterior diameters of the inlet and the outlet can be changed significantly (Figure 21B-1). However, a contracted inlet is uncommon in developed nations today, so this step may be omitted by some practitioners.
2	Transverse diameters of midplane and outlet	Sidewalls (interior surface of the ischium)	Sweep the examining fingers down the pubic rami to the inferior wall of the ischium, and move them back along the ischium toward the ischial spine.	*Convergent*: Sidewalls converge toward the outline. *Divergent*: Sidewalls converge toward the ischial spines and flare toward the outline. *Parallel*: Most common finding in gynecoid pelvis.	Convergent sidewalls are associated with deep transverse arrest.
3	Transverse diameter of midplane	Ischial spines	Proceed along the sidewalls downward and backward to locate the ischial spine. Gentle lateral pressure may be required to locate the spine. If unable to locate the spine in this manner, move the fingers medially to the sacrum and locate the sacrospinous ligament. Follow it laterally to the ischial spine.	*Blunt*: Not easily palpated, more flattened against the pelvic wall; the most common finding in gynecoid pelvis. *Prominent*: Easily palpable. *Encroaching*: Easily palpable and long, almost sharp, encroaching toward each other.	The transverse diameter of the midplane is the narrowest diameter that the fetus must traverse. A narrowed midplane can result in deep transverse arrest or failure to descend in the second stage of labor. This dystocia is associated with marked molding and caput.
4	Transverse of midplane	Interspinous diameter	Sweep the finger across the pelvic cavity to the ischial spine on the opposite side of the pelvis to estimate the transverse diameter of the midplane.	Estimate diameter in centimeters (normal is 10 cm or greater).	
5	Transverse diameter of midplane and posterior aspect of pelvis	Sacrosciatic ligament	Move the examining finger back to the first ischial spine palpated and follow the sacrosciatic ligament to the sacrum to measure the width of the sacrosciatic notch.	$>$ 2 fb (3 fb = average). $<$ 2 fb suggests forward inclination of sacrum.	

6	AP diameter of outlet	Coccyx shape and mobility	Press firmly on the coccyx to determine its shape and mobility.	Mobility: Describe as a *mobile* or *fixed*. Shape: *J-shaped* or *flat*.	A coccyx that is J-shaped or immobile may break during childbirth. Labor may or may not be impeded, but significant pain in the area of the coccyx can occur postpartum when the coccyx does break.
7	AP diameter of midpelvis	Sacrum shape	Palpate the sacrum from sacrococcygeal junction upward; "walk up the sacrum," estimating the degree of curvature and inclination.	Curve is described as *straight* (flat), *angular* (J-shaped), or *hollow*. Inclination is described as *backward, average,* or *forward*.	A hollow sacrum is indicative of an anthropoid pelvis and persistent occiput posterior position.
8	AP diameter of inlet	DC	Drop both wrists and elbow toward the floor, and extend the fingers posteriorly and cephalad with the inferior margin of the symphysis in contact with the dorsal aspect of the examining hand. Avoid undue pressure on the urethra or clitoris. Most often the sacral promontory cannot be reached.	A diameter of 11.5 cm or greater implies an adequate DC. The obstetric conjugate is approximately 1.5 cm less than the measured DC (Figure 21B-1). Recorded as (1) greater than or equal to the measured distance of the midwife's reach or (2) equal to the measured distance of the midwife's reach.	A narrow diagonal conjugate can result in failure of engagement.
9	Transverse diameter of outlet and forepelvis	Subpubic arch	The midwife's hand is rotated to the side so the fingertips face the side of the pelvis as the hand is removed from the vagina. Just prior to removing the hand, rotate the examining fingers so the palmar surface is up. Evaluate how easily two examining fingers are accommodated under the arch. If two fingers are easily accommodated, the angle is approximately 90°. If the fingers must overlap to fit into the pubic arch, the arch is $< 90°$.	Degree of angle relative to 90°. Record as (1) $> 90°$(gynecoid) or (2) $\leq 90°$ (android).	The fetal head must descend lower to traverse a narrow pubic arch, which increases the chance of perineal lacerations.
10	Transverse diameter of outlet	Intertuberous diameter	Measure the transverse diameter of the outlet (intertuberous diameter; biischial diameter) by placing a premeasured fist between the tuberosities.	Record measurement of the intertuberous diameter as greater than, equal to, or less than the premeasured width of the fist.	

Abbreviations: AP, anterior–posterior; DC, diagonal conjugate; fb, fingerbreadth.

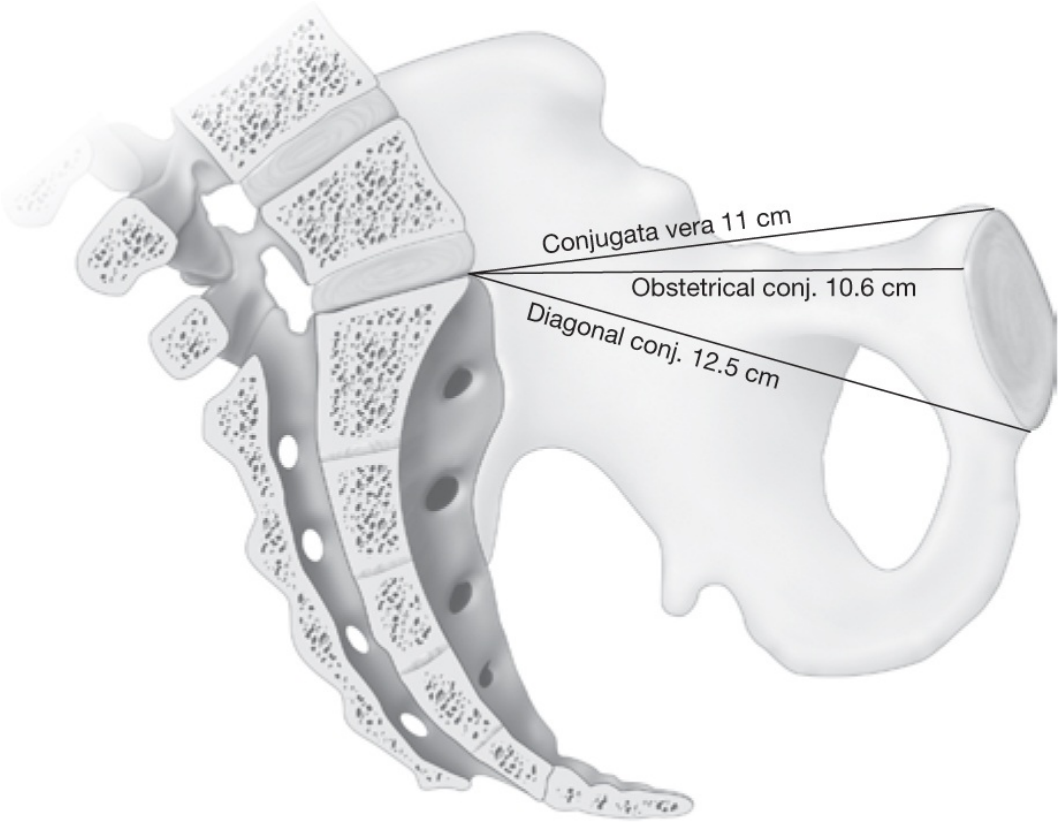

Figure 21B-1 Diameters and planes of the pelvis.

Introduction

Every woman deserves the personalized care and skill of a midwife during pregnancy and birth. The majority of women experience healthy pregnancies, and midwifery care provides the appropriate support and interventions needed. Women with pregnancy-related conditions and complications also benefit from midwifery care, although they may need physician care as well. Medical complications existing prior to pregnancy or aggravated by pregnancy are presented in the *Medical Complications in Pregnancy* chapter. This chapter first addresses management of common discomforts and first-trimester loss (e.g., miscarriage, ectopic pregnancy, and tubal pregnancy). The chapter then reviews fetal, placental, and maternal complications that are related to the condition of being pregnant.

Overview of Midwifery Management of Women with Pregnancy-Related Conditions

Assessment of women for conditions related to pregnancy begins with the first prenatal visit and continues throughout the gestation. At each visit, risks can be identified and care instituted to minimize adverse effects. **Table 22-1** lists examples of conditions that may arise during prenatal care and that indicate a need for consultation or referral to a physician. The care that a midwife provides to women who have pregnancy-related conditions or complications during their pregnancy depends on several factors, including the practice setting and institutional guidelines, the midwife's experience and education, the availability of and collaborative relationship with physician consultants, and legal or regulatory statutes.[1]

Table 22-1	Selected Indications for Medical Consultation or Referral During Pregnancy[a]
Gynecologic or Reproductive History	
Large uterine fibroids	Prior unexplained third-trimester fetal loss
History of cervical insufficiency	Uterine anomaly
Previous uterine surgery, including prior cesarean section	
Medical Complications Prior to Pregnancy or That Worsen During Pregnancy	
Anemia not responding to oral iron supplementation	Infectious disease such as hepatitis, HIV, gonorrhea, syphilis, pneumonia, or tuberculosis
Asthma requiring medication	Mental disorder that requires medication
Autoimmune disorders	Morbid obesity
Breast mass	Mitral valve prolapse without previous cardiology evaluation
Cholestasis	Renal calculi
Diabetes	Persistent proteinuria
Hypertension	Seizure disorder
Deep vein thrombosis or pulmonary embolus: history or current	Skin rashes or lesions without diagnosis
Gastrointestinal disease such as Crohn's disease, previous bariatric procedure	Suspected pneumonia
Headaches: severe, recurrent, or associated with hypertension	Syphilis
Hemoglobinopathy	Thyroid disorder
Obstetric Complications That Develop During Pregnancy	
Abnormal screening results for chromosomal conditions such as aneuploidy or genetic disorders	Post-dates pregnancy (> 41 0/7 weeks)
Short cervix via transvaginal ultrasound or clinical examination	Preterm labor
First-trimester bleeding with suspected pregnancy of unknown origin or ectopic	Pyelonephritis
Gestational diabetes	Placenta previa with significant bleeding or persisting after 20 weeks
Isoimmunization	Pregnancy-induced hypertension
	Vaginal bleeding suspected not to be bloody show or related to cervicitis

Hypertension	Varicose veins with pain, swelling, or stasis
Malpresentation of the fetus after 36 weeks	Ultrasound with abnormal findings such as fetal growth restriction, polyhydramnios, fetal anomalies, or unresolved size–dates discrepancy
Multifetal gestation	
Nausea and vomiting that requires hospitalization	

[a] This list is offered for consideration and is not absolute or all inclusive. The list is intended as an adjunct to clinical management based on the individual woman, the midwife, the consulting physician, and institutional guidelines.

In addition, the appropriate level of care for prenatal care and site of birth must be determined. Recently, levels of maternal care have been established for facilities that can help guide decisions about transfer to other facilities (**Table 22-2**).[2] Midwives provide care to women in each of these settings.

Table 22-2 **Levels of Maternal Care Considerations in Pregnancy with Obstetric Complications**

Level of Care	Capabilities	Services	Providers
Birth center	Term, singleton, vertex	Low risk, uncomplicated	Midwives
Level I	Low-risk pregnancy Term gestation Ability to manage unanticipated complications until transfer to a higher level of care	Ability to provide emergency cesarean birth on a 24/7 basis	Midwives and physicians Obstetric provider credentialed for cesarean birth
Level II	Pregnancy with complications that do not require subspecialty care	Medical and surgical consultants available to stabilize women prior to transfer	Midwives Anesthesia available on a 24/7 basis Obstetrician gynecologist available on a 24/7 basis MFM available for consultation on site or by telemedicine 24/7
Level III	Care of more complex maternal medical, obstetric, and fetal conditions	Medical and surgical ICU with ability to collaborate with MFM Subspecialists available for inpatient consultation	Midwives Anesthesia available on a 24/7 basis Obstetrician gynecologist on site on a 24/7 basis MFM available on site or by tele-medicine with inpatient privileges
Level IV (regional perinatal health center)	Care of most complex medical conditions and critically ill pregnant women	On-site obstetric ICU Medical and surgical ICU Medical and surgical subspecialists available on site on a 24/7 basis, including transplant specialists, cardiac surgery, and advanced neurosurgery	Midwives Obstetrician gynecologist on site on a 24/7 basis MFM available on site on a 24/7 basis MFM with expertise in critical care obstetrics Anesthesia with special training in obstetrics

Abbreviations: ICU, intensive care unit; MFM, maternal–fetal medicine specialist.

Based on American College of Obstetricians and Gynecologists. Obstetric Care Consensus No. 2: levels of maternal care. *Obstet Gynecol*. 2015:125:502-515.[2]

Common Discomforts of Pregnancy

The physiologic changes of pregnancy have wide-ranging effects on all body systems. These changes result in many symptoms, which, although not pathologic in nature, can distress or disrupt a woman's life to varying degrees throughout her pregnancy (**Table 22-3**). Common discomforts of pregnancy are presented in this chapter because some—such as dyspnea, nausea and vomiting, or urinary frequency—may be an indication of a disorder that requires treatment. Differentiating normal versus abnormal symptoms is the first task when these symptoms are reviewed during a prenatal care visit. A methodical approach to considering the differential diagnosis is recommended (every time for every woman), despite the tendency to assume the discomfort is a normal physiologic change of pregnancy.

Table 22-3 Common Discomforts of Pregnancy[a]

Description	Differential Diagnosis	Strategies to Decrease Discomfort
Back Pain		
Upper backache develops during the first trimester from increased size of breasts. Low back pain typically occurs in the last half of pregnancy, secondary to the increasing weight of the uterus and relaxation of the sacroiliac ligaments. The exaggerated lordosis of pregnancy strains the back muscles and causes pain.	Sciatica Early labor, pyelonephritis, kidney stone	For upper back pain: A well-fitting and supportive bra. For lower back pain: Proper body mechanics for lifting, pelvic rock/pelvic tilt exercises. External abdominal support (e.g., a maternity girdle or supportive elastic "belly band," or sacroiliac support belt). Heat, ice packs, or massage. A supportive mattress or positioning with pillows to straighten the back and alleviate pulling and strain. Evaluation and treatment by a chiropractor experienced in working with pregnant women may be beneficial.
Breast Tenderness		
Tenderness, tingling, increase in size. Appears in first trimester and discomfort resolves in second trimester but enlarged size remains.	Fibrocystic breast changes, benign breast mass, breast cancer, mastitis	Wear a correctly fitted and supportive bra. Avoiding caffeine or other methylxanthines may help prevent additional breast tenderness, although effectiveness of this practice has not been proven.
Constipation		
Effect of progesterone on gastrointestinal tract, pressure from the enlarging uterus while it is a pelvic organ. May be exacerbated by iron supplements. Occurs in first trimester and resolves by second trimester.	GI disorder	Increase fluids and change in diet. Warm liquids to stimulate peristalsis. Foods that contain roughage, bulk, and natural fiber. Mild bulk-forming laxatives, stool softeners, and glycerin suppositories are safe for use in pregnancy. Stimulant laxatives such as senna are possibly safe but are not recommended for use during pregnancy. These agents directly increase peristalsis and may cause dehydration. Castor oil should be avoided, as it can cause uterine contractions.

Dyspareunia		
Physiologic changes that cause pelvic/vaginal congestion. Most likely to appear in the second half of pregnancy.	Vaginitis, vulvovaginal hemorrhoids, preexisting dyspareunia Screen for abuse or history of abuse if indicated.	Positional changes to accommodate the larger uterus or pain from deep penetration may be all that is needed. Use of water-based vaginal lubricants may be helpful. Treat vaginitis as indicated. Referral to counseling is appropriate for women who have a history of abuse. If current abuse is suspected, offer support and referral, and assess safety.
Dyspnea		
Sensation as needing to take an “extra” breath, not associated with tachypnea. Etiology is not clearly known but may be secondary to altered respiratory center sensitivity (progesterone) and diaphragm displacement. May appear at any time in pregnancy.	Dyspnea with tachycardia: may suggest anxiety or panic attack Respiratory infection Cardiac disorder	Explain the physiologic basis for shortness of breath to relieve anxiety. Deliberately regulate the speed and depth of respirations at normal rates when aware of hyperventilating. Use diaphragmatic or intercostal breathing as opposed to abdominal breathing.
Edema		
Lower-extremity edema (dependent edema) is secondary to impaired venous circulation and increased venous pressure in the lower extremities from the enlarged uterus. Appears in the third trimester.	DVT, phlebitis (would be unilateral) Preeclampsia: rule out non-dependent edema (hands or face) and excessive edema/sudden weight gain	Regular exercise and avoiding prolonged sitting or standing may help. Elevate legs periodically and position on the side when lying down. Keep legs uncrossed when sitting. Graduated compression or support hose can reduce venous pooling in the lower extremities.
Fatigue		
Increased energy requirements, weight gain, and disrupted sleep may be present. Common during the first and third trimesters.	Anemia, depression, cardiac conditions, sleep apnea, thyroid dysfunction, viral or other systemic illnesses	Regular exercise may help improve sleep patterns if fatigue is related to disrupted sleep. Avoid caffeine at night.
Flatulence and Gas Pain		
Decreased GI motility and uterine displacement of intestines. First develops in first trimester and may occur at any time in pregnancy.	Dietary sensitivities, IBS, celiac disease Appendicitis, IBS, or GI disorder	Exercise can aid in improving GI motility. Use of caffeine can stimulate GI motility. Note that caffeine may increase the risk of heartburn, and accentuate insomnia. Caffeine has a prolonged period of metabolism during pregnancy and a standard dose will be present in higher plasma concentrations compared to that dose consumed by a non-pregnant person. The knee–chest position may help with discomfort from unexpelled gas.
Gingivitis		
Pregnancy changes in oral mucosa	Epulis (pregnancy	Increasing the frequency of oral hygiene usually

increase the likelihood of gingivitis. Appears in the second trimester.	tumor or benign overgrowth of gingiva), periodontal disease	resolves hyperemia and bleeding. Refer for dental care if gingivitis persists after increasing oral hygiene.
Heartburn (Pyrosis)		
Regurgitation, or reflux, of acidic gastric contents into the lower esophagus. Progesterone-induced relaxation of LES, slower emptying of gastric contents, smaller-capacity stomach. Appears in the third trimester.	GERD, hiatal hernia, peptic ulcer disease, cholecystitis, pancreatitis If unremitting, rule out preeclampsia	Take small, frequent meals. Avoid foods that make heartburn worse. Elevate the head of the bed, and avoid lying down after eating. A stepwise approach recommended starting with antacids, then moving as necessary to H_2 receptor antagonists and lastly to proton pump inhibitors.
Heart Palpitations or Short Period of Sinus Tachycardia		
A skipped or extra beat, or sinus tachycardia. The etiology may be a pregnancy-induced increase in blood volume and pulse; enlarged heart is more arrhythmogenic. Occurs at any time in pregnancy.	Anxiety Cardiac disorder, arrhythmia Thyroid disorder	Can be aggravated by dehydration, stress, strenuous physical activity, caffeine, tobacco, and alcohol use. No specific relief measures. Pregnancy changes in the cardiac and hematologic systems increase the incidence of short benign arrythmias. Reassurance and education that this is a normal symptom of pregnancy are usually sufficient.
Hemorrhoids		
Progesterone-induced relaxation of the vein walls in the rectum, along with the enlarged uterus, causes pelvic venous congestion. Appears at any time but is most likely in the third trimester.	Thrombosed hemorrhoid If rectal bleeding persists and hemorrhoid is not visible, consider referral for cancer evaluation	Avoid constipation and straining during defecation. Use witch hazel compresses or Epsom salt compresses. Topical anesthetics and topical cortisone creams or suppositories are safe for use in pregnancy.
Insomnia		
Difficulty sleeping may be related to frequent waking from back pain, heartburn, or nocturia.	Sleep disorder, sleep apnea, anxiety, RLS	If no signs of pathology: Take warm baths, reduce stimulation prior to bedtime, avoid caffeine. Regular exercise, and regulation of the temperature in the room may improve sleep. Antihistamines such as diphenhydramine 50–100 mg (Benadryl) or doxylamine succinate 25 mg (Unisom) orally 30 minutes before bedtime may help some women but no pharmaceutical sleep aid should be used regularly.
Leg Cramps		
Sharp sudden cramp in the calf or thigh, which often occurs at night. May be linked to changes in calcium, magnesium, and phosphorus levels or the ability of calcium to enter the muscles, but causes have not been proven. Occurs in the second and third trimesters.	DVT or phlebitis Electrolyte imbalances, muscle or neurovascular disorders Peripheral neuropathy RLS	Straighten the affected leg and dorsiflex the ankle. Magnesium supplementation of 350 mg at bedtime has been shown to be helpful to some women in studies but not all participants in these studies.

Leukorrhea		
Profuse, thin or thick vaginal secretion that typically appears in the second trimester.	STI, vaginitis, ruptured membranes, preterm labor	Avoid douching or using feminine hygiene sprays; clean the perineal and vaginal areas only with water. Reassurance and education that this is a normal symptom of pregnancy are usually sufficient.
Nasal Congestion		
Hyperemia and increased blood flow in nasal passages (estrogen effect). Occurs at any time during pregnancy.	URI, sinusitis, clotting disorder, hypertension May be an indication of drug use	Use a humidifier to generate cool mist at night. Avoid blowing the nose hard. Nasal sprays with epinephrine may provide temporary relief but can be habit forming and result in rebound congestion (especially the long-acting formulations). For epistaxis, elevate the head and compress the nose against the midline septum continuously for 5–10 minutes.
Nausea and Vomiting		
Nausea and/or vomiting and retching may be mild to severe. The exact etiology is unknown. Presents and peaks in the first trimester.	Hyperemesis with dehydration or electrolyte changes GERD or other GI disorder Viral GI infection	Consume small, frequent meals. Avoid fried fatty foods and foods with strong odors. Temporarily discontinue prenatal vitamins that contain iron, but continue folic acid supplementation. Ginger, acupressure bands, and vitamin B_6 may help women with mild to moderate symptoms. Antiemetic medications are recommended in a stepwise fashion depending on the severity of symptoms.
Ptyalism		
Excessive salivation often associated with nausea and vomiting. Etiology unknown.	Hyperemesis	Ptyalism usually resolves spontaneously, although the condition may not disappear until after the pregnancy is over. Some women obtain temporary relief from gum chewing or sucking on hard candies.
Round Ligament Pain		
Round ligaments increase in length as the uterus rises in the abdomen. The pain probably stems from ligament stretching. Often worsens or is elicited with exercise or turning the torso. Appears early in the second trimester and is usually unilateral.	Preterm labor, appendicitis, constipation, gas pain, inguinal hernia, and muscle strain or sprain	Positions that place less tension on the round ligament and wearing a maternity abdominal support or girdle may provide relief for some women.
Sciatica		
Pain in the pelvis and buttock, which may radiate down the back of the lower extremity. Can be sudden and severe. Pressure on the sciatic nerve from joint laxity, often elicited by twisting, lifting, or moving the leg. Typically appears in the third trimester and is usually unilateral.	Cauda equina syndrome: loss of bowel or bladder function Herniated disc: loss of reflex or strength	Rest in a side-lying position on the contralateral side from the affected leg. Heat packs, ice, or an abdominal support girdle may offer some relief. Rest and avoid twisting the torso. Use careful body mechanics when lifting. Acetaminophen: Maximum daily dosage is 4000 mg/day. Referral to a chiropractor or physical therapy may be indicated.

Syncope (Supine Hypotensive Syndrome)		
Dizziness or syncope when suddenly standing or lying on back. The enlarged uterus impairs venous return and causes hypotension. Typically appears in the third trimester.	Hypoglycemia Seizure disorder	If transient and no loss of consciousness, sit down with the head lowered or lie on the side.
Tingling and Numbness of Fingers		
Kyphosis places pressure or traction on nerves in the arm, which can cause tingling and numbness of the fingers. Often occurs at night.	Carpal tunnel syndrome	Move arms at the level of the shoulder to decrease pressure on the nerves when tingling starts. Wrist splints that keep the wrist in a neutral position may be worn while sleeping or during work or other activities.
Urinary Frequency and Nocturia		
Mechanical pressure from the enlarging uterus in the first trimester results in decreased bladder capacity. Frequently occurs in the first and third trimesters.	Urinary tract infection, pylonephritis	Decreasing fluid intake at night may offer some relief but women should not restrict fluids in general.
Varicosities		
Occurs secondary to venous distension from increased venous pressure and vasodilation. Familial tendency may increase risk. Most common in the legs and/or vulva Appears in the second or third trimester.	DVT, peripheral arterial or venous disease	Rest and use of compression stockings.

Abbreviations: DVT, deep vein thrombosis; GERD, gastroesophageal reflux disease; GI, gastrointestinal; IBS, irritable bowel syndrome; LES, lower esophageal sphincter; RLS, restless leg syndrome; STI, sexually transmitted infection; URI, upper respiratory infection.

[a] Educational counseling is primarily based on expert opinion and common practice. Little strong evidence exists in this area.

Most of the common discomforts of pregnancy are transient and resolve spontaneously. Many nonpharmacologic treatments are recommended but very few have been systematically studied to determine evidence for their use. The plethora of suggested remedies that may or may not be helpful for an individual woman is illustrated well in the care of women with nausea and vomiting.

Nausea and Vomiting

Nausea occurs in as many as 85% of pregnant women.[3] The peak prevalence is at 11 weeks' gestation, with the average time of onset between 5 and 6 weeks. For most women, nausea and vomiting in pregnancy (NVP) will resolve by 14 to 16 weeks' gestation, although a small percentage of women will have NVP that persists beyond 20 weeks' gestation.[4] Hyperemesis —a severe form of NVP—occurs in approximately 3% of women during pregnancy.[3] Women with a multifetal gestation and those with a hydatidiform mole may have more severe NVP. Nausea, with or without vomiting, is erroneously termed "morning sickness" because it is not

limited to the morning hours, but rather can occur at any time of day. Nausea is more severe when the stomach is empty, which may explain why some women notice it more in the morning. Women with severe NVP or hyperemesis often require hospitalization to break the cycle of vomiting and establish adequate rehydration.

The cause of NVP is not fully known. Likely causes include the interplay between hormonal changes of pregnancy (e.g., human chorionic gonadotropin, estrogen, progesterone, placental prostaglandin E_2), slowed peristalsis, and genetic factors. Other factors such as preexisting gastroesophageal reflux disease (GERD) or *Helicobacter pylori* infection can contribute to the occurrence of NVP in many women. There is little support for an older theory that NVP reflects the transformation of psychological distress into physical symptoms. Nevertheless, a woman's experience of NVP does have biological, psychological, and sociocultural components. Severe NVP can be associated with severe psychological distress, as one would expect. Thus, depression can be the result of NVP but is not the cause of the disorder.[5,6] NVP can be mild or it may be severe enough to require hospitalization. Additional differential diagnoses include thyroid dysfunction, gastrointestinal disorders such as GERD, peptic ulcer disease, cholecystitis, and eating disorders such as bulimia.

Hyperemesis Gravidarum

There is no standard definition for hyperemesis gravidarum, the most severe form of NVP. However, most diagnostic criteria include:

1. persistent vomiting before 9 weeks' gestation
2. dehydration and/or ketonuria
3. weight loss greater than 5% of initial body weight
4. electrolyte imbalance.[7]

Risk factors for hyperemesis include previous pregnancy complicated by hyperemesis, molar pregnancy, multifetal gestation, prepregnancy history of gastrointestinal disorders, and hyperthyroid disorders. Interestingly, women older than 30 years and women who smoke have a lower risk of hyperemesis, and women who have hyperemesis are more likely to carry a female fetus.[6] In the United States, hyperemesis is the second most common reason for hospitalization during pregnancy (following preterm labor).

Women with hyperemesis may have a coexisting, transient hyperthyroid state. This occurs because human chorionic gonadotropin (hCG) is structurally similar to thyroid-stimulating hormone and is able to increase production of free thyroxine (T_4). This hyperthyroid state does not need to be treated and resolves spontaneously by 18 to 20 weeks' gestation.

Assessment and Management of Nausea and Vomiting

Midwives and physicians frequently collaborate in the care of women with NVP, with midwives initiating outpatient management or conducting initial assessment and treatment following hospital admission. Physician consultation or referral is recommended for women with severe symptoms.

The initial goals in evaluating a woman with NVP (**Table 22-4**) are first to rule out differential diagnoses and then to establish the severity of the disorder, which is frequently categorized as mild, moderate, or severe. The differentiation between severe NVP and hyperemesis is a definitional subtlety that is not clinically important. In practice, severe NVP and hyperemesis are likely the same and both are treated with the same interventions.

Table 22-4 Evaluation of Nausea and Vomiting in Pregnancy

History
Abdominal pain (GI disorder)
Blood in vomitus (peptic ulcer or esophagitis from repeated vomiting)
Frequency of nausea, vomiting, and retching episodes (PUQE score to determine severity)
Dietary history (determine severity of NVP)
Elimination (frequency, amount, constipation, diarrhea)
Exposures to viral infection or contaminate food
History of eating disorders
History of chronic disease associated with nausea/vomiting
Medications (e.g., medications that cause nausea such as iron supplements)
Physical Examination
Weight (compare to previous weights to determine severity of NVP)
Vital signs with blood pressure (signs of infection)
Skin turgor, moistness of mucous membranes (signs of dehydration to determine severity of NVP)
Abdominal palpation for organomegaly, tenderness, distension (GI disorders)
Bowel sounds (GI disorders)
Assessment of uterine size (rule out multiple pregnancy or hydatidiform mole)
Laboratory Tests
Complete blood count (signs of dehydration or infection)
Urinalysis and urine dipstick for specific gravity and ketones (dehydration indicates increased severity of NVP)
BUN and electrolytes (electrolyte imbalance indicates increased severity of NVP)
Liver function tests (rule out hepatitis, pancreatitis, and cholestasis)
TSH and T_4 (rule out thyroid disease)
Ultrasound
Confirm pregnancy and rule out multiple pregnancy and/or hydatidiform mole

Abbreviations: BUN, blood urea nitrogen; GI, gastrointestinal; NVP, nausea and vomiting of pregnancy; PUQE, Pregnancy-Unique Quantification of Emesis/Nausea; T4, thyroxine; TSH, thyroid-stimulating hormone.

Several tools to measure the severity of NVP have been validated for use in clinical practice.[3,4,8] A critical component of this evaluation is assessment of how the symptoms interfere with the woman's ability to maintain and engage in daily activities. The PUQE index is based on only three questions, is highly correlated with scores on the more detailed Rhodes index, and is easy to use in practice (**Table 22-5**).[8]

Table 22-5 Modified PUQE Index

1. On an average day, for how long do you feel nauseated or sick to your stomach?				
> 6 hours (5 points)	4–6 hours (4 points)	2–3 hours (3 points)	≤ 1 hour (2 points)	Not at all (1 point)
2. On an average day, how many times do you vomit or throw up?				
7 or more (5 points)	5–6 (4 points)	3–4 (3 points)	1–2 (2 points)	None (1 point)
3. On an average day, how many times do you have retching or dry heaves without bringing anything up?				
7 or more (5 points)	5–6 (4 points)	3–4 (3 points)	1–2 (2 points)	None (1 point)

Abbreviations: NVP, nausea and vomiting of pregnancy; PUQE, Pregnancy-Unique Quantification of Emesis/Nausea.

Total score is the sum of the points for each of the three questions.

Nausea score: mild NVP = ≤ 6; moderate NVP = 7–12, severe NVP = ≥ 13.

Reproduced with permission from Lacasse A, Rey E, Ferreira AE, Morin C, Berard A. Validity of a modified Pregnancy-Unique Quantification of Emesis and Nausea (PUQE) scoring index to assess severity of nausea and vomiting of pregnancy. *Am J Obstet Gynecol.* 2008;198(1):71.31-71.37.[8]

Treatment of Nausea and Vomiting

Treatments for mild, moderate, and severe NVP are presented in **Table 22-6**. First-line treatments for mild NVP for which there is some evidence of effectiveness include ginger products, vitamin B_6, acupressure bands, and dietary changes. Extensive research has established the safe use in pregnancy of Pyridoxine (vitamin B_6) and the antihistamine doxylamine. A delayed-release version of a drug that combines doxylamine and pyridoxine (Diclegis) has been tested extensively and found to be safe and effective; it is now available in the United States for women who are not able to get effective relief from nonpharmacologic therapies.[9]

Table 22-6 Selected Treatments for Nausea and Vomiting in Pregnancy

Treatment	Drug Dosage	Clinical Considerations
Mild NVP		
Temporarily discontinue prenatal vitamins with iron but continue folic acid supplementation		Iron can increase gastrointestinal distress
Acupressure bands		
Ginger	250 mg every 6 hours	May cause acid reflux; several preparations available
Pyridoxine (vitamin B_6)	10–25 mg every 8 hours	
Moderate NVP Without Dehydration		

Doxylamine/pyridoxine (Diclegis)	Combination slow-release product containing 10 mg of pyridoxine hydrochloride and 10 mg doxylamine succinate 2 tablets at night Maximum dose: 4 tablets/day	May cause drowsiness; anticholinergic
Moderate NVP Not Resolved with Doxylamine/Pyridoxine **May add one of the following:**		
Diphenhydramine (Benadryl)	50–100 mg every 4–6 hours PO or PR if vomiting frequently	May cause drowsiness; can offset the anxiety caused by metoclopramide
Metoclopramide (Reglan)	5–10 mg every 6–8 hours PO	FDA black box warning about agitation, anxiety, and acute dystonic reactions
Ondansetron (Zofran)	4–8 mg every 6–8 hours	Headache; concern for potential cardiac arrhythmia—FDA black box warning about QT prolongation for IV single doses greater than16 mg
Promethazine (Phenergan)	12.5–25 mg every 4–6 hours PO/IM/IV/PR	Sedation, anticholinergic effects, dry mouth, dystonic reaction; hypotension if given IV too quickly
Prochlorperazine (Compazine)	5–10 mg every 6–8 hours PO/IM/IV/PR	Sedation, anticholinergic effects, dry mouth, dystonic reaction; hypotension if given IV too quickly.
Moderate NVP with Dehydration		
Non-dextrose IV fluid replacement with multivitamin supplement Physician consultation May use one of the above listed medications once the woman is hydrated and stable		Multivitamin supplement is needed with IV fluids to prevent Wernicke's encephalopathy which can develop secondary to thiamine deficiency

Abbreviations: FDA, U.S. Food and Drug Administration; IM, intramuscular; IV, intravenous; NVP, nausea and vomiting of pregnancy; PO, by mouth; PR, by rectum.

Women with moderate NVP may need medication. If they are dehydrated, intravenous dextrose-containing fluids should be avoided for initial rehydration due to the slight risk of precipitating Wernicke's encephalopathy in women with persistent vomiting. Wernicke's encephalopathy is a neuropsychiatric syndrome resulting from thiamine deficiency; it presents with a classic triad of ocular abnormalities, ataxia, and confusion. Persistent vomiting prevents adequate absorption of thiamine, and administration of carbohydrate-containing IV fluids causes rapid depletion of the limited thiamine left in the body.[10] Without thiamine, metabolic activity in the brain is reduced or switches to lactic acid pathways, resulting in neuronal injury and metabolic acidosis. The standard intravenous solution used for fluid replacement in women with NVP is normal saline, which helps prevent hyponatremia. Potassium chloride can be added as needed, and thiamine (vitamin B_1) or a multivitamin solution that includes thiamine should be added at least once a day to prevent Wernicke's encephalopathy.

For women with severe symptoms, physician consultation and hospitalization are

recommended. Intravenous or intramuscular administration of antiemetics such as metoclopramide (Reglan) or ondansetron (Zofran) is most commonly used to break the initial cycle of vomiting. Of these medications, ondansetron is particularly effective at controlling vomiting. In some studies, this agent has been associated with a slightly increased risk of fetal cardiac septum defects. For this reason, and because treatment of hyperemesis is an off-label use for ondansetron, many providers prescribe ondansetron only after other medications have been tried.[11]

As marijuana gains legal status in many states, an increasing number of women are using marijuana to manage NVP. While women's reports of improved symptoms must be acknowledged, the safety of marijuana exposure for the fetus has not been determined. While it is difficult to isolate the health impacts of marijuana due to confounding factors such as polysubstance abuse, psychiatric comorbidity, and socioeconomic status, research has associated marijuana use with risks of preterm birth, low birth weight, exaggerated startle response, high-pitched cry, and sleep cycle changes in the newborn.[12]

Midwives should also be aware of a counterintuitive response to marijuana that can be mistaken for hyperemesis gravidarum, called cannabinoid hyperemesis. Cannabinoid hyperemesis occurs following heavy marijuana use and is a response to saturated cannabinoid type 1 receptors in the gastrointestinal system.[13] With this condition, women present with symptoms of nausea and vomiting unresponsive to antiemetic treatment. Notably, many women with cannabinoid hyperemesis report that these symptoms can be relieved by hot baths or showers. If cannabinoid hyperemesis is suspected, treatment requires rehydration therapy during 24 to 48 hours of abstinence from marijuana. Symptoms will return if heavy marijuana use resumes.

Most of the common discomforts of pregnancy are not associated with adverse outcomes. However, some can be initial symptoms of a complication that requires evaluation and treatment. The rest of this chapter reviews pregnancy-related complications—those complications that are the result of the condition of pregnancy itself.

Early Pregnancy Loss

Vaginal bleeding occurs in 20% to 40% of pregnant women during the first trimester of pregnancy.[14] Vaginal bleeding may be fresh (bright red) or old (dark brown), be light, and either occur infrequently or persist for several days. The pattern of bleeding and amount of bleeding do not predict miscarriage. Most women who have an episode of minor vaginal bleeding and documented fetal cardiac motion on ultrasound will remain pregnant. The list of differential diagnoses is long, however, some of those diagnoses are associated with significant morbidity, and it can take several days or a few weeks to determine a conclusive diagnosis. Thus, all women who report any vaginal bleeding during pregnancy must be evaluated promptly and may require physician consultation or referral early in the evaluation process.

Differential Diagnoses of First-Trimester Bleeding

Vaginal bleeding in pregnancy can originate in the uterus, cervix, or vagina. Some causes of vaginal bleeding, such as miscarriage, are related to pregnancy; others, such as cervicitis, are not related to pregnancy directly. The most common etiologies of bleeding in the first trimester are miscarriage, subchorionic hemorrhage, anembryonic pregnancy, and vaginitis or lesions of the cervix. The terms *miscarriage*, *spontaneous abortion*, and *early pregnancy loss* are often used interchangeably as there is no consensus on terminology at this time. The terms miscarriage and pregnancy loss are used in this text as these terms more clearly differentiate spontaneous abortion from induced abortion and may be more acceptable to women. **Table 22-7** describes conditions related to pregnancy and early pregnancy loss that cause vaginal bleeding in the first trimester.

Table 22-7 Definitions of Conditions Associated with Early Pregnancy Loss

Term	Definition	Clinical Presentation
Ectopic pregnancy	Pregnancy that is implanted outside of the uterus Most common is tubal pregnancy, in which the fertilized egg becomes implanted in the fallopian tube Ovarian and abdominal pregnancy rare	May be asymptomatic initially and associated with irregular vaginal bleeding or no bleeding. Pregnancy test (urine or serum beta-hCG) may or may not be positive. Adnexal mass may be visible on TVUS; the mass may or may not be palpable on physical examination. The uterus may be slightly enlarged due to hormonal stimulation of the endometrium. If an ectopic pregnancy ruptures, the woman may experience hypotension, signs of shock, sharp severe pain that may be unilateral, CMT, bulging posterior vaginal fornix, and referred pain to the neck/shoulder if there is bleeding into the peritoneum.
Hydatidiform mole	Complete: Haploid sperm fertilizes an ovum that has lost DNA; the sperm DNA replicates and the resulting hydatidiform	The uterus may be larger than expected. Significant NVP and uterine bleeding are present. FHR is not detected.

	mole has a genotype of 46XX or 46 XY Partial: Two haploid sperm fertilize a normal ovum; the resulting pregnancy is triploid (69XXY) or greater	May be associated with hypertension and early preeclampsia Ultrasound has diagnostic features.
Pregnancy of uncertain viability	Ultrasound shows a gestational sac but no embryonic heartbeat	This diagnosis is based on findings on TVUS that do not definitively detect a viable fetus or a nonviable pregnancy. Examples: A gestational sac that is visible on TVUS days before a yolk sac or embryo appears Embryo with a crown rump length greater than 7 mm but no FHR
PUL	Positive pregnancy test but pregnancy cannot be detected on TVUS	Neither ectopic pregnancy nor IUP is confirmed. Women with PUL are monitored carefully until an IUP is visualized, miscarriage occurs, or ectopic pregnancy is diagnosed
Subchorionic hemorrhage	Bleeding between the chorion and the myometrium, or between the chorion and the placenta	Irregular, slight vaginal bleeding occurs. Subchorionic hemorrhage may result in miscarriage if large enough to impede placental growth. Most often the hemorrhages are small and resolve spontaneously as the placenta grows. Visible on ultrasound.
Miscarriage		
Biochemical pregnancy or anembryonic gestation (old term: blighted ovum)	Development of a gestational sac without development of an embryo	Gestational sac > 18 mm without an embryo. Declining beta-hCG levels after beta-hCG level < 1000 mIU/mL is noted with a gestational sac visible on TVUS.
Missed miscarriage[a] (also known as missed abortion)	Nonviable products of conception are retained with or without vaginal bleeding	Irregularly shaped/collapsing gestational sac; no embryo, mean sac diameter of ≥ 25 mm. Crown-rump length ≥ 7 mm and lack of cardiac motion. Absence of embryo with heart beat ≥ 2 weeks after an ultrasound showed a gestational sac without yolk sac or ≥ 11 days after ultrasound showed a gestational sac with a yolk sac.
Recurrent miscarriage	Spontaneous abortion that has terminated the course of ≥ 3 consecutive pregnancies	No diagnostic ultrasound findings.
Threatened miscarriage	Painless vaginal bleeding at < 20 weeks' gestation without cervical dilation or effacement	May or may not show sonographic signs of abnormal sac or embryo. May show subchorionic bleeding.
Inevitable miscarriage	< 20 weeks' gestation with cervical dilation and/or rupture of the membranes in addition to vaginal bleeding and lower abdominal or back pain but no passage of tissue	Embryo > 5 mm in size, without cardiac activity. Embryonic bradycardia after 8 weeks' gestation. Serum progesterone < 5 ng/mL.
Incomplete miscarriage	Passage of some fetal or placental tissue through the cervix at < 20 weeks' gestation	Tissue visible in the uterus without evidence of viable gestation.
Complete	Spontaneous expulsion of fetal and	Uterus empty on sonogram.

miscarriage	placental tissue from the uterine cavity at < 20 weeks' gestation	
Septic miscarriage	Serious maternal infection that occurs after any abortion	May or may not show retained products of conception on sonogram.

Abbreviations: Beta-hCG, beta-human chorionic gonadotropin; CMT, cervical motion tenderness; FHR, fetal heart rate; IUP, intrauterine pregnancy; NVP, nausea and vomiting of pregnancy; PUL, pregnancy of unknown location; TVUS, transvaginal ultrasound.

[a] Findings that are suggestive but not diagnostic for early pregnancy loss include crown-rump length < 7 mm without a heart beat; Mean sac diameter of 16–24 mm without embryo; Absence of embryo with heart beat 7–13 days after ultrasound that showed a gestational sac without a yolk sac or 7–10 days after an ultrasound that showed a gestational sac with yolk sac; empty amnion; enlarged yolk sac > 7 mm; small gestational sac in relation to size of embryo; absence of embryo for ≥ 6 weeks after last menstrual period.

Evaluation of First-Trimester Bleeding

The initial goal in evaluating a woman with first-trimester bleeding is to rule out life-threatening conditions such as active hemorrhage or ectopic pregnancy. **Table 22-8** reviews the history and physical components of evaluation for a woman with first-trimester bleeding. A midwife is frequently involved in the initial assessment of women who have bleeding early in pregnancy. However, ectopic pregnancy requires physician care, and depending on ultrasound and laboratory findings, close monitoring and repeat laboratory tests may be needed for several days before the diagnosis is clearly established. **Figure 22-1** presents one algorithm for evaluation and management of first-trimester bleeding that will help the midwife assess for the initial differential diagnoses which include: non-uterine source of bleeding (e.g., cervical polyp, cervicitis), viable pregnancy, nonviable pregnancy, uncertain pregnancy, pregnancy of uncertain location, or ectopic pregnancy.[15] Knowledge of all possible diagnoses and likely progression of assessment and care allows the midwife to obtain physician consultation and referral at the appropriate time. Once a plan of management is established, the midwife can support the woman with anticipatory guidance as needed.

Table 22-8 Evaluation of First-Trimester Bleeding

Data	Description and Differential Diagnosis
History	
Diagnosis pregnancy	Obtain LMP, LNMP, result of pregnancy test, and ultrasound results. If IUP is identified, ectopic pregnancy is unlikely.[a]
Reproductive history	Risk of miscarriage is increased in women who have previous miscarriages. Risk of ectopic pregnancy is increased in women with previous ectopic pregnancies.
Bleeding pattern and associated events	Profuse bleeding with clots suggests incomplete miscarriage or ectopic pregnancy. Intermittent spotting associated with intercourse or vaginal penetration indicates a cervical or vaginal source of bleeding. Chlamydia or gonorrhea can cause cervicitis that manifests as vaginal spotting. Intermittent bleeding can also suggest miscarriage.
Passage of any tissue	Passage of tissue suggests miscarriage.

Pain	Abdominal pain and referred pain to the neck or shoulder suggests intra-abdominal bleeding from a ruptured ectopic pregnancy, or possibly an ovarian cyst (a nonpregnancy cause).
Physical Examination	
Vital signs and blood pressure	Determine if the woman is hemodynamically stable.
Abdominal examination	Palpate for tenderness/pain, fundal height or other masses, and rebound tenderness (appendicitis).
	Perform Doppler fetal monitoring for FHR if gestational age is 10 weeks or greater (rule out ectopic pregnancy, hydatidiform mole, and missed abortion).
	Palpate for CVAT (pyelonephritis can present with referred pelvic pain).
Speculum examination	Inspect for lacerations, lesions, vaginitis, cervicitis, hemorrhoids, and varicosities.
	Perform a wet prep if indicated.
	Inspect the cervical os for polyps, dilation, presence of fluid, blood, clots, pus, or fetal parts or membranes.
Bimanual examination	Size of uterus.
	Cervical effacement, dilation, CMT.
	Adnexal masses or pain.
Laboratory Tests and Ultrasound	
	Obtain hemoglobin/hematocrit if indicated.
	Perform ultrasound if indicated.
	Serial serum quantitative beta-hCG or progesterone measurement may be indicated.

Abbreviations: beta-hCG, beta human chorionic gonadotropin; CMT, cervical motion tenderness; CVAT, costovertebral angle tenderness; FHR, fetal heart rate; IUP, intrauterine pregnancy; LMP, last menstrual period; LNMP, last normal menstrual period.

[a] Rarely a woman will have both an intrauterine and extrauterine pregnancy—a condition called a heterotropic pregnancy. In this situation, visualization of an intrauterine pregnancy does not rule out an ectopic pregnancy.

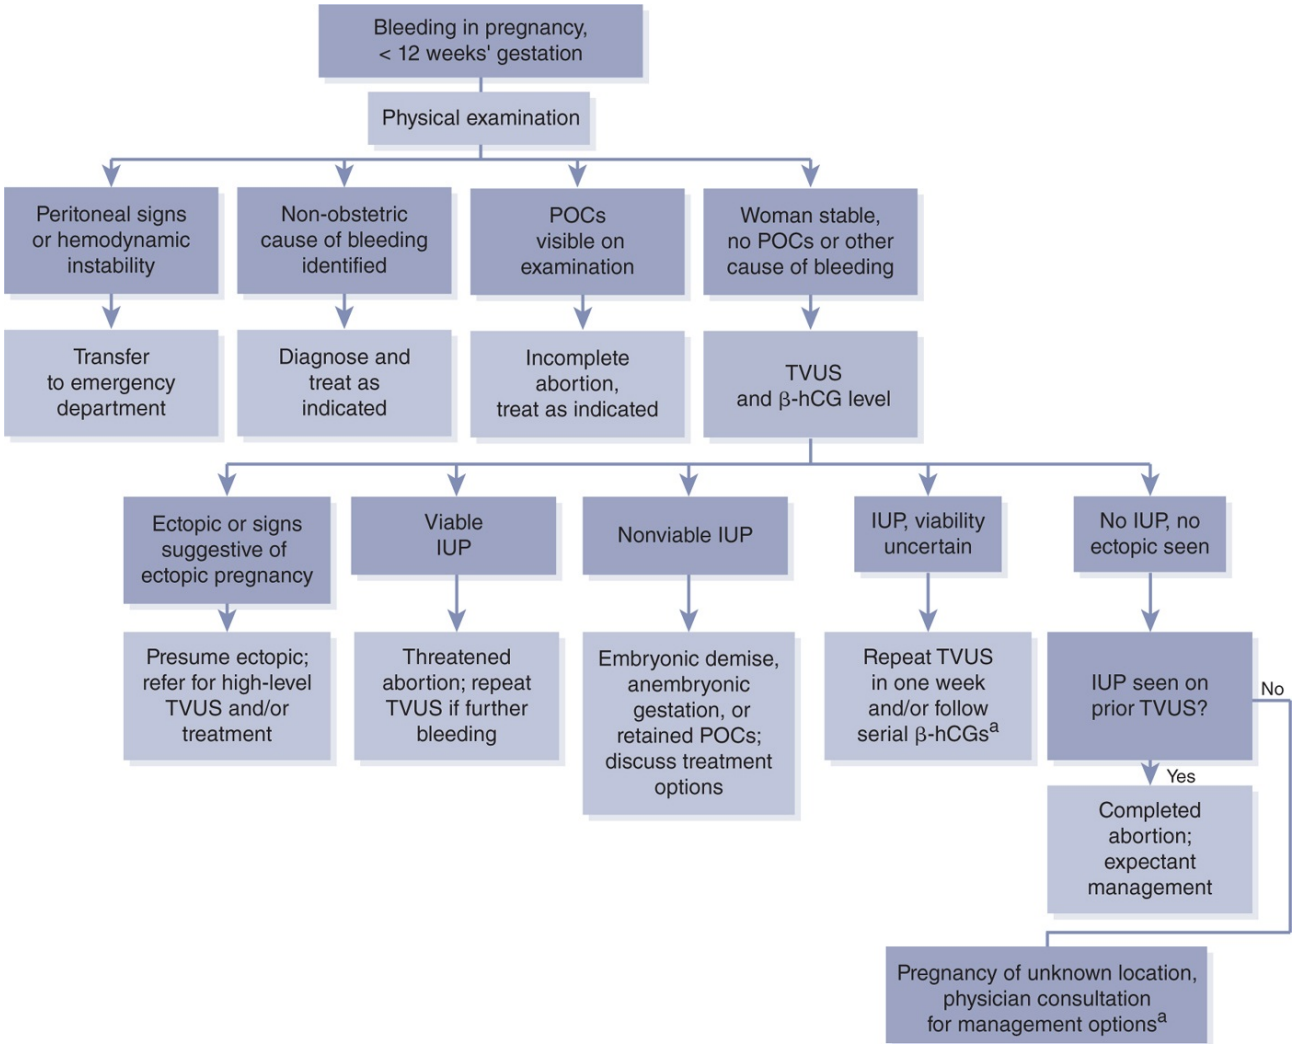

Figure 22-1 First trimester bleeding algorithm.

Abbreviations: **β**-hCG, human chorionic gonadotropin; IUP, intrauterine pregnancy; POCs, products of conception; TVUS, transvaginal ultrasound.

[a] Care of women with a pregnancy of unknown location requires physician consultation for close supervision and monitoring of beta-hcG levels. Ectopic pregnancy cannot be ruled out. The woman's desire for continued pregnancy in combination with assessment of the rise or fall in beta-hcG levels over several days will guide management.

Modified with permission from Reproductive Health Access Project. First trimester bleeding algorithm [Internet]. Available at: https://www.reproductiveaccess.org/resource/first-trimester-bleeding-algorithm/. Accessed December 6, 2017.[15]

Physical Examination

The physical examination can sometimes determine the origin of the bleeding. Cervical polyps, cervicitis, hemorrhagic cystitis, perineal lesions, and vulvar varicosities are sources of bleeding that may be perceived as coming from the vagina. Thus, the initial evaluation is to rule out non-uterine sources of bleeding.

Laboratory Tests

The normal values for beta human chorionic gonadotropin (beta-hCG) in early pregnancy are described in the *Anatomy and Physiology of Pregnancy* and *Prenatal Care* chapters. Serial quantitative measurements of beta-hCG are frequently used to help establish the presence and viability of a pregnancy during the early period before a pregnancy is visible on ultrasound. If the woman is hemodynamically stable, serum beta-hCG levels can be obtained every 2 to 3 days. These values should double approximately every 1.5 to 3 days in the first 5 to 6 weeks of gestation and every 3 to 3.5 days before plateauing at approximately 8–10 weeks' gestation.[14-18] Once the beta-hCG blood level reaches 1500 mIU/mL, a gestational sac should be visible during a transvaginal ultrasound examination. Sometimes, however, transabdominal ultrasound may not be able to visualize a gestational sac until after the beta-hCG reaches 6000 mIU/mL. Expected ultrasound findings have been linked to beta-hCG levels, although each institution will have defined cut-off values for correlating beta-hCG values with ultrasound findings, as there is significant variability in how beta-hCG is measured.[14-18]

Progesterone levels can also be used to discriminate between failing intrauterine pregnancy and viable intrauterine pregnancy. The primary limitation of this biomarker is that it does not help in determining the site of pregnancy. For this reason, assessment of a progesterone level is not a routine component of most clinical management protocols, but it may be of value in individual cases. Progesterone is produced by the corpus luteum in the first trimester of pregnancy. If the serum progesterone value is 20 ng/mL or more, the pregnancy is likely viable. Similarly, a value of 5 ng/mL or less is consistent with an abnormal or failing pregnancy. When the serum progesterone level is between 5 and 20 ng/mL, further evaluation of the pregnancy is indicated.[19] Another potential problem with the use of progesterone as a biomarker for pregnancy is that some laboratories take several days to return results, which limits the clinical utility of this test as a diagnostic tool.

Ultrasound in the first trimester can be diagnostic for most of the uterine causes of first-trimester bleeding. It can support assessment of intrauterine versus extrauterine pregnancy, gestational age (accurate within 5–7 days), viability, number of fetuses, and presence of adnexal masses, uterine fibroids, or fluid in the cul-de-sac. Ultrasound can also identify subchorionic hemorrhage, incomplete miscarriage with retained products of conception, and complete miscarriage. Such an examination can be diagnostic for hydatidiform mole via the appearance of a cluster of grape-like material, a honeycomb effect, or a "snowstorm" on the screen. However, point-of-care ultrasounds commonly performed in an outpatient setting do not have the resolution needed to make many of these diagnoses.[14] If findings of a point-of-care ultrasound performed by a midwife or other clinician are inconclusive, the woman should receive a Level 1 ultrasound under the guidance of a trained radiology technician.

Ectopic Pregnancy

An old adage states, "You have only one chance to miss an ectopic." A woman with subjective symptoms or physical findings consistent with an ectopic pregnancy, or a woman with a positive pregnancy test and no intrauterine pregnancy on ultrasound (pregnancy of unknown location), needs immediate medical assessment.

Signs and symptoms of a ruptured ectopic pregnancy vary widely. The classic presentation

of tubal rupture is a woman who may or may not realize she is pregnant who is having no bleeding or slight irregular spotting. Sudden sharp, stabbing, severe, lower abdominal pain is followed by hypotension and signs of shock. Physical examination findings include tender abdomen, painful vaginal examination, cervical motion tenderness, and a possible adnexal mass. The cul-de-sac may be full of blood, causing the posterior vaginal fornix to bulge outward. Pain in the neck or shoulder, especially on inspiration, may be present as a result of diaphragmatic irritation from blood in the peritoneal cavity. A woman with this profile is experiencing a medical emergency and requires immediate medical assistance.

Once the diagnosis of ectopic has been made, and physician care has been established, management can be surgical or medical if the woman is hemodynamically stable. Surgical removal of the pregnancy and fallopian tube has historically been the standard treatment. Currently, for women who meet specific criteria, oral administration of methotrexate (Trexall) can resolve the ectopic pregnancy, thereby avoiding a surgical procedure.[18,20] After methotrexate administration, the body slowly resorbs all products of conception and serial beta-hCG levels are monitored carefully to make certain the medication was effective in stopping the pregnancy.

Ovarian and abdominal pregnancies are rare. Abdominal pregnancy is usually the result of an early ectopic pregnancy that ruptured into the peritoneal cavity early enough that the fertilized ovum remains viable. In this scenario, the fertilized ovum implants in the abdomen. Signs and symptoms include an inability to outline the uterus and the sensation that fetal parts are just “under the skin” of the woman. The woman may have severe gastrointestinal symptoms that do not resolve with standard management. Ultrasound examination does not always suffice for making the diagnosis, especially later in pregnancy. Abdominal pregnancy is a life-threatening condition due to adverse effects of placental implantation on abdominal organs such as the liver. Birth must be by cesarean, and requires a tertiary setting wherein multiple subspecialists in maternal–fetal medicine and surgery are involved.

Pregnancy of Unknown Location

Approximately 8% to 31% of women will have a positive pregnancy test, yet an intrauterine pregnancy cannot be seen during transvaginal ultrasound. In this situation, neither intrauterine nor ectopic pregnancy can be determined.[14] This situation can resolve in one of four ways: (1) visualized ectopic pregnancy; (2) visualized intrauterine pregnancy; (3) spontaneous resolution to a nonpregnant state (no embryo is found and all biomarkers of pregnancy resolve); or (4) persistent pregnancy of unknown location. The most common outcome is spontaneous resolution. Although the site of pregnancy was never determined, it is assumed that most of these women experienced very early miscarriages.

Women with a pregnancy of unknown location may be managed expectantly or offered either an exploratory dilatation and curettage (D & C) or methotrexate.[14] Thus, an essential first determination must be made regarding the woman’s desire for ongoing pregnancy.[14] However, the recommendation of expectant management versus interventions that cause abortion is based on multiple individual clinical factors as well as the woman’s preference, and physician consultation/referral is needed. Once a plan of management is made, midwives may participate

in monitoring and supporting the woman through the process.

Miscarriage (Spontaneous Abortion)

Miscarriage is the spontaneous termination of pregnancy by expulsion of the products of conception prior to 20 weeks' gestation.[21] Approximately 10% to 15% of clinically recognized pregnancies end in miscarriage, and 50% of miscarriages are attributed to chromosomal abnormalities.[22] If a woman is hemodynamically stable when she is diagnosed with miscarriage, less than 14 weeks' gestation, with no evidence of an incomplete or septic miscarriage, she can choose expectant management, medical management, or surgical management via D & C.[23,24] A woman's choice of management is made after a review of the risks and benefits of each option within a shared decision-making process. All midwives in clinical maternity care will, at some point, need to help a woman through this process.

Regardless of the choice of management, follow-up includes administration of Rho(D) immune globulin (RhoGAM) for women who are Rh (D) negative, with this medication being given within 72 hours of the completed miscarriage. A post-miscarriage visit includes a review of the events, targeted history and physical examination, urine pregnancy test, and discussion of contraception or future pregnancy planning. If the woman appears to have significant grief or emotional difficulty, it may be appropriate to continue seeing her or to refer her for counseling.

Expectant, medical, and surgical management are equivalent with regard to the risk of infection and overall effectiveness.[23,24] Compared to surgical management, the expectant and medical management options are associated with an increased incidence of incomplete miscarriage that requires subsequent surgical intervention, as well as a higher risk of hemorrhage.[23] Approximately 25% to 30% of women with an incomplete, inevitable, missed, or anembryonic miscarriage will spontaneously expel the products of conception within 1 week. Approximately 52% to 60% will expel the products of conception by 2 weeks.[25] After 2 weeks, the additional number of women who spontaneously pass products of conception increases slowly, with a total of 85% to 90% of miscarriages being completed by 6–8 weeks. Based on these data, it is common practice to wait 2 weeks before offering medical or surgical intervention to women who chose expectant management. Some women may want to continue expectant management beyond 2 weeks, and there are no clear health risks to doing so, as long as the woman understands the warning signs and is able to seek treatment if needed.

If the woman chooses expectant management, she is counseled to call her healthcare provider if she has signs of infection (fever, chills, foul odorous vaginal discharge) or heavy bleeding (passing clots frequently and/or soaking a sanitary pad in less than an hour). If she has experienced two or more miscarriages, she may want to collect the products of conception in a container for genetic studies once the miscarriage is completed. The products of conception can also be sent to a laboratory to identify passage of placental villi, thereby confirming complete expulsion of an intrauterine pregnancy. A follow-up urine pregnancy test performed a week or more after the miscarriage can confirm that the miscarriage is complete. Ultrasound is not necessary if the history and/or physical examination findings are normal but may be employed to confirm the uterus is empty if needed.

Medical management of miscarriage involves vaginal administration of 800 mcg of misoprostol (Cytotec). The dose may be repeated up to 7 days later if there is no response to the first dose. Pain medication may be prescribed concomitantly. The success of misoprostol is 80% to 90% within 7 days in women who are up to 10 weeks' gestational age at the time of administration.[24] The success of misoprostol treatment varies somewhat by diagnosis, with slightly lower success rates being seen in women with anembryonic pregnancies and the highest success rates observed in women who have an incomplete or inevitable miscarriage. When misoprostol is the chosen management for miscarriage, the midwife counsels the woman about expected symptoms and warning signs. It is also essential to determine that the woman has access to emergency care should she need it.

Surgical management of miscarriage may be advised for women who prefer this option, after failed expectant management, in women who are more than 10 weeks' gestation, or if a woman has risk factors contraindicating medical management. Risks of surgical management include cervical trauma, uterine perforation, and intrauterine adhesions. These risks are reviewed by the provider prior to the procedure.

Pregnancy of Uncertain Viability

Management of a woman having a miscarriage depends on a definitive diagnosis of miscarriage. A woman who has expelled products of conception, has resolution of symptoms, an empty uterus on transvaginal ultrasound, and falling beta-hCG levels has had a completed miscarriage. Nevertheless, passage of tissue is not always noted, symptoms are not diagnostic, and beta-hCG values or transvaginal ultrasound findings can be inconclusive. Criteria that are diagnostic for pregnancy failure include the following:[24,26]

- Crown rump length of 7 mm or greater without a fetal heart rate
- Mean sac diameter of 25 mm or greater without an embryo
- Absence of an embryo with a heartbeat 2 weeks or more after a scan that showed a gestational sac without a yolk sac
- Absence of an embryo with a heartbeat 11 days or more after a scan that showed a gestational sac with a yolk sac
- Other findings on transvaginal ultrasound may suggest the diagnosis of pregnancy loss but are not conclusive.[22]

Recurrent Miscarriage

When a woman has experienced three or more miscarriages, genetic counseling and an endocrine evaluation should be considered. The standard evaluation for recurrent miscarriage includes ultrasound to rule out congenital abnormalities of the genital tract (e.g., uterine septum, bicornuate uterus), genetic testing, and tests for coagulation disorders, autoimmune disorders, and thyroid abnormalities. Often no direct etiology is able to be determined. Progesterone supplementation and hCG supplementation have been investigated as interventions to prevent miscarriage in women with a history of recurrent pregnancy loss but

evidence for these therapies is inconclusive.[27,28] In some settings, midwives may order initial laboratory tests before referring to fertility or perinatology specialists.

Subchorionic Hemorrhage

Subchorionic hemorrhage is the term for bleeding that occurs between the chorion and the myometrium, or between the chorion and the placenta. This finding is noted in approximately 18% to 30% of women who present with first-trimester bleeding. Its etiology is unclear, and no consensus exists regarding a specific course of treatment. Many of these hemorrhages resolve spontaneously without adverse pregnancy outcomes. Larger subchorionic hemorrhages, however, have been associated with miscarriage.

Gestational Trophoblastic Disease and Hydatidiform Mole

Gestational trophoblastic disease refers to conditions that develop from abnormal placental (trophoblastic) tissue, the most common of which is hydatidiform mole. Gestational trophoblastic neoplasms can develop from gestational trophoblastic disease and include gestational choriocarcinoma, invasive moles, and placental site trophoblastic tumor. All of these conditions can progress to become malignant and life-threatening.[29]

The term *hydatidiform mole* is derived from the combination of the Greek word *hydatisia*, which means “drop of water,” and the Latin word *mola*, which means “false conception.” A hydatidiform mole develops following an abnormal union of sperm and egg. No or limited fetal tissue develops, while abnormal trophoblastic tissue proliferates and fills the uterine space. Placental villi become edematous grape-like structures that can be identified on ultrasound.[29] Hydatidiform mole occurs in approximately 1 in 15,000 pregnancies. Risk factors include younger maternal age (< 16 years) and older maternal age (> 40 years). The risk is higher for women who have had a previous molar pregnancy.[29]

A molar pregnancy is classified as either complete or partial. A complete mole occurs when an ovum that has lost its DNA is fertilized by a sperm, and the resulting products of conception have sperm chromosomal DNA only. No embryonic tissue develops—only overgrowth of trophoblastic tissue. Complete molar pregnancy is characterized by marked enlargement of the uterus and extreme elevations of hCG as the placental tissue synthesizes large amounts of this hormone. Women with a complete mole may have hyperemesis, hyperthyroid symptoms, and often early-onset hypertensive disorders.

A partial mole occurs when two sperm fertilize a normal ovum, and the result is usually a triploid chromosomal complement. Products of conception consist of nonviable fetal tissue and a smaller amount of smaller abnormal trophoblastic tissue. Partial moles have a smaller amount of trophoblastic tissue compared to complete moles, and women’s symptoms are correspondingly less severe.[29]

A woman with molar pregnancy needs referral to a consulting physician for care and follow-up. The plan of care usually includes dilatation and evacuation (D & E) rather than dilatation and curettage (D & C), because suction lessens the chance of uterine perforation and spread of trophoblastic tissue into the abdominal cavity. Hysterectomy is also an option. Medical

abortion with methotrexate and misoprostol is not advised due to the rare but severe risk of trophoblastic embolism with uterine contractions.[29]

After resolution of molar pregnancy, a woman will be advised to avoid becoming pregnant for 6–12 months. A pregnant woman who has a history of a molar pregnancy is offered a first-trimester ultrasound, and depending on the gestational age, she may be monitored with serial quantitative beta-hCG levels until a viable pregnancy is confirmed.

Fetal Conditions

Today, the availability of genetic testing in the first trimester and standard ultrasound examination at 18–20 weeks' gestation can provide information about fetal abnormalities that could not be detected antenatally in the past. Fetal abnormalities range from relatively mild (e.g., cleft lip) to lethal (e.g., anencephaly) and are often first diagnosed in the first or early second trimester.

Congenital Anomalies

When a severe congenital anomaly is diagnosed prenatally, the woman and family may face a range of decisions, including pregnancy termination, carrying the pregnancy, accessing fetal therapy/fetal surgery, the degree of interventions desired in labor, and post-delivery care of the newborn (including perinatal hospice for lethal conditions). Depending on the condition of the newborn at birth, the woman and family may have continued decision making about parenting the child, placing the newborn in foster care, or relinquishing the child for adoption. This complex decision-making process, as well as management of prenatal care and birth, involves an interdisciplinary team of providers—including genetic counselors, pediatricians, and maternal–fetal medicine experts. The midwife can play an important role in helping women and their families identify important questions they want to ask and in interpreting some of the information they are given. It is most important to provide time for the woman and her family during this process, and to recognize that information may need to be repeated a few times. It is not uncommon for a woman with a fetus with an anatomic anomaly to request periodic reconfirmation that the anomaly still exists. A repeat ultrasound should be provided if requested. Nondirective counseling is difficult and may need to be practiced ahead of time so that the midwife can use this approach competently.[30,31]

If the anomaly is lethal, and pregnancy termination is chosen, the plan regarding procedures such as fetal heart rate monitoring and viewing the infant after birth will be detailed ahead of time. Fetal therapy may be an option for women who have a fetus with specific anomalies. The North American Fetal Therapy Network—a collaborative group of 24 medical centers—provides specialized therapy for fetuses with neural tube defects, cardiac anomalies, dysrhythmias, ventral wall defects such as gastroschisis, and other anomalies as part of research protocols.

Incidental Ultrasound Findings

Several anatomic variants in the fetus can be identified during second-trimester ultrasounds. In the majority of cases, they are normal variations in fetal anatomy that are not associated with adverse effects. A few of these findings are more often seen in fetuses with trisomy 21 or trisomy 18, but studies have shown that most of these ultrasound markers do not modify the pretest risk for trisomy sufficiently to warrant further examination.

Table 22-9 reviews the prevalence of each variant and its association with aneuploidy and/or other fetal pathology.[32-34] Because the risk of trisomy 21 or trisomy 18 is generally low,

even if the likelihood ratio increases that risk by 1.5- or even 5-fold, it rarely increases the absolute risk significantly. In addition, the risk of miscarriage associated with amniocentesis is generally higher than the post-test risk for aneuploidy following one of these ultrasound findings. Providing support and clarifying factual information can help minimize adverse psychological impacts following the detection of a soft marker on ultrasound.

Table 22-9 **Incidental Ultrasound Findings**

Ultrasound Marker	Prevalence in General Population	Association with Aneuploidy	Description and Clinical Implications[a]
Markers Not Significant in the Absence of Aneuploidy[a]			
Choroid plexus cysts	0.1–3.6%	1% of identified cases are trisomy 18; no association with trisomy 21	Small fluid-filled sacs in the neuroepithelial folds within the choroid plexus. Often transient and considered a normal developmental variant.
Echogenic intracardiac focus	3–4%; as high as 30% in Asian women	LR 1.4–1.8 for trisomy 21	Small echogenic brightness in the left ventricle thought to be a microcalcification. Usually disappears later in pregnancy, and has no association with cardiac dysfunction. Increases risk of trisomy 21 by 1.5-fold, which usually leaves women in the low-risk category. Targeted ultrasound may be recommended if other risks for trisomy are present.
Markers Associated with Other Fetal Pathologic Conditions			
Echogenic bowel	0.2–1.8%	LR 5.5–6.7 for trisomy 21	Sonographic finding in which the fetal bowel appears bright. Associated with increased risk for trisomy 21, cystic fibrosis, fetal growth restriction, and infection. Genetic counseling is recommended to recalculate trisomy 21 risk; recommend parental screening for cystic fibrosis and evaluation for CMV.
Pelviectasis	0.5–5%	LR 1.5–1.8 for trisomy 21	Mild hydronephrosis; most often a transient state but may indicate renal dysfunction. Physician consultation and comprehensive ultrasound to rule out other structural anomalies and follow-up ultrasound at 32 weeks recommended. If still present, schedule postnatal renal ultrasound.
Nuchal fold thickening	0.5%	LR 8.6–49 for trisomy 21	Measurement between the outer edge of the occiput and the outer margin of the skin. Present in 40% of fetuses with trisomy 21. Also associated with Noonan syndrome and cardiac defects. Genetic counseling and fetal echocardiogram recommended.
Shortened humerus and femur	5%	LR 2.5–7.8 (shortened humerus) and 1.2–3.72 (shortened femur) for trisomy 21	May be a normal genetic predisposition, or an early indicator of fetal growth restriction or skeletal dysplasia. Physician consultation recommended. LR for humerus only should be used to adjust risk for trisomy 21, as it is more sensitive and specific than the LR for shortened humerus. One follow-up ultrasound is recommended in the third trimester to assess fetal growth.

Markers Associated with Other Fetal Pathologic Conditions			
Single umbilical artery	0.2–1.9% in single gestation; 4.9% in twin gestation	40% with trisomy 21 if other anomalies present	Single umbilical artery is an isolated finding associated with FGR and increased risk of perinatal morbidity in some studies, though not all. More research is needed. Physician consultation for management plan if an isolated finding. Refer for genetic counseling and additional diagnostic testing if associated with other markers.
Ventriculomegaly			Larger than expected ventricles in the fetal brain, often idiopathic or a normal variant. May be associated with infection, hydrocephalus, or other chromosomal abnormalities. Physician consultation is recommended; perform comprehensive ultrasound to look for other abnormalities.

Abbreviations: CMV, cytomegalovirus; FGR, fetal growth restriction; LR, likelihood ratio.

[a] These findings are not clinically significant for a woman who has a low risk for aneuploidy according to the results of first- and second-trimester screening, or if the woman had a diagnostic test to rule out chromosomal abnormalities.

Based on Norton ME. Follow-up of sonographically detected soft markers for fetal aneuploidy. *Semin Perinatol.* 2013;37:365-369[32]; American College of Obstetricians and Gynecologists. Practice Bulletin No. 175: ultrasound in pregnancy. *Obstet Gynecol.* 2016; 128:e241-e256[33]; Rao R, Platt LD. Ultrasound screening: status of markers and efficacy of screening for structural abnormalities. *Semin Perinatol*. 2016;40(1):67-78.[34]

Fetal Growth: Large for Gestational Age

Serial measurement of fundal height is used to monitor fetal growth and as an initial screen for excessive growth or fetal growth restriction.[35] Although fundal height measurements are not highly sensitive, serial recordings following use of a standard technique is standard prenatal practice. When fundal heights are greater than expected, possible diagnoses include multifetal gestation, polyhydramnios, and macrosomia. Ultrasound can determine the number of fetuses and amount of amniotic fluid present, but does not reliably detect macrosomia. The fetus whose estimated weight is greater than the 90th percentile for gestational age is considered large for gestational age (LGA). A fetus estimated to weigh more than 4000 grams is considered macrosomic.

Risk factors for macrosomia include maternal diabetes, maternal weight gain, multiparity, Hispanic race, history of macrosomia in a prior pregnancy, and post-term gestation.[36] Macrosomia is highly associated with maternal diabetes. Fetuses of women who have diabetes develop more body fat that is preferentially centered in the shoulders and upper body. These fetuses are at increased risk for shoulder dystocia, birth trauma, and cesarean section. Because the ultrasound diagnosis of macrosomia is imprecise, the American College of Obstetricians and Gynecologists does not recommend induction of labor for suspected macrosomia. An elective cesarean section may be offered if the estimated fetal weight is more than 5000 grams in a woman without diabetes or if the estimated fetal weight is more than 4500 grams in a woman with diabetes.[36]

Fetal Growth: Fetal Growth Restriction

When serial fundal heights do not increase as expected, an ultrasound for fetal growth should be ordered. Fetal growth restriction is diagnosed when the fetus has an estimated weight less than the 10th percentile for gestational age.[37] Although some fetuses who are less than the 10th percentile for their gestational age are constitutionally small without compromise, others have some cause for their growth restriction.

Historically, fetuses who were more than two standard deviations smaller than average were termed "intrauterine growth retarded." This term was changed to "intrauterine growth restriction" (IUGR) and in recent practice has been adjusted to "fetal growth restriction" (FGR). The term "small for gestational age" (SGA) is reserved for an infant born at term who is below the 10th percentile for weight for his gestational age.[37] When FGR is related to an abnormal condition, perinatal morbidity and mortality are significantly increased. The etiology of FGR can be categorized as fetal, maternal, or placental (**Table 22-10**).[38]

Table 22-10 Etiology of Fetal Growth Restriction

Fetal Factors	Maternal Factors	Placental Factors
Chromosome abnormalities	Extremes of maternal age	Abnormal placental attachment to the uterus
Genetic syndromes	Maternal disease (e.g., hypertension, pregestational diabetes, cardiac, renal insufficiency, sickle cell anemia, systemic lupus erythematosus)	Reduced placental perfusion secondary to maternal vascular disease
Intrauterine infections: particularly viral	Malnutrition	Umbilical cord abnormalities
Multifetal gestation	Previous history of fetal growth restriction	
	Substance use	
	Teratogen exposure	
	Uterine malformation	

Based on Nardozza LM, Caetano ACR, Zamarian AC, et al. Fetal growth restriction: current knowledge. *Arch Gynecol Obstet.* 2017;295:1061-1077.[38]

Fetal growth restriction is generally subdivided into three categories: symmetrical, asymmetrical, or a combination of the two. A fetus with symmetrical fetal growth restriction will have both the fetal body and head equally smaller than expected. The most common cause of symmetrical growth restriction is congenital anomalies. Symmetrical growth restriction that occurs early in gestation and is progressively severe—that is, the delay becomes more pronounced as pregnancy continues—is associated with severe maternal malnutrition, low prepregnancy weight/no weight gain, multifetal gestation, chromosomal abnormalities, perinatal infections, and exposure to drugs or environmental teratogens. The prognosis for this fetus is poor.

The second category of fetal growth restriction is asymmetrical growth restriction. This condition is the result of compromise later in fetal life, typically after 30 weeks' gestation. Asymmetric growth restriction can be caused by any condition that causes decreased placental blood flow or decreased oxygenation of the fetus. In this case, the fetus's estimated weight is below the 10th percentile but the head circumference is larger than the 10th percentile. Factors

associated with asymmetric fetal growth restriction include maternal hypertension, renal disease, collagen vascular disease, microvascular disease of diabetes, cyanotic heart disease, and hemoglobinopathies.

The third subcategory of fetal growth restriction is a combination of symmetrical and asymmetrical growth restriction. The etiology of this type is often either maternal infection (e.g., rubella, cytomegalovirus) or exposure to toxins (e.g., medications, illicit drugs).

Perinatal complications for fetuses with growth restriction include complications associated with the etiology, such as intrauterine infection or maternal hypertension. Growth restriction from causes associated with inadequate placental perfusion places the fetus at increased risk for poor oxygenation, fetal compromise, and fetal death. Fetal growth restriction with absent or reversed end-flow Doppler velocimetry indicates a fetus at great risk.

Once fetal growth restriction is identified on ultrasound, prompt physician consultation or maternal–fetal medicine referral can provide the comprehensive fetal survey ultrasound and other evaluations that may be needed. Ongoing monitoring and determination of the best time for induction of labor will depend on the underlying etiology, gestational age, pattern of fetal growth, and results of fetal surveillance tests; therefore, physician consultation is required.

Multifetal Gestation

Multifetal gestation refers to a pregnancy in which two or more fetuses are present. The incidence of multifetal gestation in the United States increased 76% between 1980 and 2009, largely because of the increased use of assisted reproductive technologies, including ovulation-inducing medications. Twin pregnancies can develop secondary to implantation of two fertilized ova, or when one fertilized ovum cleaves and develops into two fetuses (**Figure 22-2**). Monozygotic twins (identical) develop from one egg and one sperm; dizygotic twins (fraternal) develop from two eggs and two sperm. Monozygotic twins may be monochorionic or dichorionic. Dizygotic twins will always be dichorionic and, therefore, diamniotic. Chorionicity in monozygotic twins depends on when, during the early gestational period, the zygote splits. It includes the following possibilities:

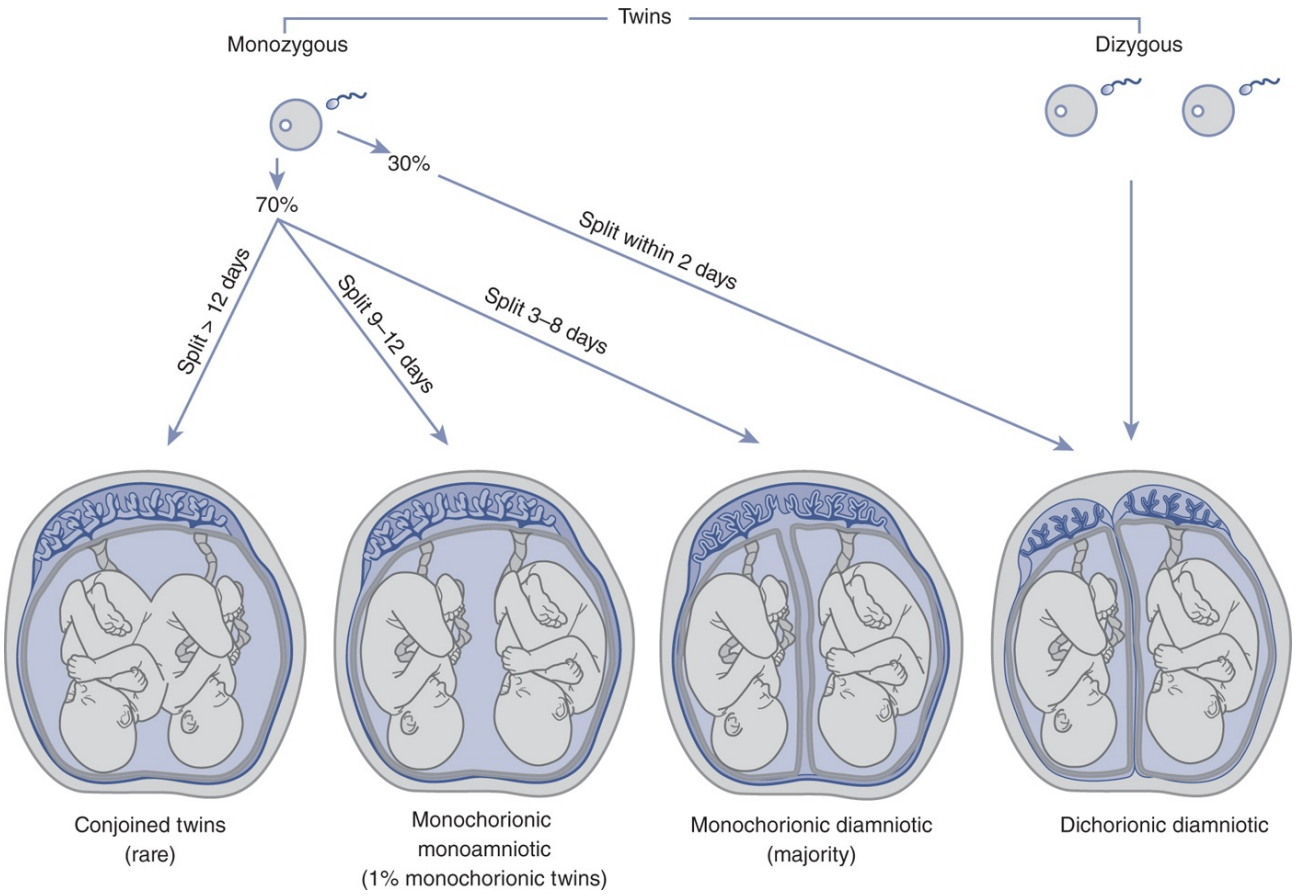

Figure 22-2 Zygosity of twin gestations.

- Diamniotic/dichorionic, which occurs if cleavage happens by day 3 after fertilization
- Diamniotic/monochorionic, which occurs if the zygote splits between days 4 and 8
- Monoamniotic/monochorionic, which occurs if cleavage happens between days 8 and 13

Zygosity cannot be determined prenatally in all cases. When both fetuses are the same gender and each has a separate placenta, the pregnancy could be either monozygotic or dizygotic. Monoamniotic/monochorionic chorionicity is rare and increases the risk for perinatal mortality, secondary to the high likelihood of cord entanglement and cord strangulation. If the zygote splits after day 13, the embryos have not had time to separate and they develop as conjoined twins.

It is common for a woman with a multifetal gestation who receives prenatal care in the first trimester to have an initial uterine size that is consistent with her dates. The uterus starts to become larger than expected in the early second trimester. Diagnosis is confirmed via ultrasound, which will determine fetal number, fetal anatomy, and chorionicity of placentation.

Once the diagnosis of multiple pregnancy is made, the woman is referred to a physician for care, although a midwife may participate in conducting prenatal visits as part of an interdisciplinary team approach. Prenatal care management includes more frequent prenatal visits, increased surveillance for complications, serial ultrasounds to monitor fetal growth, dietary counseling, iron supplementation, and earlier changes in home and work responsibilities. Fetal growth and development is monitored with ultrasound examinations that

are generally performed every 3 to 4 weeks from 20 weeks' gestation until term. Discordant growth or suggestion of lagging growth in either or both fetuses requires urgent physician evaluation.

Women with twin gestations may benefit from extra counseling and anticipatory guidance that address several topics unique to multifetal gestation. In these areas, midwifery care can complement medical care for women who are pregnant with twins. For example, women with twins need more protein and calories. The recommended weight gain with a twin gestation is 40–45 pounds for women with a normal body mass index (BMI), 42–50 pounds for underweight women, and 30–35 pounds for overweight women. Folic acid supplementation remains at 1 mg daily, as with singleton pregnancy. A daily prenatal multivitamin can provide the needed micronutrients, including 30 mg of elemental iron. Supplementation with calcium and Vitamin D is recommended and docosahexaenoic acid (DHA) should be considered for women with a twin pregnancy.[39]

Women with multifetal gestations are at increased risk for several conditions. Management is first based on chorionicity, as monochorionic twins have a higher rate of complications than do dichorionic twins. Twin-to-twin transfusion syndrome is one of the most serious complications associated with multifetal gestation; it occurs more frequently in women who have monochorionic placentation. Twin-to-twin transfusion syndrome can occur in monochorionic twins when two placentas are conjoined. Abnormal blood vessels form between the two placentas such that one twin receives an excess of blood (recipient) and the other twin (donor) receives too little blood. The donor twin may become significantly anemic and growth restricted, and may develop oligohydramnios. The recipient twin may have polyhydramnios, as well as volume overload leading to cardiomegaly and cardiac failure. The development of discordant growth in monochorionic twins with oligohydramnios in one twin and polyhydramnios in the other is diagnostic for twin-to-twin transfusion syndrome. Management of twin-to-twin transfusion syndrome requires maternal–fetal medicine and other subspecialized physicians who can consider procedures to maximize the outcome for the pregnancy.

For all women with multifetal gestations, major fetal complications are preterm birth and fetal growth restriction. Maternal complications may include placenta previa, gestational diabetes, preeclampsia, malpresentation, and dysfunctional labor. Less common complications include acute fatty liver disease, pruritic urticarial papules and plaques of pregnancy (PUPPP), and pulmonary embolus.

Prevention of preterm labor is a major priority in caring for women with a multifetal gestation. Management may include limiting activity and increasing rest periods throughout pregnancy. Bedrest has not been found to be an effective means to prevent preterm labor in multifetal gestations. Likewise, prophylactic cerclage and progesterone therapy have not been found to be effective in preventing preterm birth in such gestations. Instruction regarding sexual activity is based on cervical findings, previous obstetric history, and frequency of Braxton Hicks contractions. Careful attention to signs of hypertension, preeclampsia, and gestational diabetes is especially important for women with a multifetal gestation, and development of these signs warrants early intervention. Maternal morbidity will increase the already elevated risk of preterm birth by increasing the need to induce birth for maternal indications.

Plans should be made for a physician to attend the birth, and the mode of birth will depend on the position of both fetuses and physician expertise. The most common presentation is vertex/vertex. Next most common is breech with vertex or breech, and the third most common presentation is vertex/breech. The breech/vertex presentation creates a risk that the fetal heads may become locked. A cesarean section is recommended in that situation. Depending on the skills of the physician, a second twin breech may be delivered vaginally by the physician.

Fetal Malpresentations at Term

The three possible fetal presentations, as reviewed in the *Anatomy and Physiology of Pregnancy* chapter, are cephalic, breech, and shoulder. Subcategories of cephalic presentation include face, brow, and occiput; the latter is further categorized as occiput anterior, occiput transverse, or occiput posterior positioning. The breech presentation can present as a complete breech, frank breech, or footling breech.

Cephalic Malpresentations

Cephalic malpresentations, which include vertex, sinciput, brow, face, or chin, are diagnosed during labor and, therefore, are reviewed in more detail in the *Complications During Labor and Birth* chapter. Fetuses that are in a brow or face presentation usually convert to occiput presentation during labor and birth, but may be born in one of these positions if the fetus is very small. Risk factors for brow and face presentation include prematurity, grand multiparity, polyhydramnios, multiple nuchal cords, and congenital anomalies such as anencephaly or hydrocephalus.

Breech Presentation

By 35 to 36 weeks' gestation, the majority of fetuses will spontaneously settle into a vertex presentation. In approximately 3% to 4% of cases, however, at term the fetus will be in a breech presentation with the buttocks or feet presenting.[40] There are three types of breech presentation: frank, complete, or footling. In a *frank* breech presentation, the hips are flexed and the knees extended, with the infant's feet near the head. The buttocks (breech) are presenting at the pelvic inlet. A *complete* breech is similar, with the buttocks as the presenting part in the pelvis. The lower knees are flexed, however, and the infant is in a crossed-legged position. If one or both feet are extended down below the buttocks, this is referred to as a single or double *footling* breech. When assessing position in a fetus in a breech presentation, the fetal sacrum is used as the point of reference—for example, *left sacrum anterior* (*LSA*) (**Figure 22-3)**.

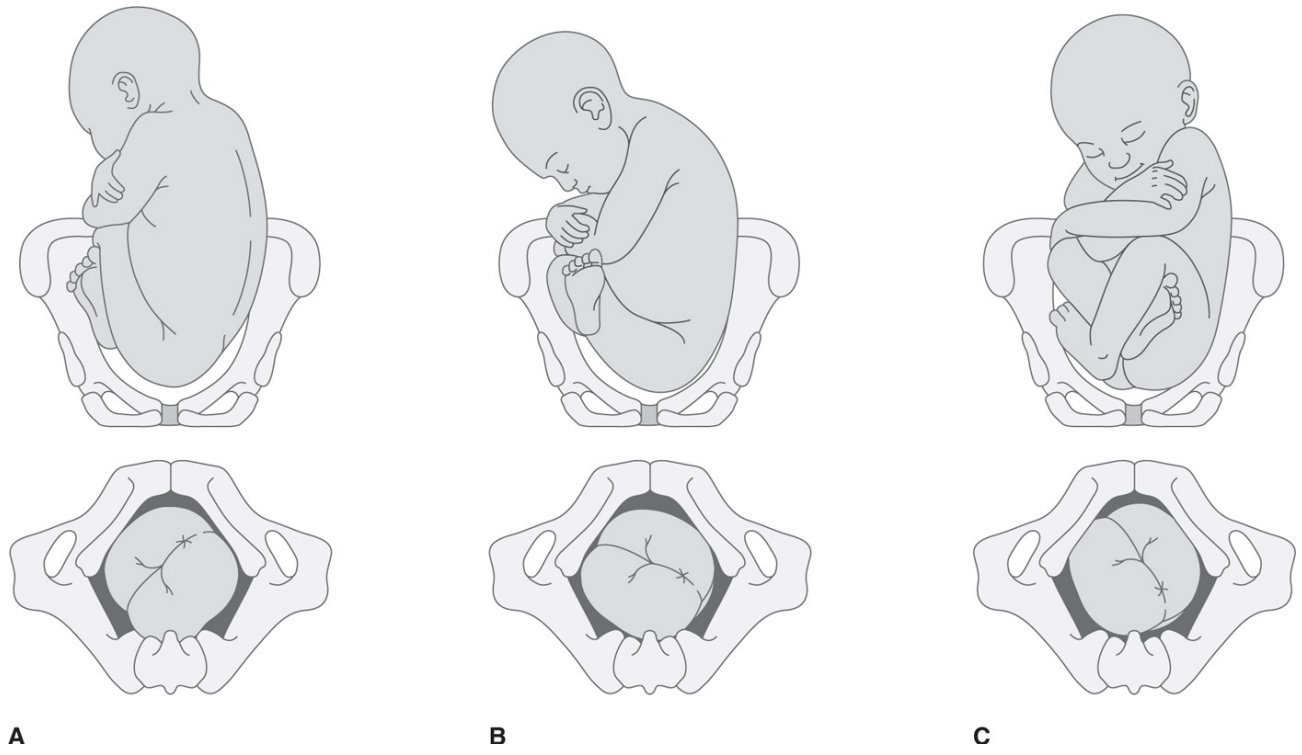

Figure 22-3 Breech positions. **A.** Left sacrum anterior. **B.** Left sacrum transverse. **C.** Left sacrum posterior.

Prematurity, multifetal gestation, multiparity with lax uterine tone, polyhydramnios or oligohydramnios, previous breech presentation, and placenta previa have all been associated with an increased risk of breech presentation.[40] In addition, uterine anomalies such as a bicornuate uterus or the presence of large fibroids in the lower uterine segment may impede a normal vertex presentation. Breech presentation is also associated with an increased incidence of fetal anomalies such as hydrocephaly or anencephaly.[40]

A breech presentation is often identified during a prenatal visit using Leopold's maneuvers when the firm ballottable vertex is palpated in the upper fundal region. The woman may report feeling increased movement in the lower pelvic area and the fetal heart tones may be found in the upper abdomen. Prior to 35 weeks' gestation, this finding is normal but should be noted in the prenatal chart, especially if the woman has any of the known predisposing risk factors. Approximately 10% of breech fetuses will spontaneously revert to vertex presentation after 36 weeks' gestation.[40] The midwife should, therefore, have a low threshold for ordering an ultrasound at 35 to 36 weeks' gestation to confirm the presentation if breech presentation is suspected.

Vaginal birth of a fetus in a breech position is associated with increased risks for perinatal morbidity and mortality. The head is the largest part of the fetus. When the fetal head passes through the cervix and vagina, the rest of the body follows without difficulty. In a breech presentation, however, the body can pass through a partially dilated cervix and cephalopelvic disproportion may not be detected until the head becomes entrapped after the body is born. If a breech presentation is diagnosed after 35 weeks' gestation but before the onset of labor, the midwife should consult with a physician to determine whether the woman is a candidate for an

external cephalic version. During this procedure, external pressure is manually exerted on the woman's abdomen to physically rotate the fetus to a vertex presentation. External cephalic version is successful in approximately 58% of cases.[41] Factors that decrease the success of external cephalic version include oligohydramnios, anterior placenta, breech engaged in the pelvis, fetal back located posteriorly ("back down"), and maternal obesity.[42] External cephalic version should not be performed if the woman has any contraindication to vaginal birth (e.g., placenta previa) or if any of the following conditions are present: ruptured membranes, fetal or uterine anomalies, nonreassuring fetal heart rate patterns, hyperextended fetal head, placental abruption, or multifetal gestation.[42]

External cephalic version is performed only in a hospital setting, ideally between 36 and 37 weeks' gestation. In addition to a prerequisite reassuring fetal heart rate assessment, the woman may be given a dose of subcutaneous terbutaline (0.25 mg) to induce uterine relaxation before the procedure is attempted.[41] External cephalic version is done under direct ultrasound guidance with continuous monitoring of the fetal heart rate (by an assistant). Women can experience considerable discomfort during this procedure, so external cephalic version is sometimes attempted under epidural or spinal anesthesia. The most common fetal side effect of external cephalic version is a transient nonreassuring fetal heart rate pattern, such as a prolonged deceleration.[41] In rare circumstances, external cephalic version has been reported to cause vaginal bleeding, placental abruption, fetal compromise, fracture of fetal limbs, and fetal death.[41] An emergency cesarean may be required if fetal compromise is noted. Midwives often assist during external cephalic version by providing ultrasound guidance during the procedure and/or offering emotional support and comfort to the woman. After the procedure, fetal heart rate and contraction monitoring should continue for at least 1 hour depending on institutional policies.

Various maternal position change exercises that might turn breech presentations to vertex have been proposed (e.g., resting with hips elevated and knee–chest positions), but research has not shown these methods to be successful.[43] Women with persistent breech presentations at 36 to 37 weeks' gestation will need a referral to an obstetrician for birth planning.

Placental, Amniotic Fluid, and Umbilical Cord Abnormalities

Placental abnormalities fall into three categories: (1) abnormal placental size or structure, (2) abnormal placement within the uterus, and (3) abnormal attachment. Some morphologic placental variations can be detected prenatally via ultrasound. Some are associated with adverse fetal effects, or may cause maternal or fetal bleeding. In general, the placental size correlates with the size of the fetus. An abnormally small placenta is associated with intrauterine infection and fetal growth restriction, whereas an abnormally large or edematous placenta is associated with conditions such as maternal diabetes and fetal hydrops.

Circumvallate Placenta

Abnormal placenta configurations are shown in **Figure 22-4**. Circumvallate placenta is a placenta with a double layer of membrane (chorion and amnion) that circles the edge of the placenta on the maternal side and appears as a whitish ring.[44] The fetal vessels do not extend beyond this ring, but extrachorionic placental tissue does. The etiology of circumvallate placenta is not well known. Retrospective studies have found an association with circumvallate placenta and an increased incidence of second-trimester bleeding, preterm birth, and preterm premature rupture of membranes.[45] In contrast, a circummarginate placenta has a ring of membrane that is flat and close to the edge of the placental disc. Circummarginate placentas are not associated with adverse outcomes.

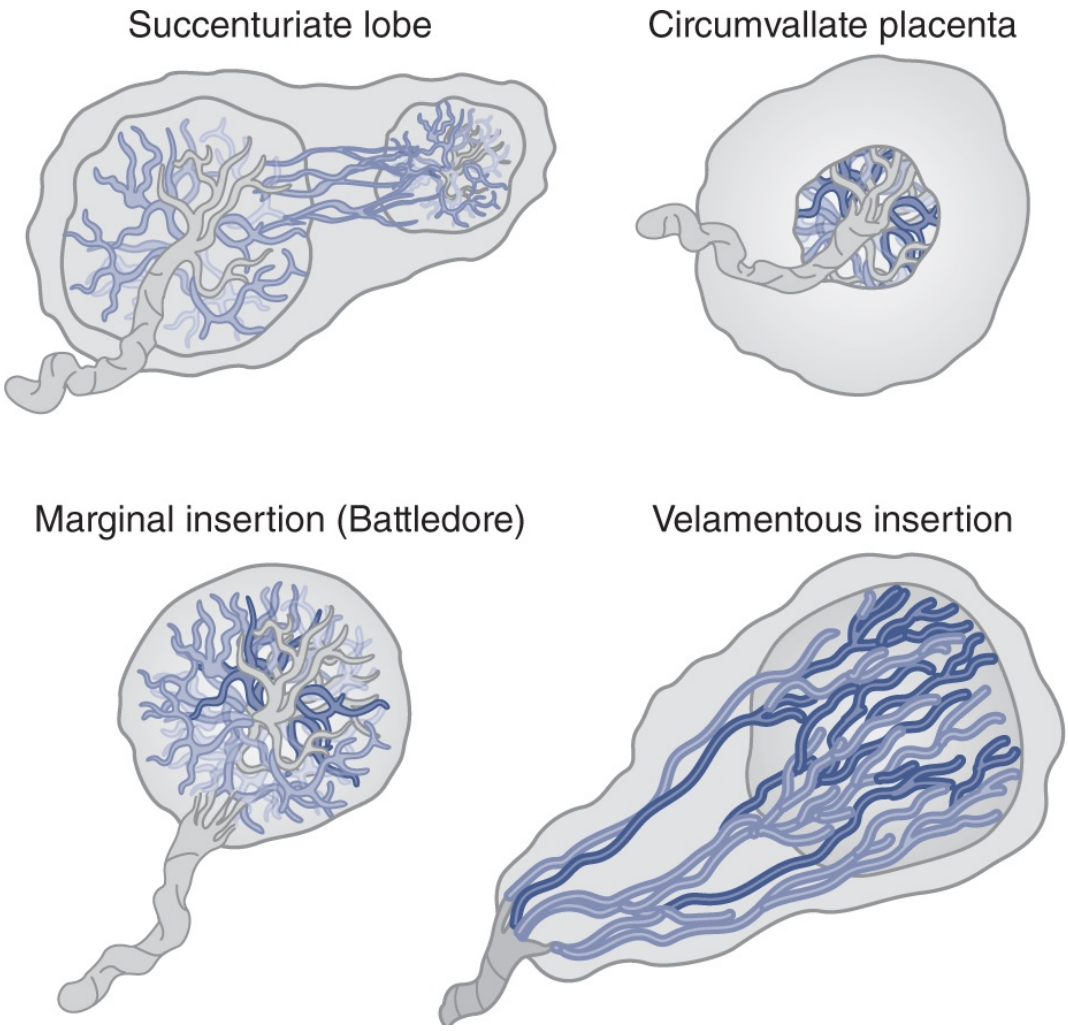

Figure 22-4 Abnormal placental configurations.

Succenturiate Lobe

A placenta with a succenturiate lobe has an accessory lobe or cotyledon separate from the primary placental mass. The succenturiate lobe, which is connected to the primary mass by a fetal artery and vein, functions normally. Succenturiate lobes are often clinically insignificant but may be associated with other placental abnormalities such as velamentous cord insertion. The most common problem associated with this placental variation is retained placenta after birth, which is one of the reasons the placental edge is examined after birth to look for torn vessels that extend beyond the placental margin.

Umbilical Cord Abnormalities

Umbilical cord variations include, unusual insertions, single umbilical artery, and excessive or low coiling. The umbilical cord is normally inserted centrally on the fetal side of the placenta. *Marginal insertion*, also called *battledore placenta*, refers to insertion of the umbilical cord on the edge of the placental mass. Fewer than 10% of placentas exhibit a marginal insertion, though this morphologic variation is not associated with adverse effects.

Umbilical Cord Insertion

Velamentous cord insertion is a structural developmental abnormality of the placenta in which the cord is inserted in the membrane some distance from the placental tissue, leaving a span of vessels not protected with Wharton's jelly that traverse the membrane before being integrated into the placenta. A velamentous cord insertion can occur with a normal placenta or between succenturiate lobes of a placenta. If the velamentous vessels cross the internal cervical os, the condition is referred to as *vasa previa*. Risk factors for a velamentous cord insertion and vasa previa include placenta previa, multifetal gestation, history of assisted reproductive technology, obesity, and smoking.[46] Doppler ultrasound may or may not identify the abnormal vessels; indeed, the diagnosis is often made at birth.

Any umbilical cord vessels that are not protected within the structure of the umbilical cord are vulnerable to rupture and compression during labor and birth.[46] Rupture of the velamentous vessels can cause rapid fetal exsanguination. These abnormalities are also associated with an increased risk for preterm birth, fetal growth restriction, and perinatal morbidity/mortality, although the absolute risk for these events is low. Notably, studies that have correlated velamentous insertion of perinatal outcomes may be confounded by other complications such as multifetal gestation or placenta previa. Nonetheless, physician consultation is indicated for a woman who has a velamentous cord insertion diagnosed prenatally. Additional antepartum surveillance may be recommended, and the woman is counseled to come into a hospital setting as soon as labor starts for continuous fetal heart rate monitoring. A note is placed in the woman's health record where the intrapartum care providers can see it, because delivery of the placenta needs to be performed gently to avoid tearing the cord off.

Labor and cervical dilation in the presence of vasa previa poses a risk for life-threatening fetal hemorrhage. Women with a vasa previa require physician management in a Level III or Level IV setting. Recommendations for care include weekly fetal surveillance, administration of corticosteroids to stimulate fetal lung maturity, and planned preterm cesarean birth that is scheduled for 34 weeks' gestation but may be considered earlier if needed.[47]

Single Umbilical Artery

The umbilical cord usually has two arteries and one larger vein. Occasionally, a fetus will have only one artery and one vein. The mechanism is presumed to be secondary atresia of one of the arteries. The prevalence of one umbilical artery is less than 1%. However, the prevalence is higher in fetuses with congenital anomalies, and those who are stillborn. When this finding is noted, a comprehensive ultrasound is performed to assess for other anatomic abnormalities, in particular cardiac and renal abnormalities. The incidence of aneuploidy is not increased and therefore invasive genetic diagnosis is not indicated although non-invasive testing for fetal DNA to screen for trisomy 21, 18, or 13 may be offered if not already performed.

If the fetus does not have other abnormalities, a single umbilical artery is associated with a small increase in small for gestational age. Other complications such as preeclampsia, preterm birth, and perinatal mortality have been reported but studies on these outcomes are inconclusive. In some settings, serial ultrasounds to monitor growth and fetal testing in the third

trimester is recommended but these recommendations are not universal so physician consultation is obtained. Most women with this isolated finding can be reassured that there are no additional risks for the fetus.

Umbilical Cord Coiling

One interesting umbilical cord finding is the degree of umbilical coiling present. Umbilical cords that are hypo- or hyper-coiled are associated with increased perinatal morbidity. Attempts to correlate the actual degree of coiling with perinatal outcomes have not been fruitful.[48] Umbilical cord coiling is not a standard component of an ultrasound examination, and changes in prenatal management are not recommended if either variation is noted. Nevertheless, hypo- or hyper-coiling is occasionally reported. In such a case, a detailed examination and review of the woman's history may be of value and physician consultation is indicated.

Placenta Previa

When the placenta implants over the internal cervical os, the condition is referred to as placenta previa. Placenta previa occurs in approximately 1 in 200 births. It is often diagnosed during routine ultrasonography in the second trimester.[46,49] Approximately 2% of women will have placenta previa identified during the second-trimester standard ultrasound, but 90% of these placentas will no longer be located over the cervical os later in pregnancy as the placenta grows toward the fundus.

In the past, placenta previa was categorized by the distance from the placental edge to the internal cervical os and classified as complete, partial, marginal, or low-lying (**Figure 22-5**). The availability of transvaginal ultrasound has allowed for a high degree of accuracy in measuring the distance between the placental edge and the cervix and has resulted in a change in terminology.[49] All placentas covering the os to any degree are now given the diagnosis of placenta previa; placentas close to but not covering the os are referred to as *low-lying placenta*.[49]

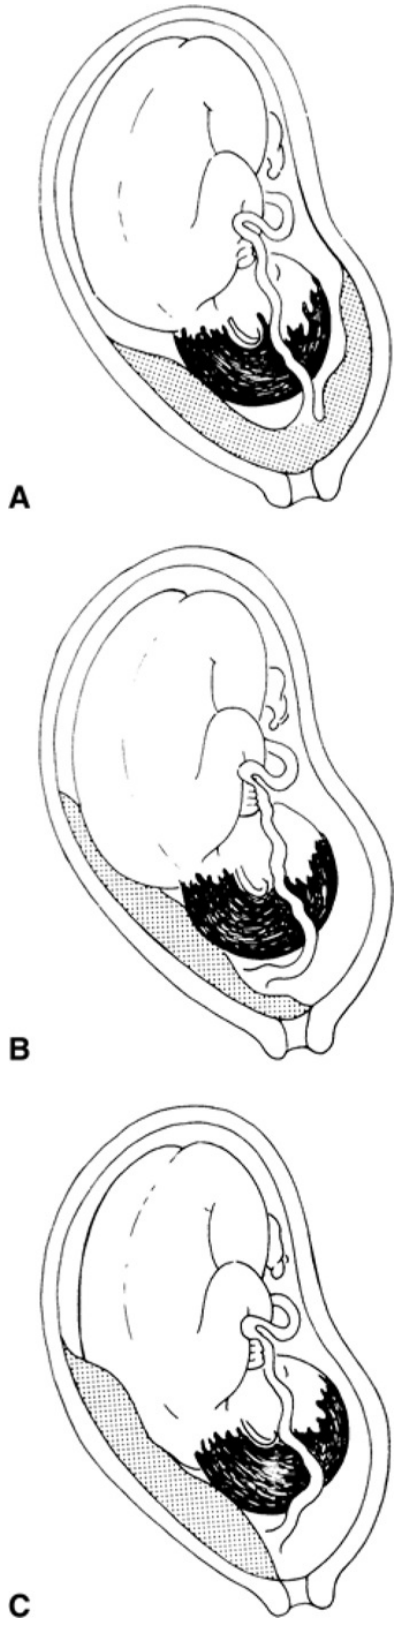

Figure 22-5 Placenta previa. **A.** Complete. **B.** Partial. **C.** Low-lying.

The primary risk factor for development of placenta previa is previous uterine scarring secondary to cesarean section or uterine surgery.[50] Additional risk factors are maternal age, parity, multifetal gestation, male fetus, smoking, cocaine usage, multiple prior pregnancy

terminations, and use of assisted reproductive technology.[49] This risk increases with repeat cesarean sections.[51]

The greatest risks associated with placenta previa are maternal hemorrhage and premature birth. When the cervix starts to remodel (effacement and dilation) in preparation for labor and birth, the portion of the placenta resting over the cervix separates, which causes bleeding. The gestational age at which vaginal bleeding first occurs is unpredictable. In the majority of women, the initial bleeding episode presents as a painless gush of blood (the amount is also unpredictable) prior to 36 weeks' gestation.

Once placenta previa is diagnosed, repeat ultrasound is recommended at 32 weeks, and then again at 36 weeks (if the placenta is still a previa at the 32-week examination). If the placenta remains encroaching over the cervix at 36 weeks' gestation, vaginal birth is contraindicated. Women are advised to avoid sexual intercourse with vaginal penetration and orgasm so as to avoid direct trauma to the cervix or uterine contractions, and to call or come to the hospital immediately if vaginal bleeding occurs. Physician consultation or referral is indicated, as the management plan for ongoing prenatal care may include administration of corticosteroids to enhance lung maturity as well as plans for cesarean birth. Acute care of women who present with vaginal bleeding is reviewed in the *Complications During Labor and Birth* chapter.

Placenta Accreta

Placenta accreta, increta, and percreta are abnormalities of placental implantation in which the anchoring placental villi attach to the myometrium instead of the decidua (endometrium). *Placenta accreta* is diagnosed when the cytotrophoblast attaches to the myometrium, *placenta increta* occurs when the cytotrophoblast invades into the myometrium, and *placenta percreta* occurs when the cytotrophoblast tissue extends through the myometrium and serosa to attach to adjacent maternal organs (**Figure 22-6**).[50,51] The term "placenta accrete" is often used to describe all three variants of abnormal placental implantation.

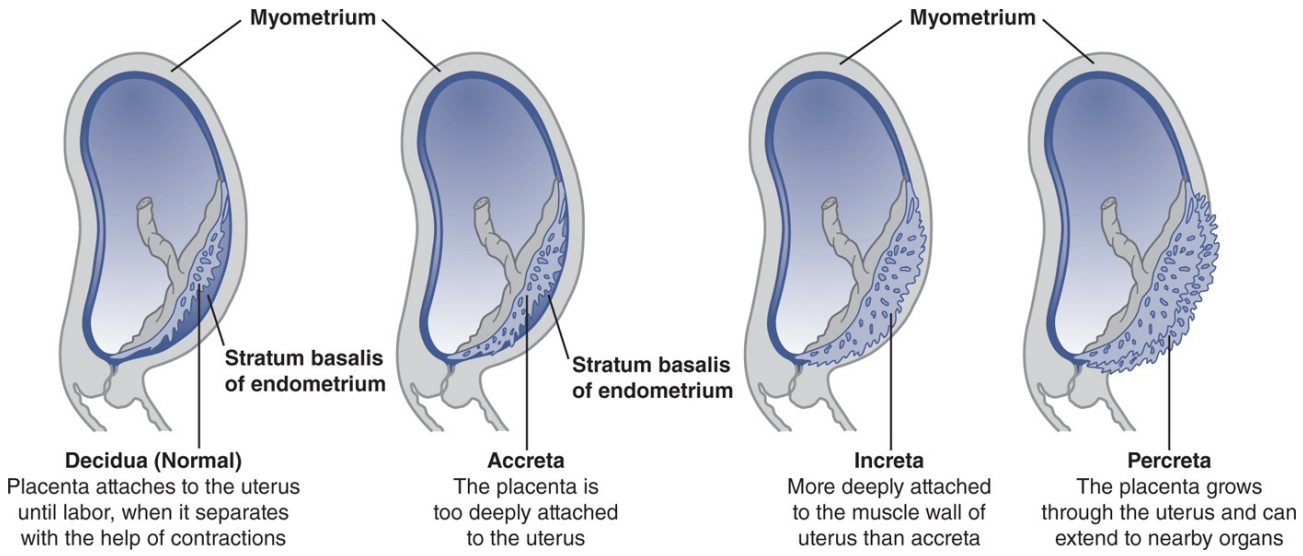

Figure 22-6 Placenta accreta.

Placenta accreta occurs when the placenta implants over an area of the uterus that is scarred or damaged. The incidence of placenta accreta is increasing as a result of the rising rate of cesarean birth and uterine procedures associated with assisted reproductive technology (such as myomectomy or resection of the uterine septum). Placenta accreta is also more common in women who have placenta previa. In women with prior cesarean births who develop placenta previa in a subsequent pregnancy, 3% will develop placenta accreta if they have a history of one prior cesarean and current previa. The incidence of accreta increases to 11% in women with placenta previa who had two prior cesareans, and to 40% in women with placenta previa who had three prior cesareans.[52]

Hemorrhage at birth is anticipated in all cases of placenta accreta. The severity of hemorrhage and associated complications are related to the type of placenta accreta. Placenta increta and certainly placenta percreta are life-threatening situations for the woman and frequently require hysterectomy for control of hemorrhage because the placenta cannot be removed.

Although placenta accreta has characteristic findings on ultrasound, ultrasound is not able to diagnose this condition in all cases. The role of the midwife is to be alert to risk factors such as an ultrasound that shows an anterior low-lying placenta in a woman who had a previous cesarean section. Consultation with or referral to maternal–fetal medicine is indicated in such cases. Specialized ultrasound and magnetic resonance imaging (MRI) can aid in determining the diagnosis. If placenta accreta is diagnosed, planned cesarean birth in a Level III or Level IV center is needed. For women with placenta increta or percreta, care in a Level IV site is recommended. Massive transfusion protocols and subspecialist resources are essential to manage this serious and often life-threatening complication of pregnancy.

Abnormal Amniotic Fluid Volume

Amniotic fluid is primarily composed of fetal urine and lung fluid. The amount of amniotic fluid increases throughout pregnancy until it reaches approximately 1000 milliliters by the beginning of the third trimester; it then gradually decreases to approximately 800 milliliters at term. Amniotic fluid volume can be measured on ultrasound in two ways: by the amniotic fluid index (AFI) or as a single maximum vertical pocket of amniotic fluid. The AFI is a composite value taking into account the maximum vertical pocket in each quadrant of the uterus. Particularly when screening for low amniotic fluid volume, using a maximum vertical pocket, rather than AFI, to diagnose abnormal volume is associated with fewer interventions without an increase in poor pregnancy outcomes.[53-55]

Polyhydramnios (Hydramnios)

Polyhydramnios, also called hydramnios, is an excessive amount of amniotic fluid. It is characterized as an AFI of 24 cm or more, or a maximum vertical pocket that is 8 cm or more.[56] This condition is idiopathic in 50% to 60% of women and most likely to become evident in the third trimester. Several conditions are associated with a higher incidence of polyhydramnios, including fetal structural anomalies, multifetal gestation (especially

monozygotic twins, twin-to-twin transfusion syndrome), diabetes, fetal infection, and fetal chromosomal abnormalities. Severe polyhydramnios (e.g., AFI > 35 cm) is more likely to be associated with fetal structural anomalies, such as tracheoesophageal fistula, anencephaly, and meningomyelocele, whereas milder forms are more likely to be idiopathic.[56] Complications of polyhydramnios include preterm labor secondary to uterine distension, premature rupture of membranes, malpresentation of the fetus, umbilical cord prolapse, abruptio placenta, dysfunctional labor, and postpartum hemorrhage.

Polyhydramnios is initially suspected when uterine enlargement, maternal abdominal girth, and fundal height are larger than expected for the fetus's gestational age. It may be difficult to auscultate fetal heart tones and to palpate the fetal outline and fetal parts. The fetus may have an unstable lie—and a change in lie may be detected during Leopold's maneuvers. In severe cases of polyhydramnios, the woman may experience dyspnea; lower-extremity and vulvar edema; pressure in the back, abdomen, and thighs; heartburn or nausea; and vomiting.

An ultrasound will confirm the diagnosis and identify any coexisting fetal or placental abnormalities. At this point, consultation with a physician is needed. Additional laboratory evaluation may include rescreening for gestational diabetes, antibody titers to detect isoimmunization, or TORCH (toxoplasmosis, other, rubella, cytomegalovirus, and herpes) titers to assess for infection depending on the degree of polyhydramnios and other findings. Of note, polyhydramnios alone is not an indication for aneuploidy screening by karyotyping.[57] Likewise, uncomplicated polyhydramnios is not an indication for delivery. The diagnosis warrants increased fetal surveillance and attention to the potential mechanical difficulties of dyspnea and edema for the woman. On rare occasions, the polyhydramnios is so severe that fluid must be removed via controlled amniocentesis to relieve maternal respiratory distress.

Oligohydramnios

Oligohydramnios is an abnormally low volume of amniotic fluid, adjusted for the gestational age of the pregnancy. This condition may be suspected on clinical examination but needs to be confirmed via ultrasound. Clinical signs include a fetus that is easily outlined during abdominal palpation, a fetus that is not ballottable, and lagging fundal height measurements. The diagnosis of oligohydramnios is made when the amniotic fluid index in the third trimester is less than 5 cm in a woman with a singleton pregnancy.

A number of fetal conditions are associated with oligohydramnios, including congenital anomalies (e.g., renal agenesis, Potter's syndrome), viral diseases, fetal growth restriction, uteroplacental insufficiency, preterm premature rupture of membranes, response to indomethacin as a tocolytic, and post-term pregnancy.

Oligohydramnios can develop at any time in pregnancy, but its clinical significance in the first trimester is not clear. The fetus normally begins to urinate and swallow fluid in the second trimester, so disorders of the fetal renal/urinary system become problematic at this time. If oligohydramnios is present between 17 and 26 weeks' gestation, the fetus is at risk for developing hypoplastic lungs.[58] In this condition, the fetal lungs do not develop to full size because the fetus is unable to breathe amniotic fluid, a process that normally causes chest expansion and growth.

Oligohydramnios that appears in the third trimester is often associated with uteroplacental insufficiency and fetal growth restriction or preterm premature rupture of membranes. Thus, evaluation of oligohydramnios focuses on physical, ultrasound, and laboratory examinations that can determine the underlying etiology.

Management of oligohydramnios is directed toward management of the underlying etiology, and physician referral is indicated to establish the plan of care. Oligohydramnios without ruptured membranes in an indication for frequent surveillance of fetal well-being, including fetal movement counts, nonstress tests (NST), a biophysical profile (BPP), and possibly umbilical Doppler studies. The timing of birth depends on the evidence for fetal well-being during frequent surveillance. When uncomplicated oligohydramnios occurs in a post-term pregnancy, and tests of fetal well-being are reassuring, there is limited high-quality evidence to support induction over expectant management.[59]

Cervical and Uterine Abnormalities

Two anatomic variations of the cervix can have adverse consequences during pregnancy. First, the cervix that is unusually short is associated with an increased risk for preterm birth. Second, cervical insufficiency refers to a structural weakness in the cervix that results in painless cervical dilation and miscarriage in the early second trimester of pregnancy. Uterine abnormalities such as bicornuate uterus can also adversely affect the course of pregnancy.

Cervical Insufficiency

Cervical insufficiency typically presents with vaginal bleeding, pelvic pressure, or ruptured membranes in the early second trimester. On examination, the cervix is effaced and dilated. Fetal parts or bulging membranes may be detected through the cervix. Risk factors for cervical insufficiency are listed in **Table 22-11**.

Table 22-11	Risk Factors for Cervical Insufficiency
Congenital Factors	
Congenital anomalies	
Uterine anatomic anomalies	
Obstetric History Factors	
History of fetal loss at 14 weeks' gestation or more	
History of cervical laceration following vaginal or cesarean birth	
Multiple first- or second-trimester pregnancy terminations	
Gynecologic History Factors	
Mechanical dilation from dilatation and curettage or hysterosalpingogram	
Previous cervical conization with a large amount of tissue removed	

A woman with a history of two or more second- or third-trimester losses is referred to a physician for an evaluation for cervical insufficiency. Depending on her current clinical situation and reproductive history, she may be a candidate for placement of a suture around the cervix, called *cervical cerclage*, that holds the cervix closed.

Historically, the management of a woman with two or more second-trimester losses included a placement of a cerclage between 14 and 18 weeks' gestation without consideration of the woman's cervical condition. The ability to monitor cervical length has provided new management options. Currently, the trend is to monitor the cervical length and perform cerclage only if the cervix becomes shorter than 25 mm before 24 weeks' gestation.[60] This shift in practice is due to recognition that cerclage has significant risks, including infection, rupture of membranes with or without infection, and subsequent pregnancy loss.

If a woman presents with signs or symptoms that suggest possible cervical insufficiency, such as increased discharge, watery discharge, or vaginal bleeding, in the early second trimester, an initial speculum examination will rule out common causes of symptoms such as

vaginitis. Observable cervical dilatation or the presence of visible membranes indicates a need for immediate physician consultation. Bimanual and digital examination will be needed but are best performed by the physician to avoid potentially rupturing membranes and introducing infection.

If the membranes are intact and the cervix is amenable, cervical cerclage may be recommended. Several types of cerclage are used, with the precise technique selected based on the clinical situation, the cervical length and dilation, and the practice experience and preference of the physician. Women who have a cerclage placed may also be offered progesterone therapy. Removal of the cerclage suture is done at the direction of the physician between 36 and 37 weeks' gestation.[61]

Short Cervix

Until a few years ago, identification of a "short cervix" on ultrasound was an incidental finding of unknown importance. Subsequent research has shown there is a strong positive association between cervical length and preterm labor (**Table 22-12**).[62,63] Ultrasound measurement of cervical length is recommended for women who have a history of preterm birth.[64,65] The routine transvaginal ultrasound measurement of cervical length in women who do not have a history of preterm birth is not universally recommended at this time, but is being increasingly adopted in many clinical settings as meta-analyses have demonstrated it to be a cost-effective screening strategy.[64,65]

Table 22-12 Predicted Probability (%) of Preterm Birth by Cervical Length (mm) and Gestational Week at Time of Measurement

Weeks' Gestation	Cervical Length (mm)							
	10	15	20	25	30	35	40	45
16	53.3	45.2	37.3	30.1	23.7	18.3	13.9	10.5
18	50.7	42.6	34.9	27.9	21.8	16.8	12.7	9.6
20	48.1	40.1	32.5	25.8	20.1	15.4	11.6	8.7
22	45.4	37.6	30.3	23.9	18.5	14.1	10.6	7.9
24	42.8	35.1	28.1	22.0	16.9	12.8	9.6	7.5
26	40.5	32.8	26.0	20.3	15.5	11.7	8.7	6.5
28	37.8	30.5	24.0	18.6	14.2	10.6	7.9	5.9

Modified with permission from Berghella V, Roman A, Daskalakis C, Ness A, Baxter JK. Gestational age at cervical length measurement and incidence of preterm birth. *Obstet Gynecol.* 2007;110:311-317.[63]

Cervical length measurement to screen for a risk of preterm labor is performed using transvaginal ultrasound to measure the distance between the internal and external os; determine the shape of the canal, such as "funneling"; and observe for the presence of membranes bulging into the cervical canal. Abdominal ultrasound is not a reliable means of measuring the cervical length because of the difficulty in achieving the appropriate angle as the ultrasound is performed. The confounding factors of maternal habitus and the need to fill the bladder may result in a false lengthening of the measurement.

Cervical length measurement for screening should be performed after 16 weeks' gestation and before 24 weeks' gestation. Prior to 16 weeks' gestation, the lower uterine segment is not well developed and measurement is not reliable. There is insufficient data about the value of interventions such as cerclage when instituted after 24 weeks' gestation.[65] Cervical length measurements may be obtained after 24 weeks' gestation as part of the evaluation for women who have signs and symptoms of preterm labor, which is reviewed in more detail in the *Complications During Labor and Birth chapter.*

The diagnosis of short cervical length is made when the cervix is less than 20 to 30 mm after 16 weeks' gestation and before 24 weeks' gestation.[65] The range of 20 mm to 30 mm that defines "short cervix" differs depending on the population studied and gestational age range of study participants. Women who are found to have a short cervix on ultrasound screening are referred to a physician for consultation and discussion of therapeutic options.

Management of women with a short cervix who have a history of preterm labor differs from

the management of women without a history of preterm labor, as depicted in **Figure 22-7**.[64] In women without a history of preterm birth, the cervical length measurement at which treatment should be instituted to prevent preterm labor has not been conclusively determined. Two major randomized controlled trials (RCTs) examining the impact of vaginal progesterone treatment for short cervix included only women with cervical length less than 15 mm or in the range of 10–20 mm. Based on these studies, the the Society for Maternal-Fetal Medicine and the American College of Obstetricians and Gynecologists recommends that women without a history of preterm birth who have a short cervix be offered treatment with vaginal progesterone if the cervical length is less than 20 mm.[64] If the decision is made to initiate vaginal progesterone for a woman who has a short cervix, this therapy consists of suppositories (200 mg) or gel (90 mg) inserted once daily from 16 weeks through 36 completed weeks of gestation.

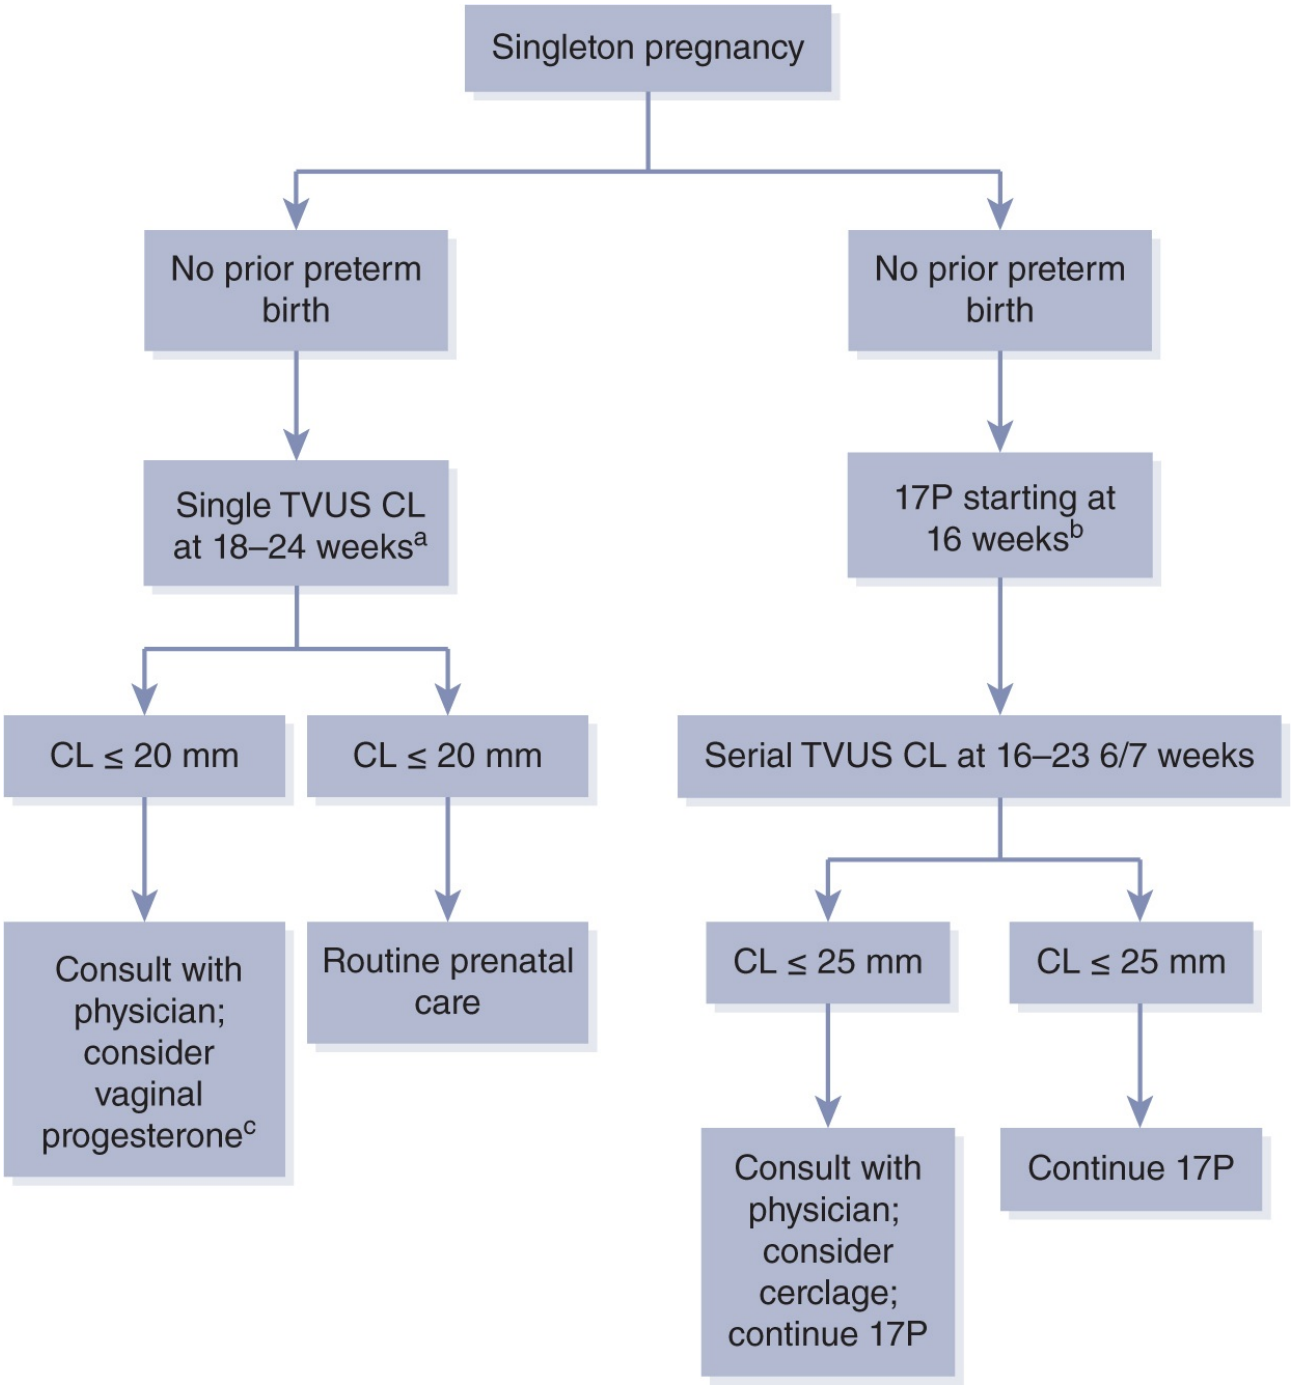

Figure 22-7 Assessment and management of women with a short cervix.

Abbreviations: CL, cervical length; TVUS, transvaginal ultrasound, 17P, 17-hydroxyprogesterone.

[a] If transvaginal ultrasound for screening is performed.

[b] 17P 250 mg intramuscularly given weekly from 16–20 weeks to 36 weeks' gestation.

[c] Daily 200-mg suppository or 90-mg gel from time of diagnosis of short cervical length to 36 weeks' gestation.

386.[64]

Uterine Anomalies

Uterine anomalies, also known as Müllerian duct anomalies, are congenital variants of the female reproductive tract (as reviewed in the *Gynecologic Disorders* chapter). Uterine anomalies have an estimated prevalence of 0.5% to 5% in the general female population.[66] The most common uterine anomalies are septate uterus, bicornuate uterus and arcuate uterus.

Uterine anomalies are associated with infertility. Once pregnancy is achieved, such anomalies are associated with increased risks of miscarriage, fetal growth restriction, preterm labor/birth, malposition, and placental abruption.[67] Some Müllerian duct anomalies are also associated with the rare but serious risk of uterine rupture in a rudimentary horn. A rudimentary horn is often noncommunicating with the body of the uterus and has an underdeveloped myometrium that limits the horn's ability to expand with a growing pregnancy. It may rupture either catastrophically or silently. Catastrophic rupture has symptoms similar to ruptured tubal pregnancy; silent rupture can lead to a secondary abdominal pregnancy.

Uterine anomalies may be identified for the first time during pregnancy, such as during first-trimester ultrasound, or on clinical examination when the uterine outline is displaced to one side of the abdomen. Depending on the gestational age of the fetus and type of anomaly suspected, 3-D ultrasound or magnetic resonance imaging may be needed to confirm the diagnosis.

Management of a woman who has a uterine anomaly requires consultation with a physician or specialist group. Depending on the anomaly and plan for care, midwives may participate in prenatal care under the guidance of the consulting specialists.

Preterm Birth

Preterm birth is defined as birth that occurs before 37 completed weeks of gestation. Because numbers are not assigned until the end of a completed week, 37 completed weeks of gestation occurs when the fetus is 37 weeks and 0 days gestational age. Approximately 10% of births in the United States occur at a preterm gestational age.[68] Overall, congenital anomalies are the leading cause of infant mortality and preterm birth is the second most common cause.[69] Globally, preterm birth is the leading cause of neonatal deaths, accounting for 35% of all neonatal deaths. Survivors of preterm birth are at risk for health complications that extend into adulthood. Preterm birth is more common in non-Hispanic black women compared to women from all other racial and ethnic backgrounds.[70] This racial disparity remains even after accounting for other risk factors such as smoking, socioeconomic background, or educational level. Although the reasons for the racial disparities in the incidence of preterm birth are not fully known, contributing factors include a mix of environmental, genetic, and social factors.[70] Furthermore, many of these risk factors are interrelated. For example, some of the genetic differences such as changes in telomere length maybe related to environmental influences.

Table 22-13 presents subcategories of preterm gestation based on a combination of the definitions used by the United States Centers for Disease Control and Prevention and the World Health Organization. For those infants who survive preterm birth, short-term adverse outcomes include respiratory distress syndrome, intraventricular hemorrhage, and infection. Long-term adverse outcomes following preterm birth include neurodevelopmental disabilities, altered pulmonary function, increased risk for metabolic and cardiovascular disorders, and decreased long-term survival. Morbidity and mortality rates increase as the gestational age at the time of birth decreases. Infants born in the periviable period have the lowest survival rates and highest rates of long-term morbidities among those who do survive, whereas infants born in the moderate or late preterm gestational age categories have a high chance of surviving without long-term complications.

Table 22-13 Gestational Age Categories and Associated Mortality Rates

Category	Definition
Periviable gestation	20 0/7–25 6/7 completed gestational weeks
Extremely preterm	26 0/7–27 6/7 completed gestational weeks
Very preterm	28–31 6/7 completed gestational weeks
Moderate preterm	32 0/7–33 6/7 completed gestational weeks
Late preterm	34 0/7–36 6/7 completed gestational weeks

This chapter presents an overview of preterm labor, including risk factors, diagnostic criteria, and prenatal care for women who have a history of preterm labor. Some of the initial work-up for preterm labor is often completed in the outpatient setting, but the definitive diagnosis requires uterine monitoring for a period of time and possibly hospitalization. For this reason, the steps involved in a thorough evaluation of a woman with suspected preterm labor

are presented in the *Complications During Labor and Birth* chapter.

Pathophysiology of Preterm Labor

Labor is caused by a release from inhibitory mechanisms that sustain uterine quiescence throughout the pregnancy. At least five discrete mechanisms have been identified that initiate premature uterine activity in pregnant women:[71-77]

- *Premature activation of the maternal or fetal hypothalamic–pituitary–adrenal (HPA) axis.* Physical or psychological stress activates the maternal HPA axis and leads to subsequent release of high levels of corticotropin-releasing hormone (CRH), which in turn increases prostaglandin production and directly stimulates the uterus. Preterm activation of the maternal HPA axis can be caused by maternal stress (depression, post-traumatic stress disorder [PTSD], anxiety) or physical stress.[71,72] Premature activation of the fetal HPA axis can occur secondary to genetic factors, an inhospitable uterine environment, or inflammation (e.g., intra-amniotic infection).[73]
- *Inflammation/infection.* Microorganisms in the genital tract may cause inflammation at the choriodecidual interface, which in turn stimulates contractions.[73]
- *Decidual hemorrhage (placenta abruption or subchorionic hemorrhage).* Localized uteroplacental ischemia can cause necrosis of the decidua. This necrosis is a type of oxidative stress that releases thrombin. Thrombin, in turn, stimulates uterine contractility.[74]
- *Overdistension of the uterus (e.g., polyhydramnios, multifetal gestation).* Overstretching of the myometrium induces formation of gap junctions and upregulation of oxytocin receptors.
- *Genetics.* Genetic factors have long been suspected as an etiology in preterm birth, but that relationship has only recently been confirmed. Four genetic loci have been identified as being associated with length of gestation, and variants in three of those loci are associated with preterm birth: *EBF1*, *EEFSEC*, and *AGTR2*.[75,76]

Risk Factors for Preterm Labor

Known risk factors are listed in **Table 22-14**.[77-86] However, approximately 50% of women who give birth prematurely do not have an identified risk factor for preterm birth,[77] so with a few exceptions, risk factors do not reliably predict preterm labor. The most significant risk factor for preterm birth is a history of preterm birth: Women with such a history are significantly more likely to experience a subsequent preterm birth.[78,84]

Table 22-14 Risk Factors for Preterm Labor

Maternal Demographic and Lifestyle Factors	Fetal Factors
Age < 17 years or > 35 years	Congenital anomalies
African American ethnicity	Fetal growth restriction

Genetic variants	Infection
Low prepregnancy maternal body weight (BMI < 19.8)	Isoimmunization with hydrops
Low socioeconomic status	
Short interpregnancy interval (< 18 months)	
Stress (depression, anxiety, post-traumatic stress disorder)	
Smoking during pregnancy	
Substance abuse (cocaine, crack, heroin, tobacco)	
Maternal Medical and Reproductive History	**Current Pregnancy Factors**
Previous preterm birth	Cervical insufficiency/short cervix
Pregnant woman born preterm	Infections during pregnancy
Prior cervical surgery (cone, dilatation and curettage)	Intrauterine infection
	Hydramnios (polyhydramnios)
Müllerian tract abnormalities	Multifetal gestation
Short cervical length measured on transvaginal ultrasound	Maternal disorders (e.g., pregnancy-induced hypertension/HELLP syndrome, placenta previa)
	Pyelonephritis
	Vaginal bleeding during > one trimester
Factors with Conflicting Evidence Regarding Risk for Preterm Birth	**Preventable Iatrogenic Factors**
Asymptomatic bacteriuria, lower UTIs	Unknown gestational age
Genital tract infections	Elective induction of labor before term
Periodontal disease	
Vaginal bleeding	

Abbreviations: BMI, body mass index; HELLP, hemolysis, elevated liver enzymes, and low platelet count; UTIs, urinary tract infections.

Evaluation and Diagnosis of Preterm Labor

The choice of site for an evaluation of a woman who might be in preterm labor will depend on the institution, role of the midwife in that setting, severity of the

woman's symptoms, and gestational age of the fetus. The adverse outcomes of preterm birth can be profound, so rapid referral to physician care is indicated for a woman whose fetus is at an early gestation or a woman with significant symptoms. In all settings, the primary role of the midwife is to recognize significant risks for preterm labor and signs of preterm labor.

The diagnosis of preterm labor can be challenging. Before preterm labor is well established and clearly active, it can be difficult to distinguish normal pregnancy symptoms from early preterm labor. Indeed, many early symptoms of preterm labor are quite common during pregnancy. Most women with symptoms of preterm labor do not go on to have a preterm birth,[87,88] and over-intervention is a concern. Delays in treatment, however, have the potential to adversely affect outcomes. Symptoms of preterm labor, listed in **Table 22-15**, are not predictive of ongoing preterm labor. For example, contraction frequency is a poor predictor of subsequent preterm birth, although the risk of preterm birth does increase with frequency of contractions.[87] For this reason, it is important to evaluate a woman with any symptoms of preterm labor carefully by reviewing her history for risks for preterm labor, asking her about any additional symptoms from the list in **Table 22-15**, and observing her over time if needed.

Table 22-15	Signs and Symptoms of Preterm Labor[a]
Symptoms	**Signs**
Abdominal tightness or “menstrual-like cramps”	Short cervix
Diarrhea	Change in cervical effacement or dilation
Fetus dropping low into the pelvis before 36 weeks	Positive fetal fibronectin test
Increased vaginal discharge (clear, pink, or slightly bloody mucus)	Ruptured membranes
Lower back pain	
Pelvic pressure	
Vaginal bleeding	
Uterine contractions that are increasing in frequency, duration and intensity	

[a] Individual clinical signs and symptoms of preterm labor are not highly predictive.

Diagnostic criteria for active preterm labor include regular uterine contractions plus a change in cervical effacement and/or cervical dilation. Rupture of membranes or vaginal bleeding increases the diagnostic certainty. Some institutions use specific criteria such as regular painful contractions plus cervical dilation of 3 centimeters or more, or cervical length less than 20 millimeters, or cervical length between 20 and 30 millimeters with a positive test for fetal fibronectin. The March of Dimes recommends six or more contractions per hour as the threshold prompting evaluation for preterm labor.[89] If active preterm labor is suspected, in-patient obstetric triage/emergency department assessment is warranted.

Prevention of Preterm Birth

Urinary tract infections, periodontal disease, and several urogenital infections—group B *Streptococcus* (GBS), *Chlamydia trachomatis*, bacterial vaginosis, *Neisseria gonorrhea*, syphilis, and *Trichomonas vaginalis*—are associated with preterm labor. Even so, a causal relationship between these infections and preterm labor has not been established. Furthermore, treatment is not associated with a lowered incidence of preterm labor,[83,90-95] and a few studies have found an increase in preterm labor associated with treatment of bacterial vaginosis or *T.*

vaginalis infection with metronidazole (Flagyl).[83] Although asymptomatic bacteriuria is not associated with preterm birth per se, treatment of asymptomatic bacteriuria is recommended to decrease the incidence of pyelonephritis—a condition that is associated with preterm birth. Women with human immunodeficiency virus (HIV) should be screened and treated for *T. vaginalis* infection to reduce the risk of vertical transmission of HIV. All sexually transmitted infections should be treated per guidelines reviewed in the *Reproductive Tract and Sexually Transmitted Infections* chapter. Finally, women with symptomatic infections and women with periodontal disease should be treated per standard protocols for general health promotion.

For women who have a history of preterm birth use of progesterone therapy (17-alpha hydroxyprogesterone caproate [17-OHPC]) to prevent preterm labor has demonstrated effectiveness in multiple RCTs and subsequent systematic reviews.[90] Although the mechanism of action is not well understood, progesterone is thought to have an anti-inflammatory effect that curtails the inflammatory process associated with preterm labor. Another theory suggests that exogenous progesterone increases the level of progesterone in maternal tissue and prevents the drop in progesterone level associated with the onset of labor.

The safety of progesterone for the developing fetus and child has been studied in children exposed to progesterone in utero. The studies conducted to date indicate that children 2 to 4 years old have no difference in health status or cognitive skills when compared to a similar cohort of children who were not exposed to this drug in utero.[91],[92] Longer-term follow-up is needed before safety can be fully assured. Nonetheless, the balance of unknown long-term risks to the child versus benefits of avoiding preterm birth is such that progesterone is recommended for selected women at risk for preterm labor.

The dose of 17-OHPC is 250 mg, administered via weekly injections from 16 to 36 weeks' gestation. The injections are continued until 36 completed weeks of pregnancy. 17-OHPC is not effective for prevention of preterm birth in women with a multifetal gestation. Likewise, it is not effective for women who have current preterm rupture of membranes or as a tocolytic for women in active preterm labor. This agent has not been shown to prolong gestation in women with a cerclage who did not have a prior preterm birth. Women with short cervix alone and no history of preterm birth may benefit from vaginal progesterone, but no value has shown for injected 17-OHPC in this group. Similarly, for women who had a prior preterm birth and are receiving 17-OHPC for prevention of preterm labor in the current pregnancy, no benefit has been found if vaginal progesterone is added to treat the additional finding of a short cervix.

Premature Prelabor Rupture of Membranes

Spontaneous rupture of membranes prior to the onset of labor is termed prelabor rupture of membranes (PROM). If the rupture occurs before 37 weeks' gestation, it is called *premature prelabor rupture of membranes* (PPROM). In the United States, PPROM occurs in approximately 3% of all pregnant women.[96] Risk factors for PPROM are the same as the risk factors for preterm labor. Infection can be both a cause of PPROM and a consequence of PPROM. Suspected PPROM is an indication for physician consultation and referral.

Ruptured membranes may present as a "gush" that the woman notices or as "a trickle" or constant wetness. In rare cases, a small tear may seal over during the course of a few days or weeks. In that situation, pregnancy is expected to progress normally, although careful monitoring for any additional significant fluid loss is needed. A woman who reports possible PPROM is best evaluated in a labor and delivery inpatient setting. The procedure for assessment and diagnosis is reviewed in the *First Stage of Labor* chapter.

Post-Term Pregnancy

A post-term pregnancy is one that has reached or continues beyond 42 0/7 weeks (294 days) of gestation, which is 42 completed weeks.[97] Historically, term pregnancy was defined as a gestation of 37 0/7 weeks to 41 6/7 weeks. In an effort to address the variation in perinatal outcomes in the period between 37 0/7 and 41 6/7 weeks, a 2012 work group recommended the following terminology for term pregnancy:[98]

- Early term: 37 0/7 weeks through 38 6/7 weeks
- Full term: 39 0/7 weeks through 40 6/7 weeks
- Late term: 41 0/7 weeks through 41 6/7 weeks
- Post term: 42 0/7 weeks or more

Management of late term and post-term pregnancy is reviewed here. The term "postdates" is imprecise and should be avoided when discussing late term or post-term pregnancy management.

In the United States, births during the 41st week of gestation account for 6.5% of all births; births at 42 weeks of gestation and beyond account for 0.4%.[68] Beyond an error in the dating, the causes of a truly prolonged pregnancy are unknown. In many cases, maternal or fetal genetic influences on initiation of labor may play a role. The incidence is higher among women who are older, who are nulliparous, and who have a history of a prior post-term birth.[99] Caucasian women are more likely to have a post-term pregnancy than are women of other racial/ethnic groups. Rare causes of prolonged pregnancy include placental sulfatase deficiency, fetal adrenal insufficiency, and fetal anencephaly.[99]

Pregnancy at 41 weeks' gestation and greater is associated with increased incidence of fetal and maternal adverse outcomes, most of which are the result of excessive fetal growth or placental insufficiency. Maternal risks include severe perineal lacerations, infection, postpartum hemorrhage, operative vaginal birth, and cesarean birth.[99] Study results vary

somewhat regarding specific risks, but include an increased fetal risk of oligohydramnios, meconium aspiration syndrome, macrosomia, shoulder dystocia, fetal dysmaturity syndrome, and perinatal mortality.[100]

The term *fetal dysmaturity syndrome* is used to describe a fetus/newborn exposed to chronic malnutrition. Such a fetus is small for gestational age, with little body fat, and is at increased risk for oligohydramnios, umbilical cord compression, and abnormal fetal heart rate patterns. As a newborn, the fetus is also at greater risk for hypoglycemia, polycythemia, meconium aspiration, and perinatal asphyxia. There is a clear increased risk of perinatal mortality (which includes stillbirth and early neonatal death) for women with a late term and post-term gestation.[101] A large retrospective study involving more than 3 million women found that the risk of stillbirth was 4.2 cases per 10,000 women at 40–41 weeks, 6.1 cases per 10,000 women at 41–42 weeks, and 10.8 cases per 10,000 women at 42–43 weeks.[102]

Women without medical or obstetric complications who are in the late term gestational period are managed expectantly with watchful waiting. At 41 0/7 weeks, the woman is offered expectant management with fetal surveillance twice weekly (antepartum testing) or induction of labor. After 42 0/7 weeks and by 42 6/7 weeks, the recommendation is to induce labor.[98]

During the week between 41 0/7 and 42 0/7 gestational weeks, induction is associated with a lower risk of perinatal death (relative risk [RR], 0.31; 95% confidence interval [CI], 0.12–0.88), cesarean delivery (RR, 0.89; 95% CI, 0.81–0.97), and meconium aspiration syndrome (RR, 0.50; 95% CI, 0.34–0.73).[103] However, the perinatal death rate is low and a high number of inductions (n = 410) are needed to avoid one perinatal death. There are no significant differences in birth asphyxia or neonatal intensive care unit admissions when induction is compared with expectant management for women in this gestational age range.[103] Thus, the choice of management during this period of time should follow a process of shared decision making that includes assessment of biologic factors such as gravidity, cervical status, and fetal well-being, and the woman's preferences.

Membrane Sweeping

Membrane sweeping is a common intervention performed by both midwives and physicians in the outpatient setting at term in pregnancy to try to hasten the onset of labor. Evidence shows a reduced rate of pregnancy continuing beyond 41 weeks when membrane sweeping is done, with no increase in adverse outcomes.[104] Most women find this procedure uncomfortable but say they would choose to do it again in a subsequent pregnancy. This elective procedure is done only after the woman is informed of the risks and benefits and gives her consent for the procedure. It should not be offered or performed prior to 40 weeks' gestation. Membrane sweeping, historically called stripping of the membranes, involves gently dislodging the membranes from where they attach to or lay over the cervix; this process releases prostaglandins, which aid in the preparation and initiation of labor. Numerous studies have demonstrated that membrane sweeping increases the likelihood of spontaneous labor in conjunction with oxytocin.[104] Evidence has also found membrane sweeping to be safe with no increased risks of fetal or maternal infection.[104] Women may experience discomfort during the examination, and they may experience slight vaginal bleeding and irregular contractions after membrane sweeping. Accidental rupture of the membranes could also occur but is rare.

The technique for performing membrane sweeping is as follows: The examining fingers of the practitioner's sterile gloved hand are introduced into the vagina, enter the cervical os, and swing circumferentially around the internal os, separating the membranes from the uterine wall. If the cervical os is closed and membrane sweeping cannot be performed, some clinicians recommend massage of the cervix at the vaginal fornices, as this intervention may cause release of prostaglandins. Membrane sweeping can be repeated in 36 to 48 hours.

Dermatoses of Pregnancy

Pruritus is a common problem for pregnant women. Skin conditions related to or caused by the unique physiologic aspects of pregnancy are classified into four categories: (1) atopic eruption of pregnancy, (2) intrahepatic cholestasis of pregnancy, (3) pemphigoid gestationis, and (4) polymorphic eruption of pregnancy.[105,106] Because both intrahepatic cholestasis and pemphigoid gestationis are associated with serious adverse fetal outcomes, early recognition and differentiation is important to minimize potential fetal risks and provide adequate relief for the woman. These four dermatoses can be differentiated by appearance, location on the woman's body, and time of onset during pregnancy (**Table 22-16**).[105-109]

Table 22-16 **Dermatoses in Pregnancy**

Characteristics	Atopic Eruption of Pregnancy	Intrahepatic Cholestasis of Pregnancy	Pemphigoid Gestationis	Polymorphic Eruption of Pregnancy	Pustular Psoriasis of Pregnancy
Nomenclature: Historical term	Eczema in pregnancy[a] Pruritic folliculitis of pregnancy[a] Papular dermatitis of pregnancy	Obstetric cholestasis Icterus gravidarum Pruritus gravidarum	Herpes gestationis	PUPPP[a] Erythema multiforme of pregnancy	Impetigo herpetiformis
Associated conditions		Hepatitis C	Multiparity, hydatidiform mole (rare)		Rare variant of psoriasis triggered by pregnancy
Trimester(s) of onset	First and second	Late second or third	Second and third	Third and postpartum	Third
Symptoms	Eczematous rash	Pruritus without rash, jaundice	Urticarial papules, plaques, bullae	Urticarial papules, plaques	Symmetric erythematous plaques with sterile pustules. Enlarge from the periphery as center becomes crusted over. Systemic symptoms but pruritus is often absent
Location	Entire body, including palms/soles	Entire body; may be most intense on palms/soles	Begins on abdomen, then body; spares the face	Abdominal striae, then body; spares the face, palms, soles, and periumbilical area	Begins in flexural areas and spreads centrifugally
Diagnosis	Clinical symptoms and appearance	Clinical symptoms and elevated bile acids	Skin biopsy, ELISA	Clinical symptoms and appearance	Clinical symptoms and appearance
Maternal risks	No known risks	Cholelithiasis, steatorrhea, hemorrhage	Increased risk for Graves' disease; recurrence in future pregnancy	No known risks	None
Fetal risks	No known risks	Meconium, preterm birth, stillbirth	Preterm birth, low birthweight, IUGR, neonatal lesions	No known risks	Placental insufficiency, miscarriage, fetal growth restriction, stillbirth
Management	Topical corticosteroids	Ursodeoxycholic acid, possible induction; screen for hepatitis C; consider delivery at 37 weeks or later Antenatal fetal testing, fetal movement counts	Topical and systemic corticosteroids, antihistamines Antenatal fetal testing, fetal movement counts	Topical corticosteroids, antihistamines, emollients	Systemic corticosteroids
Resolution after birth	Soon after	2–3 weeks	Weeks or months	7–10 days	Soon after birth
Recurrence in future pregnancies	Possible	Possible	Frequent (50–70%)	Low	Not known

Abbreviations: ELISA, enzyme-linked immunosorbent assay; IUGR, intrauterine growth restriction; PUPPP, pruritic urticarial papules and plaques of pregnancy

[a] Acceptable term for this condition.

Atopic Eruption of Pregnancy

Atopic eruption of pregnancy is a benign dermatosis of pregnancy characterized by intense itching. This group of dermatoses includes eczema, prurigo of pregnancy, and pruritic folliculitis of pregnancy. It is considered to be the most common skin disorder during pregnancy, accounting for almost 50% of all rashes experienced by women when pregnant.[105]

The presentation of atopic eruption of pregnancy includes intense pruritus with papular, eczematous lesions primarily appearing in the first or second trimester. The rash usually involves the face, neck, and antecubital and popliteal fossae, but can occur on all parts of the body, including the palms and soles. Approximately one third of women develop the rash on the trunk and the abdomen.[105,107]

This condition resolves early in the postpartum period, but recurrence in subsequent pregnancies is possible.[107] There are no known adverse effects of atopic eruption of pregnancy on maternal or fetal outcomes.[105] Treatment involves topical corticosteroids for maternal relief. Moisturizers and lukewarm showers with mild soap can also provide symptom relief.[107]

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy is a hepatic condition specific to pregnancy that features intense itching without rash, elevated serum bile acids, and increased liver enzymes.[105,108] Slowed emptying of bile from the gallbladder underlies the development of this condition. Multifetal gestation, a personal history of hepatitis C, cholelithiasis, and dyslipidemia are associated with increased risk for this disorder.[105] Environmental, dietary, genetic, and ethnic influences also contribute to the relative risk of developing intrahepatic cholestasis of pregnancy. There is wide variation in the incidence of this dermatosis, with rates ranging from 2% or less in the United States and Europe to as high as 28% in Chile.[105] The reoccurrence rate of intrahepatic cholestasis of pregnancy in subsequent pregnancies is approximately 60%.[105,108]

Symptoms of intrahepatic cholestasis of pregnancy develop in the second and third trimesters, although in as many as 10% of women, the symptoms manifest in the first trimester.[105,108] Intense itching, without rash, occurs all over the body; it may be most severe on the palms and soles, and intensifies at night. In addition, some women have diarrhea or steatorrhea.

Fetal risks include increased incidence of meconium-stained fluid (20–30%), preterm birth (20–60%), and stillbirth (1–2%).[105,108] Stillbirth occurs suddenly among women with intrahepatic cholestasis of pregnancy. The underlying etiology appears to be related to sudden vasospasm of placental veins secondary to exposure to toxic bile acids that the immature liver cannot clear.[105,108]

The differential diagnoses include the hemolysis, elevated liver enzymes, and low platelet count syndrome (HELLP), preeclampsia, hepatitis, choledocholithiasis, and other liver disorders. The diagnosis is based on the presence of pruritus without rash and laboratory tests that indicate liver dysfunction in the absence of any other dermatologic diagnosis. Jaundice develops in 10% to 25% of women with intrahepatic cholestasis of pregnancy.

Aminotransferase levels rise dramatically, conjugated bilirubin is increased, and bile acids become elevated to more than 10 mmol/L.[105,108] Elevated bile acids are the most accurate biomarker of intrahepatic cholestasis.[105,108] Nevertheless, bile acids are not markedly elevated in all women with this disorder, perhaps because bile acid elevation is a later sign in the natural course of the disorder. Because the risk of stillbirth is high, severe pruritus without rash is sufficient to make a presumptive diagnosis and start treatment, before laboratory values are available.

Maternal complications of intrahepatic cholestasis of pregnancy are not common. Theoretically a woman with intrahepatic cholestasis can develop vitamin K deficiency secondary to fat malabsorption when bile acids do not function normally. Some, but not all, physicians who care for these women recommend supplemental vitamin K. The risk of postpartum hemorrhage does not appear to be higher, and coagulation studies are not usually indicated but may be considered in individual circumstances.

Physician consultation and antenatal fetal testing should be initiated promptly. Maternal treatment with ursodeoxycholic acid (Ursodiol, Actigall) is the most effective treatment. The usual dose is 10 to 15 mg/kg body weight daily. Additional treatments include cholestyramine (Questran), a bile acid sequestrant; hydroxyzine (Vistaril) to treat pruritus; and occasionally dexamethasone (Decadron). Antepartum fetal surveillance will be initiated but its value is uncertain, as stillbirth happens rapidly and without warning in women with this disorder. Induction of labor is planned at approximately 36 weeks' gestation to prevent stillbirth.

Pemphigoid Gestationis

Pemphigoid gestationis is a rare autoimmune disorder that is most common among Caucasians and occurs in approximately 1 in 50,000 pregnancies. Due to the similar appearance of the lesions, pemphigoid gestationis was originally called herpes gestationis; in reality, it is not related to the herpes viruses. This dermatosis is most common in multigravidas in the third trimester and often occurs in subsequent pregnancies. However, presentation in the first trimester is possible.[105,107]

A prodrome of malaise, fever, nausea, and headache may precede the skin eruptions. Pruritus begins initially with urticarial and annular plaques that make it difficult to distinguish pemphigoid gestationis. The initial symptoms are followed by vesicobullous eruptions that begin on the abdomen and spread to the extremities, sparing the face. Enzyme-linked immunosorbent assay (ELISA) is an effective method for diagnosing pemphigoid gestationis. This technology's high sensitivity and specificity allow for differentiation between pemphigoid gestationis and polymorphic eruption in pregnancy.[105] Skin biopsy is also used for diagnosis.

Pemphigoid gestationis has been linked to several adverse effects in the fetus. Low birth weight and prematurity are associated with earlier onset of this dermatosis and the formation of blisters.[107] In addition, there is an estimated 5% to 10% maternal–fetal transfer rate.

Maternal risks include a long-term increase in the risk of Graves' disease. Remission may occur in the latter part of the third trimester. Pemphigoid gestationis may flare in the postpartum period, then resolve without causing scars. It recurs in most, but not all, subsequent pregnancies and tends to worsen with recurrence.

Treatment in the early stages of pemphigoid gestationis includes potent topical steroids, topical or oral antihistamines, and oral prednisolone. If pemphigoid gestationis progresses to the bullous stage, systemic corticosteroid therapy is required. Antenatal fetal testing is initiated in the third trimester, including weekly biophysical profiles, as well as Doppler studies if placental insufficiency is suspected. Infants born with the disease do not require treatment and the condition typically resolves spontaneously.[105]

Polymorphic Eruption in Pregnancy

Polymorphic eruption in pregnancy (PEP) is also known as pruritic urticarial papules and plaques of pregnancy (PUPPP). Most common in primigravid women, this condition typically occurs in the third trimester. Excessive stretching of abdominal skin causing tissue damage and high levels of estrogen and progesterone may be related to the development and severity of the outbreaks. The rash resolves spontaneously approximately 4 to 6 weeks after its onset. Recurrence in subsequent pregnancies is rare.[105,109] The red, painfully itchy urticarial papules initially present in the striae, but then spread to cover the trunk and extremities. The abdomen and proximal thighs are the most common sites of involvement. The face, palms and soles, and periumbilical area are not involved.[105,109] Except for the discomfort, polymorphic eruption in pregnancy is a benign condition with no adverse effects on the mother or fetus. Low-potency topical steroids and antihistamines can be used to treat the discomfort. Severe cases may require systemic corticosteroids.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a rare form of heart failure that develops in the last month of pregnancy or the first 5 months postpartum in the absence of heart disease or another identifiable cause for failure. The majority of women who develop peripartum cardiomyopathy do so in the postpartum period; thus, this disorder is reviewed in more detail in the *Postpartum Complications* chapter.

Risk factors for peripartum cardiomyopathy include African American race, obesity, maternal age older than 30 years, multiparity, and chronic hypertension/preeclampsia. The disparity in the prevalence of this condition is dramatic: Compared to white women, African American women have a 4- to 6-fold increase in the incidence and mortality of peripartum cardiomyopathy.[110] The reasons for the disparity are unclear, but may reflect an increased rate of underlying cardiovascular disease, known risk factors, and less access to care.

Signs and symptoms of peripartum cardiomyopathy may be inaccurately attributed to normal physiologic changes in pregnancy and postpartum and women with this diagnosis frequently report being given an incorrect diagnosis initially.[111] The role of the midwife is to maintain a high index of suspicion. Signs and symptoms of peripartum cardiomyopathy include all the signs of pulmonary edema: shortness of breath that is particularly noticeable when the woman reclines, cough, tachycardia, palpitations, and chest pain. Women with symptoms should be seen immediately, and a complete history and physical examination performed. Care of women with peripartum cardiomyopathy requires a multidisciplinary team of cardiologists, intensive care physicians, maternal–fetal medicine specialists, and respiratory specialists.

Red Cell Alloimmunization

Alloimmunization (also referred to as isoimmunization) is the process by which a woman develops antibodies against human tissue antigens not present in her own body. Events that can lead to isoimmunization include pregnancy and birth, wherein the woman is exposed to fetal red blood cells, blood transfusion, and tissue/organ transplant. The topic of isoimmunization is introduced in the *Prenatal Care* chapter and interventions to prevent Rh (D) sensitization are addressed there.

In addition to the Rh (D) antigen, red cell isoimmunization can develop secondary to other red cell membrane proteins. Red cell isoimmunization affects approximately 1.5% to 2.5% of women during pregnancy, although only a small proportion of fetuses and newborns of women with alloantibodies to non-Rh (D) red blood cell antigens will develop hemolytic disease of the fetus and newborn (HDFN).[112] Although Rh (D) alloimmunization is no longer the most common antibody identified among pregnant women, Rh (D) remains the most common cause of isoimmunization-associated pregnancy complications.[112]

The pathophysiology of red cell alloimmunization in pregnancy involves maternal exposure to the foreign antigen secondary to exposure to the fetal red blood cells, development of antibodies to that antigen, and finally transport of those antibodies across the placenta to the fetus, where they attack and lyse fetal red blood cells that carry the specific antigen.[113,114] The resulting hemolytic disease of the fetus and newborn can lead to mild to severe fetal anemia, depending on the type of antibody–antigen complex causing disease and on the level of immune response a woman mounts to the antigen in question. If severe fetal anemia develops, a fetus may also develop hydrops fetalis, a condition associated with hepatosplenomegaly, third-space fluid in the abdomen, and heart failure. Newborns who survive may have anemia and hyperbilirubinemia. The common course of this process occurs over two subsequent pregnancies. First, a woman is exposed during one birth to a fetus with Rh (D) antigen as fetal cells enter the maternal blood stream at the time of birth and placental separation. The woman develops antibodies, and in a subsequent pregnancy with an Rh (D) positive fetus, those antibodies cross the placenta to attack fetal red blood cells.

In addition to the Rh (D) antigen, the non-Rh (D) antigens most likely to cause hemolytic disease of the fetus and newborn are Rh G(c), Rh (E), Kell, and Duffy (**Table 22-17**).[112,114] The Lewis antigen is common but not associated with hemolytic disease of the fetus and newborn because it is an immunoglobulin M (IgM) antibody and, therefore, too large to cross the placenta.

Table 22-17 **Red Cell Antibodies and Relationship to Hemolytic Disease of the Fetus and Newborn**

Red Cell Antigen	Association with Hemolytic Disease of the Fetus and Newborn
Diego D1^{a}, Di^{b}	Mild to severe
Duffy Fy^{a}	Mild to severe
Duffy Fy^{b}	Not associated with HDFN
Duffy By[3]	Mild to severe HDFN

Kell K	Mild to severe HDFN
Kell k, Ko, Kp^a, Kp^b, Js^a, Js^b	Mild HDFN
Kidd Jk^a	Mild to severe HDFN
Kidd Jk^b, Jk^3	Mild HDFN
Lewis	No association with HDFN
Lutheran Lu^a, Lu^b	Mild HDFN
MSS Mt^a	Moderate HDFN
MSS Vw, Mur, Hil, Hut	Mild HDFN
Rh (D)	Mild to severe HDFN
Rh (non-D), E, C	

Abbreviation: HDFN, hemolytic disease of the fetus and newborn.

Note: This list is not an exhaustive list of atypical antibodies that can cause HDFN. Women with any atypical antibody is referred for physician consultation and management.

Based on American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 75: management of alloimmunization during pregnancy. *Obstet Gynecol.* 2006;108:457[112]; De Haas M, Thurik FF, Koelewijn JM, van der School CE. Haemolytic disease of the fetus and newborn. *VOX Sanguinis*. 2015;109:99-103.[114]

Alloimmunization is diagnosed via a maternal antibody screen (indirect Coombs test) that is one of the routine tests offered to all pregnant women. Results from red blood cell (RBC) antibody screens are reported as positive or negative. A positive antibody screen identifies the antibody and if it is one that is associated with alloimmunization, titers are performed that measure how much antibody-positive maternal serum is required to agglutinate a standardized sample of antigen-positive RBCs. Titers are reported as dilutions; that is, 1:1 means one full quantity of maternal serum agglutinates a sample of antigen-positive RBCs, whereas 1:16 means 1/16 the standard quantity of maternal serum agglutinates a sample of antigen-positive RBCs. A critical titer level depends on the risk for hemolytic disease of the fetus and newborn. Titer levels associated with onset of pregnancy complications vary between 1:8 and 1:32, depending on the antibody–antigen complex in question.[114]

Management of isoimmunization begins with identification of women who are alloimmunized. Women who have a positive antibody screen are referred for additional testing and if the resultant antibody and titer are associated with alloimmunization, physician consultation is obtained. Depending on the titer, the antibody titer maybe repeated every 4 weeks until 28 weeks, at which time screening frequency increases to every 2 weeks.[113-115] If a woman's titers reach critical levels for the antibody in question [1:32 for Rh (D), 1:8 for Kell], Doppler studies are used to screen for evidence of fetal anemia. Follow-up monitoring may involve serial amniocentesis to monitor bilirubin levels in the amniotic fluid. In addition, ultrasound monitoring for hydrops fetalis may be initiated.

Population-Specific Special Considerations During Pregnancy

Adolescent Pregnancy and Advanced Maternal Age

Pregnancy at both ends of the age spectrum, younger and older, is associated with increased risks of adverse outcomes. The age range for adolescent or teen pregnancy is defined as 13 to 19 years. Advanced maternal age (AMA) describes women who will be 35 years or older at the time of birth. The incidence of pregnancy in young women age 15 to 19 years is approximately 22 pregnancies per 1000 women in the United States; although this incidence is decreasing, the United States still has one of the highest rates of adolescent pregnancy among all developed nations.[116] By comparison, approximately 9% of pregnant women in the United States are 35 years or older when they give birth.[117]

Adolescent Pregnancy

Adolescent pregnancy is associated with increased rates of adverse maternal and fetal health outcomes, more social risks, and living in poverty. Approximately 80% of adolescent pregnancies are unplanned.[118] Worldwide, complications related to pregnancy and birth are the second leading cause of death in women between ages 15 and 19 years.[118] Studies that evaluate the effects of pregnancy during adolescence often subcategorize this population as younger (less than or equal to age 15 years) or older (age 16 to 19 years) because they have different profiles and different risks. The prevalence of adolescent pregnancy and risks associated with adolescent pregnancy are also highly related to race/ethnicity, geographic setting, family support, financial status, and educational attainment. Likewise, the social perceptions of early parenting differ greatly among different cultures. It is important to view the individual within the framework of her environment and support structure.

Overall, adolescent pregnancy is associated with increased risks for anemia, preterm birth, low birth weight, preeclampsia, postpartum hemorrhage, stillbirth, sexually transmitted infections, and substance use disorder.[118,119] Younger women are also less likely to receive adequate prenatal care as compared to older women.

Prenatal care for adolescents requires increased awareness and screening for social risks such as tobacco use, substance use, intimate-partner violence, food insecurity, and financial instability. In addition, adolescents are minors and subject to different regulations with regard to mandatory parental involvement.[120] Younger women often need detailed health education regarding nutrition, sexuality, and preparing for labor, birth, and parenting.[121] The skills needed to care for adolescents during pregnancy are within the scope of practice for independent midwifery care. Midwives have a long history of providing care to adolescents, and in many settings, they lead teen clinics. In many settings, an interdisciplinary team can provide the best care for this population. The benefits of the CenteringPregnancy group prenatal care model is most promising for adolescents.[122] The Resources section at the end of this chapter includes reviews and guidelines that address the specific prenatal needs of

adolescents.

Advanced Maternal Age

Women who are older than 35 years when they give birth have increased risks for miscarriage, aneuploidy, gestational diabetes, hypertensive disorders of pregnancy, placenta previa, preterm labor/birth, and stillbirth. There is also an age-related increase in maternal morbidity/mortality once pregnancy complications arise, particularly regarding the severity of cardiovascular complications.[123]

The association between advanced maternal age and these conditions is widely recognized, but little evidence exists regarding their causal mechanisms. A key question emerging from the available data is how much of the association between advanced maternal age and pregnancy complications can be accounted for by parity, comorbid conditions, use of assisted reproductive technology, and/or socioeconomic status, all of which commonly change as a woman ages. Another question is whether obstetric risks apply to all women older than 35 years, or whether these risks increase at specific age increments, as is seen in younger versus older adolescents. Screening for conditions associated with advanced maternal age should occur according to general guidelines, and management of each condition should be guided by the details of the woman's condition rather than by her age.

Pregnancy After Assisted Reproductive Technology

There is a positive association between assisted reproductive technology and certain pregnancy complications, including multifetal gestation, miscarriage, ectopic pregnancy, congenital anomalies, preterm birth, low birth weight, preeclampsia, placenta previa, placental abruption, and cesarean birth.[124,125] The increased incidence of multifetal gestation is related to the procedure, whereas some of the identified complications are related to multifetal gestation. Other pregnancy-related complications are more likely in women with singleton pregnancies. It is not clear whether the process of assisted reproductive technology or the underlying infertility is the etiologic factor that explains these associations.

There are no specific guidelines for prenatal care in the absence of signs or symptoms of a complication or other indications for increased surveillance. Some institutions recommend antenatal fetal surveillance in the late third trimester for women who conceived via assisted reproductive technologies, but the evidence for this recommendation is not substantial.

Female Genital Mutilation

In Western medical practice, female circumcision or "cutting" is called female genital mutilation (FGM). This procedure is practiced in parts of Africa, Asia, and the Middle East, affecting more than 90% of all women in some countries.[126] As women from these regions have immigrated to Europe and the United States, practitioners in areas previously unfamiliar with this practice have found themselves caring for pregnant women with FGM.

The World Health Organization classifies the degree of FGM as type I, involving the removal of the prepuce and clitoral tissue; type II, which includes removal of the prepuce,

clitoris, and labia minora; and type III, called infibulation, in which the clitoris, labia minora, and inner surface of the labia majora are excised. The sides of the labia majora are then stretched toward each other and stitched together, creating a false hood of skin over the urethra and anterior part of the vaginal orifice. Infibulation narrows the vaginal opening and leaves only a small opening at the introitus through which menstrual blood and urine can exit.[126] Long-term complications of infibulation include urinary tract infections, menstrual irregularities and retention, dyspareunia, perineal and pelvic pain, recurrent vaginal infections, infertility, pelvic infections, inclusion cysts, and abscess formation.

Although women with type I and type II FGM do not usually experience obstetric complications, type III FGM can cause obstruction from the resulting anatomy and scar tissue, necessitating the need for deinfibulation or "anterior episiotomy" prior to birth.[127] Deinfibulation generally does not injure underlying structures, as the scar tissue that forms following infibulation does not fuse with tissue of the female genitalia. Discussion of deinfibulation is best initiated early in pregnancy. Counseling includes information about the medical and obstetric risks associated with birth and the options for deinfibulation. Counseling about deinfibulation can take several visits, and physician consultation and involvement early in pregnancy will allow this process to take place over time. Deinfibulation may occur prenatally or during labor.

Substance Use In Pregnancy

Tobacco, alcohol, and illicit and/or prescription medications all have fetotoxic properties, as summarized in **Table 22-18**.[128] A midwife's role in caring for a woman with substance use disorder during pregnancy includes identification of substance being used at the earliest opportunity, provision of counseling resources, accessing medically assisted treatment, and referral to social services to address housing, employment, parenting, and transportation issues.

Table 22-18 **Substances and Associated Harm During Pregnancy**

Pregnancy-Related Complication	Opioids	Cocaine	Amphetamines	Cannabis	Tobacco	Alcohol	Marijuana

Neonatal abstinence syndrome	X				X	X	
Behavioral and cognitive dysfunction in childhood							X

Based on Foeller ME, Lyell D. Marijuana use in pregnancy: concerns in an evolving era. *J Midwifery Womens Health.* 2017;62(3): 363-367[12]; Finnegan L. Licit and illicit drug use during pregnancy: maternal, neonatal and early childhood consequences. Canadian Centre on Substance Abuse. 2013. Available at: http://www.ccsa.ca/Resource%20Library/CCSA-Drug-Use-during-Pregnancy-Report-2013-en.pdf. Accessed October 6, 2017.[128]

Women with substance use disorders have an increased risk for sexually transmitted infections (STIs), hepatitis, and HIV. Rescreening for STIs in the second and/or third trimester may be indicated and should be considered on an individual basis. Fetal risks are related to the substance and amount of exposure as noted in **Table 22-18**.

Screening for substance use is recommended for all women early in pregnancy. Women may not self-disclose substance use during pregnancy out of fear of intervention by Child Protective Services and because of the potential to have their child taken away at birth. Providing a positive, compassionate, and nonjudgmental prenatal setting can encourage disclosure, although it may take time to build a trusting relationship.

The recommended process of screening, brief intervention, and referral to treatment is referred to as SBIRT. This process has been validated by the U.S. Preventive Services Task Force and other professional organizations.[129] Screening should occur via use of a validated questionnaire such as the 4P's which screens for any substance and asks the woman about past, present, parents, or partner use of substances. The goal of the screening portion of SBIRT is to identify women at low, moderate, or high risk for substance use disorder.

Drug testing is not recommended for universal screening.[129] Urine drug tests have many limitations including the number of substances detected (these tests do not detect alcohol metabolites for example). Urine drug testing requires the woman's permission. In addition, some states require reporting of substance abuse in pregnancy and in the hospital if a drug screen is positive on admission and/or neonatal stool is positive for drugs.

Brief intervention is a woman-centered form of counseling that uses the principles of motivational interviewing. The purpose is to identify the desire to change behavior. Women who are at high risk are referred to specialty treatment.[129] Training in SBIRT is available and resources are listed at the end of this chapter.

Treatment of the substance use disorder is most effective if it involves a multidisciplinary

group of professionals. Social workers, psychologists, substance abuse counselors, and medical addiction specialists are all needed. Referral to a structured program for pregnant women is ideal. Medical addiction specialists in a facility registered with the Substance Abuse and Mental Health Administration will be able to prescribe opioid agonist therapy (OAT) when indicated. Such therapy comprises substitution of an illicit or prescription opioid being overused with an opioid agonist that helps relieve cravings and prevent withdrawal symptoms. OAT medications used during pregnancy are methadone or buprenorphine. Because OAT reduces or eliminates risks associated with dramatic changes in blood opioid levels, perinatal outcomes are improved for both the woman and her fetus/newborn.

Finally, prescription opiate overdose is emerging as an important cause of maternal death in many states within the United States. Coordination of prescriptions within a practice group, reviewing the state prescription registry of controlled substances, and urging referral to pain management specialists may help reduce the rate of prescription misuse. Opioid agonist therapy which is provided by specialists is available for women with opioid use disorders but may be difficult to access in some locales.

Stillbirth

After 20 weeks (or 350 grams if gestational age is uncertain), fetal death is classified as a stillbirth. This term, rather than “fetal death” or “demise,” is preferred. The overall stillbirth rate in the United States is approximately 5.6 per 1000 fetal deaths and live births.[130] Half of all stillbirths occur between 20 and 27 weeks’ gestation, and the other half occur at 28 weeks or later. Of particular concern is the racial disparity in the rate of stillbirth, which is twice as high in non-Hispanic black women (11.3 per 1000 fetal deaths and live births) compared to non-Hispanic white women (4.79 per 1000 fetal deaths and live births). Factors known to contribute to this disparity include social stress, access to health care, and genetic responses to infection, but the full picture of why non-Hispanic black women are at increased risk for stillbirth compared to non-Hispanic white women is not fully known.[131]

The determination of the cause of the stillbirth is extremely difficult. The causes of stillbirth can be maternal, fetal, or placental. In the United States, more than half of all stillbirths have no identifiable cause, and approximately 20% are related to infection (which causes preterm labor and/or preterm premature rupture of membranes). In low-resource countries, infection accounts for more than half of all stillbirths. Other causes of stillbirth include congenital or genetic anomalies, fetomaternal hemorrhage, hydrops fetalis secondary to alloimmunization, umbilical cord abnormalities, maternal disorders such as diabetes or hypertension, and maternal substance use disorder. It is best to refrain from discussing any possible cause for the loss until objective facts are clear and post-delivery studies are completed.

Often the first sign of a stillbirth is the woman’s perception of loss of fetal movement. Inability to detect the fetal heart tones with a Doppler fetal monitor indicates the need for immediate ultrasound to confirm the diagnosis. The midwife should accompany the woman to the ultrasound appointment if at all possible, and notify the ultrasound staff ahead of time that fetal heart tones could not be found. Once the diagnosis is made, immediate physician consultation is recommended. In many states, a physician must make the determination of death,

including fetal death. After birth, midwives may be able to complete the required death certificate, but these regulations vary by state.

The decision to induce labor or wait for labor to occur spontaneously will depend on the woman's choice, her cervical status, and any concomitant medical issues that need to be addressed.[132] Although most women choose immediate induction, expectant management is a viable option for a short period of time. The majority of women (80–90%) will go into labor spontaneously within 2 weeks following a fetal demise. An unusual chronic form of disseminated intravascular coagulation (DIC) can occur if the fetus is retained in utero for more than 4 to 5 weeks; this DIC occurs secondary to slow release of tissue factor from the fetal tissue. If expectant management continues beyond a week or two, coagulation studies measuring prothrombin, partial prothrombin, fibrinogen, and platelets may be performed to screen for DIC prior to induction and at intervals.

Pregnancy After Prior Stillbirth

When a woman has experienced stillbirth, intensified surveillance is indicated in a subsequent pregnancy. Prior to pregnancy or at the first prenatal visit, a detailed history is obtained to review all information available about the prior stillbirth. Medical records can be ordered if needed and physician consultation is recommended to determine a management plan. Plans can be made to mitigate any modifiable factors such as smoking, cocaine use, or glycemic control for women with diabetes. Genetic counseling, as well as thrombophilia and antiphospholipid antibody assessment, may be considered. A detailed anatomic ultrasound (Level II) at 18 to 20 weeks' gestation may be ordered to screen for fetal anomalies and provide reassurance to the woman and her family if the ultrasound findings are normal.

The third trimester is likely to be a time of special anxiety for the woman, her family, and the providers. Although there is no evidence that heightened surveillance lowers the risk of a recurrent stillbirth, many providers offer women frequent prenatal visits or serial nonstress tests, and elective delivery at 38 weeks' gestation. Serial ultrasounds for fetal surveillance including fetal growth are recommended every 2 weeks beginning at 28 weeks.[132]

Perinatal Mood Disorders, Post-traumatic Stress Disorder, and Previous Birth Trauma

Perinatal mood disorders include depression, anxiety disorders, post-traumatic distress disorder (PTSD) and others. Women who have a mental health disorder during pregnancy are at increased risk for perinatal mood disorders in the postpartum period. Compassionate midwifery care can be very helpful for these women as midwives work in concert with other specialists as needed. Screening and treatment of perinatal mood disorders are reviewed in the *Mental Health Conditions* chapter.

Trauma specifically related to childbirth is a recognized cause of PTSD. A compassionate question—"How did your birth go for you?"—is a good approach to initiating assessment for PTSD related to prior traumatic birth (e.g., emergency cesarean, hemorrhage, newborn illness). Factors that increase the risk of PTSD after traumatic birth include history of mental

health disorders, sexual abuse, family violence, loss of a child or spouse, or other emotional/physical trauma. The addition of a traumatic birth can initiate new-onset PTSD symptoms or exacerbate symptoms in cases of preexisting PTSD.

Just as midwives recognize the need to take special care during examinations for women who have experienced abuse or rape, they should appreciate that the same caution applies to women who had a previous traumatic birth. Time needs to be provided to make plans to avoid triggers and reminders of the event in the current pregnancy and birth. Referral to therapists or counselors is indicated to provide the depth and ongoing treatment for PTSD.

Vaginal Birth After Cesarean

Cesarean birth rates have been increasing for two decades in the United States, with repeat cesarean section as the leading cause. Both repeat cesarean birth and vaginal birth after cesarean (VBAC) have health benefits and health risks (**Table 22-19**).[133-135] The decision of whether to perform a repeat cesarean birth or a trial of labor after cesarean (TOLAC) involves balancing several considerations including: (1) the chance of success versus (2) the risks for the woman associated with each option and (3) the risks for the fetus/newborn associated with each option.

Table 22-19 **Risks Associated with Trial of Labor After Cesarean Versus Elective Repeat Cesarean**

Outcome	Trial of Labor After Cesarean	Elective Repeat Cesarean	Analysis
Short-Term Effects: Maternal			
Risk of uterine rupture	7 per 1000 women	2.6 per 10,000 women	4/5/1000 more uterine rupture in women undergoing TOLAC
Maternal mortality	3.8 per 100,000 women at term	13.4 per 100,000 women at term	Approximately 9/100,000 fewer maternal deaths in women undergoing TOLAC
Hysterectomy	1.57 per 1000 women	2.8 per 1000 women	No significant difference
Blood transfusion	6.6 per 1000 women at term	4.6 per 1000 women at term	No significant difference
Operative injury	4.0–5.1 per 1000 women	2.5–4.4 per 1000 women	Differing study methodologies make this comparison difficult.
Infection	46 per 1000 women	32 per 1000 women	Differing study methodologies make this comparison difficult. No significant difference
Hospital stay	2.5 days	3.92 days	Longer for ERCD but longest for women who have failed TOLAC that results in repeat ERCD
Urinary incontinence	No data	No data	Inconclusive evidence
Pelvic floor disorders	No data	No data	Inconclusive evidence
Short-Term and Long-Term Effects: Infant			
Perinatal mortality	13 per 10,000	5 per 10,000	Approximately 1 more death per 1000 TOLAC
Hypoxic ischemic encephalopathy if uterus ruptures	8.9 per 1000	3.2 per 1000	Strength of evidence is low secondary to methodologic differences in studies
Respiratory problem in the first days after birth	5.4 per 100	2.5 per 100	Insufficient studies to assess differences
Effects on Subsequent Pregnancy Following Cesarean Birth			
Placenta previa in subsequent pregnancy	1% in women with 1 prior cesarean 1.7% in women with 2 prior cesareans 2.8% in women with ≥ 3 prior cesareans		
Placenta accreta in subsequent pregnancy with placenta previa	5% in women with 1 prior cesarean 24% in women with 2 prior cesareans 47% in women with 3 prior cesareans		

Abbreviations: ERCD, elective repeat cesarean delivery; TOLAC, trial of labor after cesarean.

Based on Guise J-M, Eden K, Emeis C, Denman MA, Marshall N, Fu R, et al. Vaginal birth after cesarean: new sights. Vol. No. 10-E001. Rockville, MD: Agency for Healthcare Research and Quality, 2010.[134]

A woman's chance of having a successful VBAC is affected by several individual factors, such as the indication for the prior cesarean, history of a vaginal birth, and current obstetric factors such as spontaneous onset of labor versus induced labor. For example, although the overall chance of success is approximately 70%, women who have had one prior vaginal birth in addition to a cesarean have a much higher chance of success. Conversely, women who had one prior cesarean for possible cephalopelvic disproportion have a much lower chance of success.

The risks associated with repeat cesarean birth include excessive blood loss, post-operative

infection, accidental tissue laceration such as bladder nicking, anesthesia reaction, and increased risk for placenta previa and placenta accreta in future pregnancies.[133-135]

The risks associated with TOLAC include unplanned repeat cesarean, which is associated with more morbidity than a repeat cesarean and uterine rupture. A complication unique to vaginal birth after cesarean, uterine rupture has significant adverse sequelae for both the woman and the infant.[133-135]

Women approaching this decision require a detailed review of the benefits and risks of each option based on their individual history as part of a shared decision making process.[133-136] Birth in an out-of-hospital setting is not recommended given the most recent analyses of outcomes following labor and/or birth at home.[137,138] Women considering TOLAC should also be informed about available hospital and provider resources. Online VBAC success rate calculators can assist the midwife in providing guidance. Although these calculators have limitations with regard to prediction of adverse outcomes, they can be helpful for estimating an individual's success of a trial of labor. (See the Resources section at the end of this chapter.)

Pregnancy After Bariatric Surgery

Midwives increasingly provide care for women after bariatric surgery as this procedure becomes more common for treatment of diabetes and infertility. Bariatric surgery is recommended when lifestyle, diet and medication therapies have failed and BMI exceeds 35 kg/mm^2 or when BMI exceeds 30 kg/mm^2 and there are comorbid conditions such as diabetes or hypertension.[139] There are two common types of bariatric surgery procedures: (1) restrictive (laparoscopic gastric banding or LAP-BAND) and (2) restrictive/malabsorptive (Roux-en-Y gastric bypass). Current recommendations advise women to wait between 12 and 18 months postbariatric surgery so that weight loss is stabilized before starting a pregnancy.[140]

Pregnancy following bariatric surgery is safer than pregnancy when BMI exceeds 40 kg/mm^2. Reviews to assess the advantages of bariatric surgery prior to pregnancy found that bariatric surgery reduced the risk for gestational diabetes, preeclampsia, hypertension, and large-for-gestational-age neonates, with most women experiencing no complications during pregnancy.[139,141,142]

Knowing the type of bariatric procedure done allows the midwife to provide appropriate nutritional advice and risk screening. Pregnancy weight gain recommendations are based on pregravid BMI even after bariatric surgery. LAP-BAND slippage and movement can occur during pregnancy and result in severe vomiting.[142] Some advocate for deflating the band prior to pregnancy to allow for adequate nutrition, though there are no national guidelines.

Malabsorptive surgeries reduce food, micronutrient and medication absorption. Deficiencies in iron, vitamin B_{12}, folate, vitamin D, calcium, and protein can be common. Baseline vitamin and mineral status is evaluated at the first prenatal visit with supplements recommended as needed. A complete blood count and measurement of B_{12}, iron, ferritin, calcium, and vitamin D levels every trimester should be considered.

Women are prone to dumping syndrome following malabsorptive surgeries. Gestational diabetes testing can be done by following fasting and postprandial blood glucose levels after

breakfast for 1 week.[140] Third trimester serial ultrasounds document fetal growth if maternal weight gain has been limited or abdominal adipose limits palpation.

The midwife providing prenatal care for women following bariatric surgery coordinates care among a network of clinicians including maternal-fetal medicine physicians, nutritionists, and ultrasonographers. Care within this team optimizes a woman's chance for a safe and satisfying birth.

Techniques for Fetal Surveillance

The terms “fetal surveillance” and “antenatal testing” refer to tests that assess fetal well-being in the late second or early third trimester. The goals of antenatal fetal testing include (1) prevention of stillbirth, (2) identification of the fetus whose oxygen status is compromised so as to allow intervention before irreversible metabolic acidosis ensues, and (3) avoidance of unnecessary interventions when other clinical parameters are equivocal. This section reviews the theory, indications, methodology, and normal versus abnormal findings for the following tests: fetal kick count, nonstress test (NST), biophysical profile (BPP), contraction stress test (CST), and Doppler indices. Antenatal testing is a classic “screening test” in that if the results are normal, fetal well-being is assured. In contrast, if results are abnormal, further assessment is indicated to determine fetal well-being or fetal compromise.

Tests for fetal well-being are clinically useful primarily because their negative predictive value is 99% or higher.[143,144] The incidence of false-positive tests varies between 50% and 60% depending on the test. Because the positive predictive values are much lower than the negative predictive values, clinical management of abnormal fetal surveillance tests varies depending on other clinical factors.[145] The interpretation of these testing methods is summarized in **Table 22-20**.

Table 22-20 Interpretation of Fetal Surveillance Tests

Name	Results	Criteria
Contraction stress test (CST) or breast stimulation test (BST)[a]	Negative	Normal FHR without late decelerations
	Equivocal suspicious	Intermittent late decelerations or variable decelerations
	Equivocal hyperstimulation	Decelerations that occur in presence of tachysystole
	Unsatisfactory	Unable to obtain a satisfactory FHR tracing
	Positive	Recurrent late decelerations following 50% or more of contractions even if fewer than 3 contractions in 10 minutes
Nonstress test (NST)[b]	Reactive	≥ 2 accelerations within 20 minutes (some settings extend to 40 minutes)
	Nonreactive	< 2 accelerations in 40 minutes
	Inconclusive	Unable to obtain a satisfactory FHR tracing
		Variable or late decelerations or other Category II FHR tracing
		Reactive NST with FHR decelerations
Biophysical profile (BPP)	Normal	≥ 8/10 or 8/8 if NST excluded
	Equivocal	6/10
	Abnormal	≤ 4/10
Modified NST	Normal	Reactive NST and AFI > 5 cm
	Abnormal	Nonreactive NST and/or AFI ≤ 5 cm

Abbreviations: AFI, amniotic fluid index; FHR, fetal heart rate.

[a] This test is interpreted once the woman has at least 3 contractions within 10 minutes.

[b] An acceleration must be 15 beats per minute above the baseline, and must last 15 seconds or more from onset to resolution, after 32 weeks' gestation. The acceleration must be 10 beats per minute above baseline and last 10 seconds in a preterm fetus.

Fetal Physiologic Indices and Factors That Affect Fetal Behavior

Prenatal surveillance of fetal well-being is based on the observation that specific fetal behavior states reflect adequate oxygenation. The fetal heart rate pattern, level of fetal activity, and degree of muscle tone are sensitive to hypoxemia and acidosis. Therefore, fetal oxygenation can be indirectly evaluated by assessing biophysical parameters, just as vital signs are used to assess well-being in an adult or child. Fetal biophysical behavior that is assessed in the various prenatal fetal tests includes fetal heart rate parameters, fetal movement, fetal breathing, and quantification of amniotic fluid (because the amount of amniotic fluid is an indication of fetal renal function and renal perfusion). Each of these parameters can be affected by a multitude of factors.

Maternal awareness of fetal movement begins in the second trimester; multiparous women usually start feeling the fetus between 16 and 18 weeks, whereas primiparous women usually start feeling the fetus between 18 and 22 weeks. Women who have an anterior placenta may begin detecting fetal movement somewhat later than women whose placenta is posterior. Fetal movement is initially slight and irregular, gradually becoming stronger and more frequent. Fetal movement maximizes around 34 weeks, but then appears to become less frequent. This pattern occurs because, as the central nervous system matures, the fetus begins to exhibit longer and cyclic sleep or quiet alert states wherein movement does not occur. Thus, the woman's perception can be one of decreased movement toward the end of the pregnancy. Women usually perceive approximately 50% of isolated limb movements and 80% of movements that involve both the trunk and the limb.[146] **Table 22-21** lists maternal factors that affect perception of fetal behavior.

Table 22-21	Factors That Influence Maternal Perception of Fetal Movement
Decreased Fetal Movement	
Obesity	
Maternal position (fetal movement is perceived best in a recumbent position as compared to sitting or standing)	
Anterior placenta	
Amniotic fluid volume (polyhydramnios and oligohydramnios)	
Drugs:	
Corticosteroids	
Sedatives and alcohol prolong quiet sleep states	
Tobacco (short period of time after smoking a cigarette)	
Hypoglycemia	
Fetal spine in an anterior position (occiput anterior)	
No Difference in Perception of Fetal Movement	
Parity	

Maternal anxiety
Increased Fetal Movement
Maternal meal or increase in blood glucose levels
Evening hours: fetal movement is the least evident in the morning

Fetal behavior—including fetal tone, movement, breathing, and fetal heart rate characteristics—changes as the fetus becomes hypoxic. The functions that appear first in gestation disappear last as hypoxia and acidosis increase. In general, loss of fetal heart rate reactivity, fetal heart rate decelerations, and reduced fetal activity are fetal responses to acute hypoxia, whereas oligohydramnios, fetal growth restriction, and altered umbilical artery blood flow are responses to chronic hypoxia. Additional information on the fetal heart rate responses to acute hypoxia can be found in the *Fetal Assessment During Labor* chapter.

Indications for Antenatal Testing

Although indications for antenatal testing vary between institutions, **Table 22-22** lists those that are most common to all settings.[145] Likewise, determining when to start testing will vary depending on the condition. Most antenatal testing is started at 34 to 36 weeks and is conducted either weekly or biweekly.

Table 22-22 Selected Indications for Antenatal Testing[a,b]

Maternal	Pregnancy Related	Fetal
Age > 40 years	Abnormal maternal serum screening (one or two abnormal values, unexplained)	Abruption in current pregnancy
Active substance use	Assisted reproductive technology	Congenital abnormalities
Antiphospholipid antibody syndrome	Cholestasis of pregnancy	Decreased fetal movement
Cyanotic heart disease	Late term or post-term pregnancy	Fetal growth restriction
Chronic hypertension	Multifetal gestation	Oligohydramnios
Diabetes requiring insulin	Pemphigoid gestationis	Polyhydramnios
Hemoglobinopathies	Preeclampsia	Congenital abnormalities
Hypertension		Decreased fetal movement
Hyperthyroidism, poorly controlled		Fetal growth restriction
Renal disease		Umbilical cord abnormalities
Stillbirth in previous pregnancy		
Seizure disorder, poorly controlled		
Sickle cell disease		
Systemic lupus erythematosus		

[a] This table presents a representative list of common indications. Individual practices will have indications for prenatal testing identified in collaboration with consulting physicians that may include additional conditions and that

may not include some conditions that appear in this table.

[b] Additional indications for women hospitalized in the prenatal period include conditions such as preterm premature rupture of membranes, Rh isoimmunization, and fetal surgery.

Fetal Movement Counting (Kick Counts)

The rationale for formal fetal movement counting is that 30% to 50% of stillbirths occur in women with low-risk pregnancies and structurally normal fetuses in whom there were no indications for prenatal testing. In addition, fetal movement starts to decrease several days prior to stillbirth, and women who report decreased fetal movement have a higher incidence of fetal growth restriction and stillbirth. These observations became the basis for introducing fetal movement counts for the purpose of preventing stillbirth.

More than 40 years of literature and research has now been accumulated on the relationship between fetal movement and adverse pregnancy outcomes. Formal fetal movement counting does not prevent all stillbirth in the general population, but women who have a heightened awareness of fetal movement will detect decreased movement and these women self-select into a higher risk category in which more intense evaluation is of value. The clinical question has long been, “Should all women perform formal fetal movement counts during the third trimester or just women who are at high risk for stillbirth?” This question has not been definitively answered, and the RCTs conducted on routine fetal movement counting have yielded mixed results.[146,147] Currently, some clinicians recommend formal fetal movement counting for all pregnant women, whereas others recommend formal fetal movement counting only for those women who are at increased risk for fetal growth restriction or stillbirth. The American College of Obstetricians and Gynecologists does not recommend formal fetal movement counting for women who are not at risk for chronic fetal hypoxia.[145]

The specific fetal movement count that is the best “alarm” or trigger for additional evaluation has not been determined. The method most commonly used is the “Count to 10” method, whereby a woman focuses attention on fetal movement and records how long it takes to document 10 fetal movements. If it takes longer than 2 hours, the woman is to call her midwife; she is then asked to come in for a formal nonstress test (**Figure 22-8**).

Name _____

At the same time each day, count the baby's movements. When you have felt 10 movements, record the length of time it took. All movements, even small ones, count toward the total. If you have not felt 10 movements in the usual amount of time, please call your midwife.

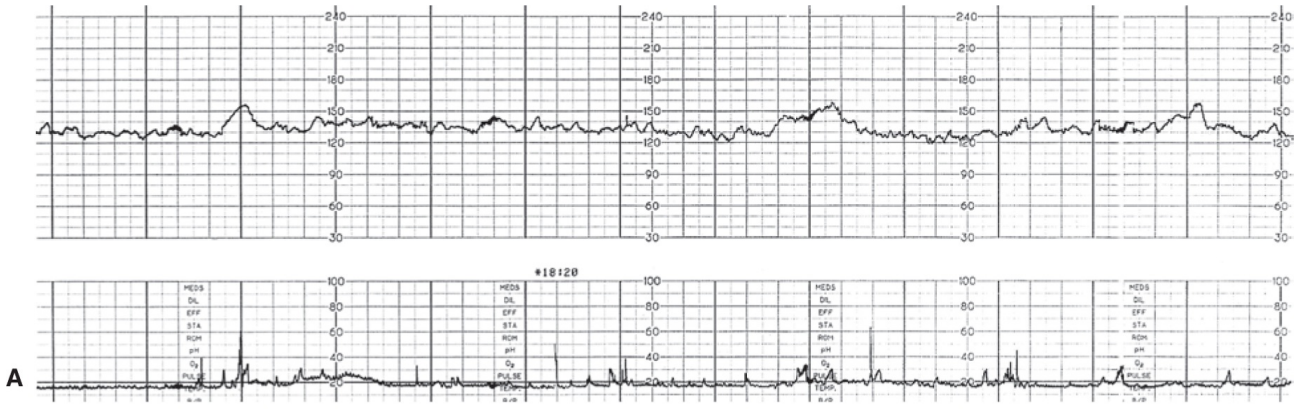
Week of _____

Day	Start Time	Hours taken to feel 10 movements of the baby: 1	2	3	4	5	6	7	8	9	10
M											
T											
W											
T											
F											
S											
S											

Figure 22-8 Fetal movement counting chart.

Women close to term often call their midwives to report decreased fetal movement. If the woman has no risks for uteroplacental insufficiency, it is reasonable to recommend that she eat something, rest in a semirecumbent position, and then count fetal movement. If she notes 10 movements in an hour, she can be reassured and the midwife may recommend that she repeat the formal fetal movement counts for a few days at the same time of day. If she notes fewer than 10 movements, the midwife can either have her count for another hour to see if 10 movements occur or have her be seen for a formal auscultated acceleration test or nonstress test. Because women who report decreased fetal movement have an increased risk for adverse outcomes, the midwife should have a low threshold for having a woman come for additional testing.

Contraction Stress Test



The CST was the first antenatal fetal test employed in clinical practice. It is based on the observation that uterine contractions transiently restrict blood flow to the intervillous space, thereby lowering oxygen availability to the fetus. The compromised fetus will respond with a late deceleration. (For more description of the pathophysiology of the fetal heart rate response to contractions, see the *Fetal Assessment During Labor* chapter.) The CST entails intravenous administration of oxytocin to initiate uterine contractions and continuous electronic fetal monitoring. A breast stimulation test (BST) may also be performed to initiate contractions, as an alternative to administering intravenous oxytocin. In the BST, the woman massages one nipple through her clothing for 2 minutes, followed by a rest for 5 minutes and then a repeat of the procedure on the other nipple. She should not stimulate the breast during a contraction. The BST and CST are performed in similar fashion, but the BST is associated with more uterine hyperstimulation. Interpretation of results is the same, however.

The fetal response to 3 contractions in a 10-minute window is measured during the test. The CST has the lowest false-negative rate of all antenatal fetal tests (0.04%) but a high false-

positive rate of approximately 30% and is expensive to perform. The NST and the BPP have largely replaced the CST except in inpatient settings, where it is important to establish the fetus's ability to tolerate uterine contractions prior to induction of labor.

Nonstress Test

The NST is the most common method of antenatal testing used in practice today. Its false-negative rate ranges from 0.3% to 0.65%, and the false-positive rate is approximately 55% to 90% depending on the population studied.[148] External fetal monitoring is initiated when the woman is in a side-lying semirecumbent position. The test is concluded when 2 fetal heart rate accelerations appear within a 20-minute window in a fetal heart rate tracing that has moderate variability, no decelerations, and a normal baseline, or when accelerations are unable to be elicited (**Figure 22-9**). If accelerations do not appear in the first 20 to 30 minutes, vibroacoustic stimulation may be applied. Vibroacoustic stimulation lowers the incidence of nonreactive results. The generation of accelerations via vibroacoustic stimulation appears to be as valid as the observation of spontaneous accelerations in predicting fetal well-being. The interpretive criteria for NST results are listed in **Table 22-20**. Management of inconclusive and nonreactive NSTs varies by practice and by the condition for which the NST was performed.

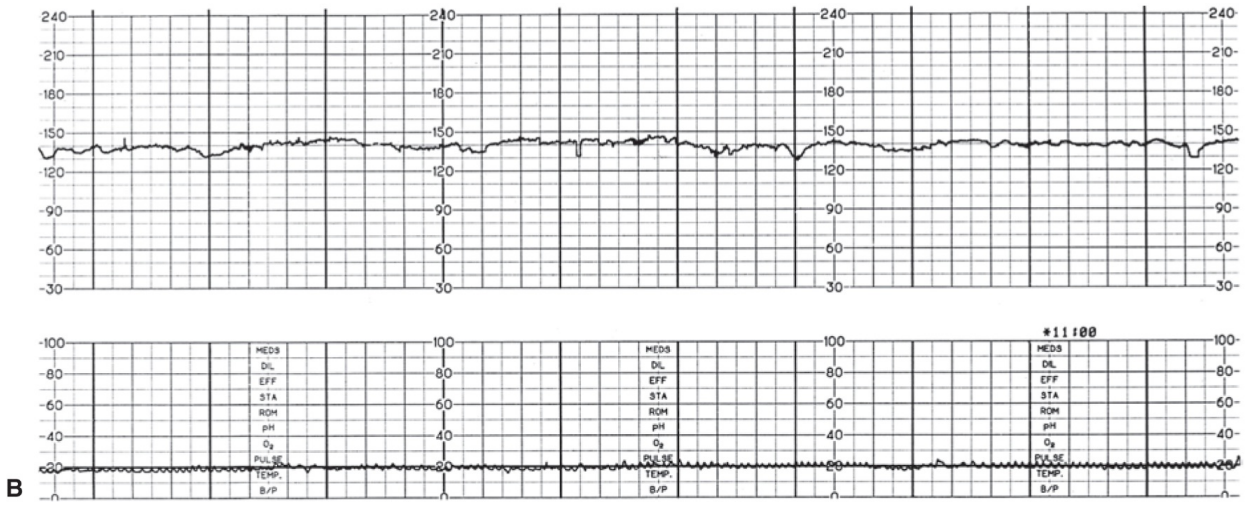


Figure 22-9 **A.** Reactive nonstress test. **B.** Nonreactive nonstress test.

Because a rise in blood glucose can initiate fetal movement, clinicians have traditionally believed that a sudden infusion of glucose via juice or candy would stimulate fetal accelerations. Studies of this practice, however, have found that glucose does not improve the results of antenatal fetal testing.[149]

Auscultated Nonstress Test

A nonstress test can be performed via auscultation with a fetoscope. During the 1980s, Paine et al. researched the use of auscultation of the fetal heart rate as a means of predicting fetal well-being prenatally.[150] From this work, a method of auscultation was devised as a simple alternative to the nonstress test and as a formal method of auscultation for antenatal testing. The auscultated acceleration test (AAT) has been validated as a predictor of both reactive and nonreactive NST results. The procedure and interpretation for an auscultated acceleration test are described in **Appendix 22A**. Anecdotal accounts indicate that use of low-technology techniques such as fetal movement counting and the AAT has led to appropriate management of compromised fetuses that would not otherwise have been identified as high risk by usual prenatal care services in midwifery practice.

Biophysical Profile

The BPP employs both ultrasound and NST. The ultrasound portion is an “intrauterine Apgar score” that includes observation of AFI, fetal breathing, fetal tone, and fetal movement. The NST provides the fifth component of the test. Each examined factor has a possible score of 2, for a maximum total score of 10 (**Table 22-23**). The BPP has a lower false-negative rate (0.08%) and fewer false-positive tests (60%) when compared to the CST or NST.[148]

Table 22-23 **The Biophysical Profile**

Variable	Adequate Score = 2	Inadequate Score = 0
Fetal breathing movement	≥ 1 episode of fetal breathing movements of ≥ 30 seconds in duration	< 30 seconds of sustained fetal breathing movements
Fetal movement	≥ 3 discrete body/limb movements (simultaneous limb and trunk movements are counted as a single movement)	≤ 2 movements
Fetal tone	≥ 1 episode of active extension with rapid return	Either slow extension with return to partial flexion or movement of limb in full trunk, or hand extension, or absent fetal movement
Fetal heart rate over 20 minutes	≥ 2 accelerations of ≥ 15 beats/min, peak amplitude lasting ≥ 15 seconds from the baseline with moderate variability in 20 minutes	< 2 accelerations or accelerations < 15 beats/min peak amplitude or accelerations < 15 seconds duration in 20 minutes Minimal or absent variability
Amniotic	Single deep pocket > 2 cm that does not include	No pocket of fluid that is > 2 cm

fluid volume[a]	umbilical cord or fetal extremities	
Amniotic fluid index (AFI)[a]	≥ 5.0 cm	< 5.0 cm, oligohydramnios
	5.1–8	Low normal
	8.1–24	Normal
	> 24	Polyhydramnios

[a] Amniotic fluid volume or AFI can be used as the fifth component of the biophysical profile. Evidence from randomized controlled trials has found the amniotic fluid volume of a pocket < 2 cm to be a reliable diagnosis of oligohydramnios and associated with fewer obstetric interventions when compared to the AFI.

Individual biophysical activities appear at different stages of fetal development. Fetal tone appears at approximately 8 gestational weeks, fetal movement at 9 gestational weeks, fetal breathing at 21 gestational weeks, and fetal heart rate reactivity by the late second trimester. The biophysical activity that appears first is also the last to disappear when acidemia is present. Thus, fetal heart rate variability is first to disappear; conversely, the absence of fetal tone predicts fetal acidemia 100% of the time.

The relationship between the BPP score and fetal acidemia has been studied extensively. A full-term fetus with a score of 8 to 10 has a risk of fetal asphyxia occurring within a week after the test of approximately 1 per 1300 tests, whereas the risk of fetal asphyxia for a fetus with a score of 1 to 4 is between 91/1000 and 600/1000, respectively.[148]

Modified Biophysical Profile

The full BPP can take some time to perform. The modified BPP, composed of an NST and AFI, has similar false-negative and false-positive rates as the full BPP, and has become the most common prenatal testing conducted. Nonstress testing can identify acute hypoxia, and decreased amniotic fluid is considered to reflect the presence of chronic hypoxia. The modified BPP has a predictive value similar to that of a full biophysical profile when the NST is reactive and the AFI is higher than 5.0 cm. If the NST is nonreactive or if the AFI is less than 5.0 cm, a complete BPP should be performed. If all of the ultrasound components of the BPP are reassuring, performing the NST is not necessary for confirmation of fetal well-being.

Doppler Indices

Doppler ultrasound uses the waveform properties of arteries or veins to analyze the passage of blood through that vessel. Evaluations of the Doppler velocimetry within the umbilical arteries, fetal aorta, and middle cerebral artery are recently introduced antenatal tests used to assess placental function in women who may have a growth-restricted fetus.

The end-diastolic flow in the uterine artery normally increases with advancing gestation secondary to decreased resistance in the placenta. As more tertiary vessels develop, the pressure within the artery drops slightly. The systolic/diastolic (S/D) ratio of the umbilical artery normally decreases as gestational age increases. This development takes place secondary to the higher diastolic velocity that occurs as the number of placental villi increase. Abnormal umbilical artery Doppler studies have been consistently linked to abnormal fetal

outcomes. It is estimated that no diastolic flow reflects a loss of 60% to 70% of placental vascularity. Abnormal elevation of the umbilical artery S/D ratio occurs before fetal heart rate variability decreases, which makes this assessment a useful data point when evaluating a fetus with fetal growth restriction. The rate of perinatal death is decreased when uterine artery Doppler studies are added to standard antepartum testing in the setting of FGR. Assessment of the umbilical artery S/D ratio is a standard component of care for the fetus with fetal growth restriction.

Prediction of fetal risks based on umbilical artery Doppler indices may be improved with the addition of assessments of umbilical vein Doppler indices, the middle fetal cerebral artery, and, most recently, the ductus venosus. For example, vasodilation and high diastolic flow in the middle fetal cerebral artery reflects the “brain-sparing” response to hypoxia, although tests using this observation are still being evaluated for clinical utility. Flow through the ductus venosus is being used to assess fetal cardiac function.

Conclusion

Although midwives primarily care for women without pregnancy-related conditions, an essential component of that care is careful risk screening and early detection of complications. In addition, when a woman does have a condition that is troubling or a complication, she can be reassured when given accurate information and emotional support. The midwife who understands the pathophysiology and the maternal, fetal, and newborn risks associated with a pregnancy-related condition, as well as the interventions for complications when they occur and risks associated with those interventions, will be best positioned to provide continuity of care and the information women need most for the current pregnancy, future pregnancy, and ongoing health.

Auscultated Acceleration Test

TEKOA L. KING

© hakkiarslan/iStock/Getty Images Plus/Getty

The auscultated acceleration test (AAT) detects fetal accelerations using a specific counting method via use of an Allen or Doppler fetoscope.**1** The procedure for conducting an AAT should be performed by two clinicians; one auscultates and reports the fetal heart rate (FHR) count, and the other records the findings.[2-6]

Background

FHR accelerations of 15 bpm or more above the baseline that last for 15 seconds or more from onset to return to the baseline are a reliable indicator of fetal oxygenation. When two accelerations are noted in a 20-minute FHR recording, the chance of stillbirth within the next 7 days is less than 1% (the false-negative rate is 0.3%).[7]

Mendenhall et al. evaluated the efficacy of a single acceleration (n = 1005 AAT tests, 367 women) and found the single acceleration was associated with no perinatal losses. The nonreactive AAT in this series predicted the 4 stillbirths that occurred in the cohort.[8] Other authors have shown that a clinician listening to an FHR recording will detect 77.7% of all FHR accelerations that are 15 bpm or more above baseline and 94% of the nonreactive FHR recordings.[9]

In settings where electronic fetal monitoring is not available or chosen for use, the AAT is a reliable and valid method of detecting fetal accelerations.

Procedure

- Place the woman in a semi-recumbent, comfortable position.
- Auscultate the FHR for a maximum of 6 minutes.
- Count every other 5-second interval.

- Record each 5-second count on the AAT graph (**Figure 22A-1** and **Figure 22A-2**).

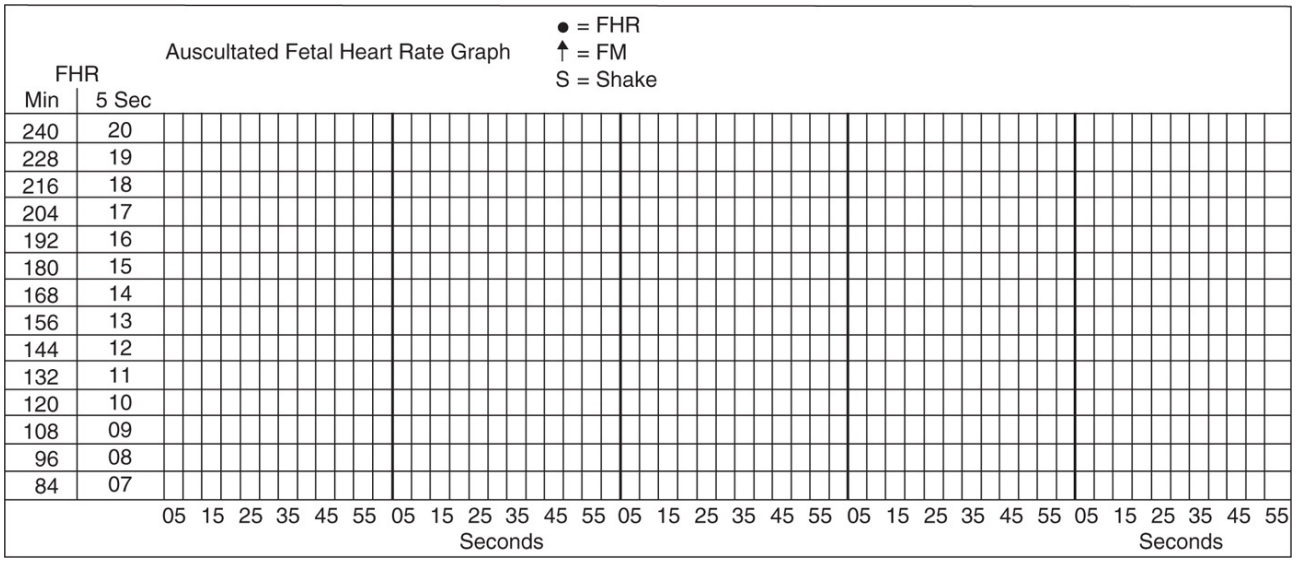

Figure 22A-1 The AAT graph used to document the FHR pattern.

Modified with permission of Lisa L. Paine from Paine LL, Payton RG, Johnson TR. Auscultated fetal heart rate and accelerations: part I. Accuracy and documentation. *J Nurs Midwifery*. 1986;31(2):68-72.[2]

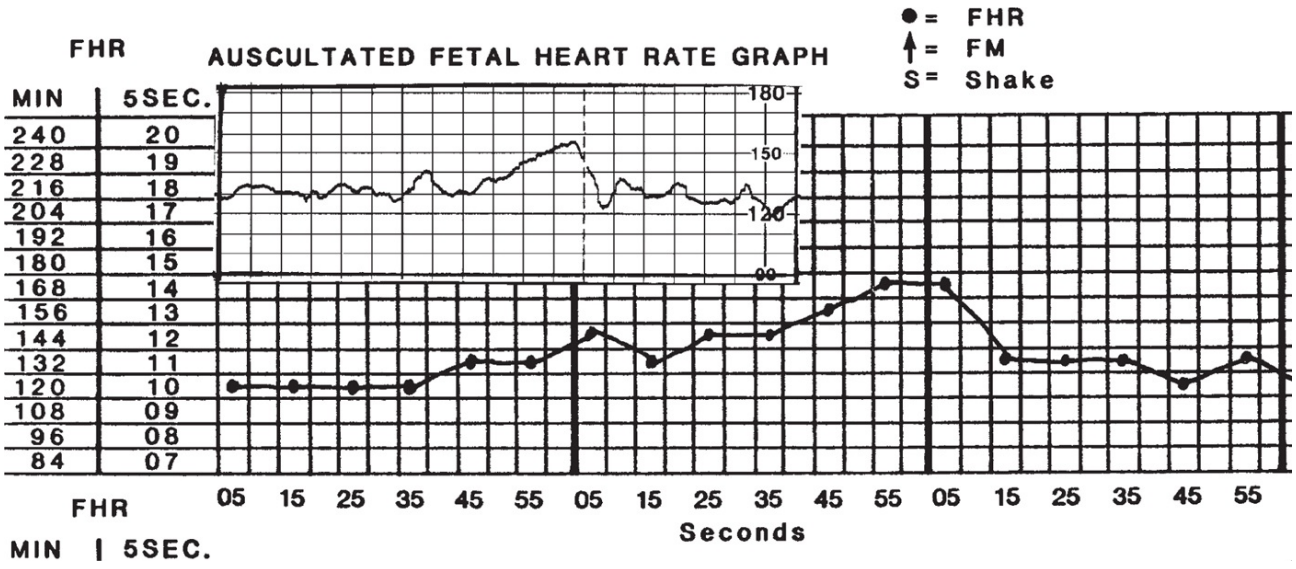

Figure 22A-2 AAT with inset of a nonstress test completed simultaneously.

Reproduced with permission of Lisa L. Paine, who first developed the AAT with colleagues at Malcolm Grow Medical Center, Andrews AFB, Maryland, and later studied its validity and refinement at the Johns Hopkins Hospital in Baltimore, Maryland, with funding from the NIH National Center for Nursing Research Grant No. R-01-NR-01705-01.

- If an acceleration of 2 bpm in a 5-second counting interval is noted in conjunction with fetal movement (FM), the test can be stopped.
- If no acceleration is noted after 3 minutes, the maternal abdomen can be gently shaken in an attempt to waken the fetus or elicit a more active state. The clinician grasps the fetal head and buttocks and slowly moves the fetus slightly from side to side in a gentle

shaking motion for 5 seconds.
- The FHR auscultation procedure is again repeated for a maximum of 2 to 3 minutes.
- Identify baseline FHR and any accelerations by plotting the numbers obtained on the AAT chart (**Figure 22A-1** and **Figure 22A-2**).

Interpretation

Reactive Nonstress Test (NST)

- An acceleration is present when the FHR is up by two grid points (2 bpm in a 5-second period).
- A single FHR acceleration indicates reactivity.[8]

Unsatisfactory

- No acceleration and no fetal movement after fetal stimulation are noted.

Nonreactive

- No accelerations are noted.

Introduction

This chapter reviews medical complications that may occur during pregnancy. Medical disorders may develop for the first time during pregnancy. Preexisting medical disorders may worsen, be unaffected, improve, or have a variable course during pregnancy, particularly because the physiologic changes of pregnancy can alter the course of many illnesses. Medical complications in pregnant women are best cared for by a collaborative, team-based care or by physician referral. Midwives practice in a wide variety of settings with different resources. The model of collaborative care provides a powerful interdisciplinary consensus structure for delivering this kind of practice.[1] Ideally, care models should be flexible, dynamic, and responsive to the unique needs of the individual woman and family. In all circumstances, the optimal care of the woman and her fetus will drive care decisions.

Midwives may be the first healthcare provider to see a woman who has increased risks for adverse perinatal outcomes secondary to a medical disorder, including individuals who present for preconceptional counseling. Identification of risks and consultation, when indicated, is an essential component of midwifery care. Thus, midwives need the knowledge necessary to identify perinatal risks so that they can obtain a thorough history, consult with the appropriate specialist, and initiate evaluations when required.

Midwives also often identify social determinants of care and provide ancillary and supportive care for women with increased risks of poor outcomes. For women with complex medical disorders, prenatal visits can involve many tests and discussions of possible adverse outcomes. Midwifery visits can help a woman who has a high-risk pregnancy in several ways. For example, a midwife visit may focus on the “normal” aspects of her pregnancy and thereby help the woman preserve her sense of well-being. The midwife may also participate in education and support for the extra care required to treat a medical complication.[1]

This chapter does not include a comprehensive review of all possible medical conditions that can adversely impact the course of pregnancy. Instead, a review of commonly encountered problems is provided as exemplars of the approach one takes in caring for a woman with any preexisting medical disorder. For the convenience of the readers, these conditions are generally presented in an alphabetical order rather than incidence of occurrence.

Autoimmune Disorders in Pregnancy

Autoimmune disorders are a broad classification of disorders in which aberrations in the immune response result in the immune system attacking the individual's healthy body tissue. Examples include systemic lupus erythematosus (SLE), multiple sclerosis, rheumatoid arthritis, and irritable bowel syndrome. During pregnancy, the immune system changes in response to accommodation of the fetal immune system. Because of pregnancy, some autoimmune disorders (e.g., rheumatoid arthritis, multiple sclerosis) improve during pregnancy. For others, pregnancy has no effect on the progress of the disorder but the disorder or treatment can have adverse effects on the course of pregnancy (e.g., SLE). Treatment of autoimmune disorders focuses on suppressing abnormal immune function, and a similar group of medications is used to treat many of these disorders. SLE is presented as a common exemplar of the topics of import involved in caring for a woman with different autoimmune disorders during pregnancy.

Systematic Lupus Erythematosus

Systemic lupus erythematosus is an autoimmune connective tissue disorder involving multiple body systems. The pathogenesis of SLE occurs secondary to an immune dysregulation of B cells that results in abnormally increased production of antibodies to nuclear antigens and other self-antigens not usually identified by the immune system as "abnormal." The target antigens for these autoantibodies are membranes, intracellular material, or nuclear material. SLE is more common among women than among men, and appears primarily during the reproductive years. African Americans and Asians have a higher prevalence than Caucasians.[2] The nature of the disease is highly variable, characterized by multiple symptoms, periodic remissions and flare-ups, and differing patterns of progression and prognosis.

Diagnostic criteria for SLE include having four or more of the following signs and symptoms: antinuclear antibodies, lupus antibodies, hemolytic anemia or thrombocytopenia, seizures or psychosis, persistent proteinuria, pleuritic or pericarditis, arthritis in two or more joints, oral pharyngeal ulceration, photosensitivity, discoid lupus, or "butterfly" rash on the face.[3] Some of these symptoms mimic findings associated with normal pregnancy changes, such as malar erythema (cholasma of pregnancy), anemia, and mild thrombocytopenia—which makes detection of an SLE flare-up in a pregnant woman challenging.[3]

Several medications from different drug classes are used to help women manage SLE. Some are safe for the woman and the fetus, some do not affect the fetus, and some are contraindicated. Thus, a thorough review of current medications is one of the initial assessments to be made in a woman with SLE, or other autoimmune disorder.

SLE does not significantly affect a woman's fertility, but pregnancy may increase disease activity and, depending on the systems affected, can lead to serious complications for both the woman and her fetus. One meta-analysis of 37 studies on SLE in pregnancy reported increased maternal risks of lupus flare (25.6%), hypertension (16.3%), nephritis (16.1%), preeclampsia (7.6%), and eclampsia (0.8%). Women with SLE are also at increased risk for thrombophilia, thromboembolism, and thrombocytopenia. With the added SLE activity that can occur in pregnancy, some women with lupus nephritis may experience accelerated progress toward

end-stage renal disease.[2]

Potential pregnancy complications include miscarriage (16.0%), intrauterine growth restriction (12.7%), stillbirth (3.6%), and neonatal death (2.5%).[2] Neonatal lupus is an autoimmune disorder acquired by the fetus secondary to passive transfer across the placenta of maternal autoantibodies; these autoantibodies primarily attack the fetus's skin and heart. Congenital heart block occurs is approximately 2% of fetuses in women with anti-Ro/SSA or anti-La/SSB antibodies. Risks for all complications increase if the woman has lupus nephritis and antiphospholipid, anti-Ro/SSA, or anti-La/SSB antibodies.[1]

Management of Women with Systematic Lupus Erythematosus

The best pregnancy outcomes occur among women who have not had a lupus flare for 6 or more months preceding pregnancy.[3] Women who are having a lupus flare are best managed in a setting that has access to providers of high-risk obstetrical care and subspecialists. Monitoring during pregnancy includes baseline and serial laboratory tests to assess for SLE flare, serial ultrasonography, weekly biophysical profile in the third trimester, and fetal echocardiography for women who have anti-Ro/SSA or anti-LA/SSB antibodies. Women are followed closely for disease exacerbation, indications of thrombotic events, and hypertensive disorders.

Treatment with hydroxychloroquine (Plaquenil) that was started before conception is continued throughout the pregnancy. When antiphospholipid antibodies are present, prophylactic aspirin or low-molecular-weight heparin is indicated to help prevent fetal loss. In the absence of any signs or symptoms of active SLE, affected women usually require no specific treatment during pregnancy. Additional medications are indicated for women who experience an SLE flare during pregnancy.[3]

SLE provides a good example of how the midwife can collaborate in the care of a woman with a high-risk medical condition during pregnancy. The first step is to conduct a thorough history and identify any immediate concerning symptoms, such as hypertension. The midwife should then review the woman's list of current medications to determine whether any are contraindicated or of concern for use in pregnancy. Women with significant risks are referred to physician care for urgent evaluation. For women who have SLE but no immediate risks, physician consultation is obtained to identify tests or laboratory evaluations that need to be scheduled and the appropriate timing for a physician visit. Once the woman is under the care of the appropriate obstetric specialist, the midwife can participate in conducting subsequent prenatal visits as indicated. When a woman with SLE is seen for a prenatal visit by a midwife, accurate assessment of blood pressure and urinalysis are essential, as these tests will help detect the onset of a lupus flare. The fetal heart rate should be counted and the number of beats per minute recorded in the chart at each visit. Breastfeeding is not contraindicated for a woman with SLE and is discussed as usual prenatally.

Diabetes

Approximately 6% to7% of women are affected by diabetes mellitus (DM) during pregnancy. The three types of diabetes are type 1, type 2, and gestational diabetes mellitus (GDM). Type 1 and type 2 diabetes are collectively termed *pregestational diabetes mellitus* (PGDM).[4-6] A fourth syndrome, *prediabetes*, is defined as a high blood glucose level in a person who does not have all the criteria for the diagnosis of diabetes; such an individual is at increased risk for developing diabetes.

Gestational diabetes and type 2 diabetes are diseases of insulin resistance, whereas type 1 diabetes is characterized by beta cells in the pancreas that produce little or no insulin. GDM is further subcategorized as A1GDM (diet changes result in euglycemia) and A2GDM (medication is needed to maintain euglycemia). In the United States, PGDM and GDM have a prevalence of 0.82% and 5.34%, respectively.[7] The incidence of type 2 diabetes before pregnancy and the incidence of GDM are increasing in parallel with the rising rates of obesity in this country.[4] The prevalence of GDM is higher among Hispanic, African American, Native American, Asian, and Pacific Islander women than Caucasian women.

Overall, approximately 29.3% of women in the United States have prediabetes.[8] This condition is associated with obesity as well as dyslipidemia including high triglycerides and/or low high-density lipoprotein (HDL) cholesterol.[5] Research has found that lifestyle intervention and appropriate treatment of prediabetes in pregnancy can significantly lower the associated risks of prediabetes with preeclampsia, macrosomia, shoulder dystocia, and cesarean birth.[6]

Women with diabetes have an increased risk of several pregnancy complications, including spontaneous abortion, preterm birth, preeclampsia, and cesarean section. Risks to the fetus include fetal anomalies, intrauterine fetal demise, neonatal jaundice, hypoglycemia, hyperbilirubinemia, and shoulder dystocia. Adverse effects are more likely with increasing blood glucose levels and longer duration of elevated blood glucose levels.

Historically, gestational diabetes was thought to be a condition unique to pregnancy that increased the risk of having a large infant but resolved after the woman gave birth. The multinational Hyperglycemia and Pregnancy Outcomes (HAPO) trial published in 2008 clarified the issue. This trial placed women (n = 23,316) into three categories based on the degree of hyperglycemia found in fasting and postprandial blood glucose levels. The HAPO trial identified a strong, significant increase in several adverse pregnancy outcomes as maternal glucose levels rose, including macrosomia, shoulder dystocia, cesarean section, preeclampsia, preterm birth, hyperbilirubinemia, polycythemia, neonatal hypoglycemia, and neonatal intensive care admission.[9] Subsequent studies have also shown that women with gestational diabetes are at increased risk for developing type 2 diabetes and their infants are at increased risk for childhood obesity, type 2 diabetes, and metabolic syndrome.[10-12] Treatment of an individual with GDM, however, reduces the risk of adverse outcomes.[13-15]

Although GDM has historically been considered a pregnancy-related complication that is unique to pregnancy, today it is evident that the outcomes, and treatments of women with all types of diabetes are directly related to the severity of glucose dysregulation. Therefore, it is

useful to consider this group of diseases together.

Pathophysiology of Diabetes During Pregnancy

The dynamics of glucose metabolism in pregnancy evolve from early to late pregnancy, as insulin resistance gradually increases and peaks in the late second to third trimester. As the placenta grows, levels of human placental lactogen (hPL) and other diabetogenic hormones increase. These hormones increase cellular resistance to insulin, which results in higher blood glucose levels. In most women, the pancreas can increase the production of insulin to counterbalance the insulin resistance effect of placental hormones. Overt hyperglycemia occurs when the pancreas is unable to produce adequate insulin. The peak effect of hPL occurs around 26 to 28 weeks of pregnancy, which is the recommended window for screening for GDM. Pre-pregnant insulin sensitivity returns in the postpartum period. Optimal care for women with diabetes in pregnancy is responsive to these dynamic changes.[16]

The metabolic milieu of diabetes increases the risk for endothelial dysfunction, which in turn can result in impaired placental growth and fetal growth restriction. In contrast, hyperglycemia and hyperinsulinemia can stimulate hypergrowth in both the placenta and the fetus. Thus, the fetus of a woman with diabetes is at increased risk for fetal growth restriction or macrosomia depending on the degree of hyperglycemia, placental response, and presence of absence of other comorbidities that can adversely affect placental development. As increasing amounts of glucose cross the placenta, the fetus must increase production of insulin to metabolize the increased glucose. This response causes dramatic growth in the fetus, characterized by both hyperplasia and hypertrophy that can result in macrosomia. The result is a change in fetal physiology that can affect the individual throughout life.[6]

Women with GDM have increased risks for the same pregnancy complications as women with PGDM, but their risk is somewhat lower because the degree of hyperglycemia in women with GDM is reduced and the duration of hyperglycemia is shorter compared to women with PGDM. For women with GDM, the critical risk is emergence of type 2 diabetes later in life. Approximately 70% of women with GDM will develop type 2 diabetes within 22 to 28 years after pregnancy.[4] In the United States, approximately 60% of Latina women with GDM develop type 2 diabetes within 5 years after pregnancy.[4]

Diagnosis of Diabetes

The diagnosis of diabetes in nonpregnant adults is reviewed in the *Common Conditions in Primary Care* chapter. However, some women who are given the diagnosis of gestational diabetes actually have undiagnosed PGDM.[6] To clarify the distinction between pregestational type 2 diabetes and gestational diabetes, the American Diabetes Association (ADA) defines GDM as “diabetes diagnosed in the second or third trimester of pregnancy that is not clearly type 1 or 2 diabetes.” Diabetes that is initially detected in the first trimester should be considered pregestational type 2 diabetes.[5] Screening for diabetes during pregnancy is reviewed in the *Prenatal Care* chapter. Diagnosis and prenatal care for women with all types of diabetes is presented in this chapter.

To review, testing for diabetes in pregnancy includes an early assessment for PGDM and a later assessment for GDM:

- *First trimester test for PGDM in women with risk factors.* A hemoglobin A1c level (HbA1c) of 6.5% or higher is diagnostic for diabetes in nonpregnant individuals, and this value is also used for diagnosis of PGDM during pregnancy. However, HbA1c levels are lower in pregnancy due to increased red blood cell turnover, and mild elevations (5.7% to 6.4%) are associated with an increased risk for developing GDM (27.3% versus 8.7%; odds ratio [OR], 3.9; 95% confidence interval [CI], 2.0–7.7).[17] Therefore, the specific HbA1c value used to indicate a need for further testing or closer surveillance during pregnancy is based on institutional guidelines and population-specific parameters. HbA1c is an indirect measure of glucose level, and a fasting glucose or 2-hour postprandial glucose value following a 75-gram glucose load may be recommended for direct measurement.
- *Screening for GDM via a one- or two-step process.* Diagnostic criteria are presented in **Table 23-1**.[5,6] Choice of the screening method is primarily based on local or regional guidelines.

Table 23-1 Diagnostic Criteria for Gestational Diabetes in Pregnancy

Test Strategy	Glucose Load	Fasting (mg/dL)	1-Hour Postprandial (mg/dL)	2-Hour Postprandial (mg/dL)	3-Hour Postprandial (mg/dL)	Diagnostic Criteria
One-step	75 gm	≥ 92	≥ 180	≥ 153	NA	≥ 1 abnormal value
Two-step						
a. Screening	50 gm	NA	≥ 140	NA	NA	NA
b. GTT						
NDDG criteria	100 gm	≥ 105	≥190	≥ 165	≥ 145	≥ 2 abnormal values
Carpenter-Coustan criteria	100 gm	≥ 95	≥ 180	≥ 155	≥ 140	≥ 2 abnormal values

Abbreviations: GTT, glucose tolerance test; NDDG, National Diabetes Data Group.

Note: Some institutions use a cut-off value of 130–135 mg/dL for the screening step. Either the NDDG or the Carpenter-Coustan cut-off values may be used.

Based on American Diabetes Association. Classification and diagnosis of diabetes. *Diab Care.* 2017;40(suppl 1):S11-S24[5]; Salmeen K. Gestational diabetes testing: making sense of the controversy. *J Midwifery Womens Health.* 2016;61(2):203-209.[6]

Management of Women with Pregestational Diabetes Mellitus

Table 23-2 presents an overview of prenatal care for women with diabetes. Women with PGDM are referred to a physician for pregnancy care. Midwives may participate in prenatal care visits as a member of a multidisciplinary team.[18] Depending on the type of diabetes, the

woman's health status, and the healthcare setting, care may include working with diabetes educators and physicians who are specialists in diabetes during pregnancy.

Table 23-2 Overview of Management of Pregestational and Gestational Diabetes

Management	PGDM	GDM	Clinical Considerations
Eye examination	X		First trimester; monitor each trimester, then every 3 months to 1 year
Assessment of renal function	X		First trimester
Four-chamber view of fetal heart including outflow tracts (fetal ultrasound and possible fetal echocardiography)	X		Increased risk for congenital heart defects
Ultrasound for fetal growth, amniotic fluid volume	X		28, 32, and 36 weeks depending on clinical situation to assess for fetal growth restriction, polyhydramnios, and macrosomia
Nutrition therapy	X	X	All women with diabetes manage blood glucose levels via diet; many women with GDM achieve euglycemia with diet changes alone
Glucose monitoring: fasting and postprandial	X	X	Some women with PGDM may benefit from preprandial testing
Glucose monitoring: measure HbA1c	X		Target HbA1c is less than 6%
Medication: Insulin, metformin (Glucophage), or glyburide (Micronase)[a] may be used	X	X	Effectiveness of oral medications is the same as that for insulin; data on long-term effects are lacking
If chronic hypertension coexists with diabetes	X	X	Target blood pressure is 120–160 mm Hg systolic and 80–105 mm Hg diastolic
If EFW ≥ 4500 gm, counseling regarding option of cesarean delivery		X	
Postpartum oral GTT 6–12 weeks after birth		X	
Lifelong screening every 3 years for diabetes and prediabetes		X	

Abbreviations: EFW, estimated fetal weight; GDM, gestational diabetes mellitus; GTT, glucose tolerance test; HbA1c, hemoglobin A1c; PGDM, pregestational diabetes mellitus.

[a] Contraindicated for women with sulfa allergy.

Women with PGDM receive an initial evaluation of HbA1c, thyroid function, echocardiogram, eye examination to assess for retinopathy, and renal function.[5] The goal of care in the first trimester is to maintain euglycemia and avoid hypoglycemia. Care during the second and third trimesters additionally focuses on monitoring fetal growth and preventing stillbirth.[18] Overall, women with PGDM will be seen more frequently during pregnancy and blood glucose values monitored intensively via daily self-monitoring of preprandial and postprandial blood glucose values. Target blood glucose values and target HbA1c values are listed in **Table 23-3**. The lowest risk for congenital malformations exists when the diabetes is well controlled and HbA1c is less than 6.5%.[16]

Table 23-3 Target Blood Glucose Values During Pregnancy

Time of Test	Target Value (mg/dL)
Fasting	≤ 95
Preprandial	≤ 100
1-hour postprandial	≤ 140
2-hour postprandial	≤ 120
HgA1c	≤ 6%

Abbreviation: HbA1c, hemoglobin A1c.

Insulin remains the treatment of choice throughout pregnancy for women with type 1 diabetes. Close monitoring is needed, and adjustments in doses may be necessary, due to the increased dynamic changes in insulin sensitivity throughout pregnancy. Women with this condition are especially vulnerable to hypoglycemia in the first trimester, and ketoacidosis can occur at lower glucose levels than it would outside of pregnancy.[18] For women with type 1 diabetes, insulin requirements are often lower in the first trimester, gradually increase during the second trimester, and decrease again in the late third trimester and in the immediate postpartum period, paralleling the plasma levels of placental hormones that induce insulin resistance.

In women with type 2 diabetes, medication may involve changing from oral agents used before pregnancy to insulin so as to more closely control blood glucose values. Glycemic control in these women often requires higher doses of insulin than are required for women with type 1 diabetes. Combination therapy with an oral agent and insulin is also an option when diet, exercise, and oral agents do not provide sufficient control of glucose levels.[4],[18] However, it is important to remember that insulin does not cross the placenta, whereas oral agents do. The long-term safety of the latter medications has not been established.[5]

Monitoring during pregnancy is directed toward minimizing risks and managing comorbidities. Women with both types of PGDM have an increased risk for developing preeclampsia and, therefore, low-dose aspirin (81 mg) daily is recommended after 12 weeks' gestation. Ultrasounds for fetal growth are generally performed at 28 to 32 weeks. Women with any type of diabetes who require insulin or an antiglycemic oral medication to maintain euglycemia are usually offered antenatal testing twice weekly starting at approximately 32 weeks and asked to perform daily fetal movement counts.

Fetuses of women with diabetes develop respiratory maturity later than do fetuses of women without diabetes, so early delivery poses increased risks for respiratory distress. Nevertheless, the presence of comorbidities, fetal growth restriction, or poorly controlled glucose values may indicate a need for preterm induction of labor. If no complications are present, glucose values are stable, and fetal growth is normal, induction of labor is usually recommended by 39 to 40 weeks' gestation.

Management of Women with Gestational Diabetes Mellitus

Women with GDM can often attain euglycemia via lifestyle modification, improved diet, and exercise. Medication is used when adequate glycemic control is not achieved through these

changes.[18] Recent studies have demonstrated that insulin and oral medications have equivalent efficacy in pregnancy, and that either may be considered for first-line therapy.[4] Women with GDM who are able to maintain euglycemia via diet and exercise alone (Class A1GDM) do not appear to be at risk for stillbirth and are not usually referred for antenatal testing, although induction of labor is usually recommended at 39 to 40 weeks.[4] Diabetes is not a contraindication to breastfeeding. Postpartum care includes follow-up to assess for type 2 diabetes at 6 to 12 weeks postpartum. Lifelong screening for diabetes is recommended every three years.

Gastrointestinal Conditions

Diagnosis of gastrointestinal disorders in pregnancy can be difficult because many symptoms —such as nausea, vomiting, diarrhea, and abdominal discomfort—are prevalent during pregnancy. This section reviews serious gastrointestinal disorders that are common in pregnancy, including those that increase the risks of pregnancy complications and those that are adversely affected by pregnancy.

Acute Abdomen

The definition of acute abdomen is sudden severe abdominal pain. The differential diagnoses for women who present with acute abdomen in pregnancy include the same diagnoses considered in nonpregnant women, but also some additional life-threatening conditions. For example, ectopic pregnancy, placental abruption, acute fatty liver, HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome, or uterine rupture may cause severe abdominal pain during pregnancy. An acute abdomen is a medical emergency that requires urgent medical evaluation.

Appendicitis

Appendectomy is the most common non-obstetric indication for surgery during pregnancy.[19] Signs and symptoms of appendicitis in pregnancy generally mimic those that occur in nonpregnant individuals, including abdominal pain, nausea, abdominal rebound, and tenderness and leukocytosis. Although the appendix is displaced by uterine growth, right lower quadrant pain is the most common presentation regardless of gestational age.[19,20]

Fever and leukocytosis are not considered diagnostic for appendicitis during pregnancy because leukocytosis is a normal physiologic change of pregnancy. However, white blood cell counts may be useful in trending changes over time. Compression ultrasound is the primary diagnostic tool, but because ultrasound visualization of the appendix can be obscured in pregnancy, magnetic resonance imaging (MRI) may be necessary.

Surgery is the definitive therapy for confirmed appendicitis. The rate of appendix perforation is higher in pregnancy, with the highest incidence found in the third trimester—likely due to delays in diagnosis.[20] While a perforated appendix may result in uterine contractions, tocolysis before surgery for prophylaxis is not generally recommended. Possible complications include preterm labor, early birth, or fetal loss as well as increased maternal morbidity.

Inflammatory Bowel Disease, and Irritable Bowel Syndrome

Ulcerative colitis and Crohn's disease are chronic disorders collectively known as inflammatory bowel disease. Pregnancy does not affect the course of Crohn's disease, whereas ulcerative colitis may worsen during gestation. The effect of these disorders on the course of pregnancy depends on the activity and severity of the disease. Women with active disease are at increased risk for low birth weight and preterm birth. It is not clear if women with

inflammatory bowel disease have an increased risk for congenital anomalies.[21]

The primary consideration in caring for women with inflammatory bowel disease during pregnancy is the risk versus benefits of various medications. In general, the risks associated with active disease are higher than the risks associated with adverse effects of the medications used to treat it, with the exception of a few medications (e.g., methotrexate) that are teratogenic and contraindicated during pregnancy. Women with inflammatory bowel disease should be referred to a physician to establish a plan of care; gastrointestinal specialists may be involved in their care as well.

Gallbladder Disorders: Cholecystitis

Cholecystitis (inflamed gallbladder) is the second most common etiology of acute abdomen in pregnancy, after appendicitis. Cholecystitis usually occurs secondary to the development of gallstones that cause biliary obstruction.[22] Biliary sludge accumulates secondary to increased estrogen levels, leading to increased cholesterol synthesis. This process combines with the decreased emptying rate in pregnancy to lead to stone formation and stasis.[20,22]

Pregnant women with gallbladder disorders often present with acute epigastric pain or the classic biliary colic (pain exacerbated by a fatty meal). Other common symptoms include pain in the right upper quadrant, radiation to the right scapula, flank pain, and a positive Murphy's sign.[22] Guarding is not usually present. Anorexia, nausea, vomiting, low-grade fever, tachycardia, and intolerance of fatty foods may also be present. The differential diagnoses include HELLP syndrome, acute fatty liver, and hepatitis.

Diagnosis of cholecystitis is made via ultrasound imaging. Management depends on gestational age and symptom severity. Pain medications, antispasmodics, antibiotics, intravenous fluids, and a low-fat diet constitute conservative management. Risks of conservative treatment include recurrence, increased likelihood of induction, and preterm birth. Surgery may be indicated for women with recurrent or severe symptoms.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a common disorder in the general population. Pregnancy changes such as slower gastrointestinal motility and relaxation of the lower esophageal sphincter may contribute to exacerbation of preexisting disease; alternatively, GERD may initially appear during pregnancy, usually in the second or third trimester. Symptoms are similar to those observed in nonpregnant women.[22] Typical symptoms include heartburn, nausea, and acid reflux. Atypical symptoms that indicate increasing severity and a need for medical consultation include dysphagia, noncardiac chest pain, dyspepsia, abdominal pain, hoarseness, sore throat, and dental erosions.[23]

Initial recommendations for management of GERD include nonpharmacologic measures such as elevating the head of the bed, avoiding eating before lying down, lying on the left side, and avoiding acidic foods. When pharmaceutical methods are needed, antacids, which neutralize the stomach contents decreasing the acidity, are the first-line medication. Antacids containing calcium aluminum, and magnesium are considered safe in pregnancy, whereas those containing

sodium bicarbonate should be avoided. Some authors suggest magnesium-containing antacids should be avoided in the third trimester. Antacids interfere with iron absorption and are therefore not recommended for women who need supplemental iron or should be taken several hours remote from ingestion of iron.

Histamine 2 receptor antagonists reduce gastric acid secretion and are typically the next step if previous measures do not improve symptoms. Cimetidine (Tagamet) and ranitidine (Zantac) are the two H_2-receptor antagonists commonly prescribed for GERD, but ranitidine is the only one of these agents that has proven effectiveness during pregnancy.

Proton pump inhibitors are more effective than H_2-receptor antagonists in inhibiting gastrointestinal acid secretion. Early observational studies suggested proton-pump inhibitors may be associated with teratogenic effects while later larger studies did not find this association. Lansoprazole (Prevacid), rabeprazole (Aciphex), esomeprazole (Nexium), and pantoprazole (Protonix) are all considered safe for use during pregnancy. Omeprazole (Prilosec) is associated with teratogenic effects in animal studies but not in humans.[23]

Pancreatitis

Pancreatitis is a rare but serious condition in pregnancy that occurs in approximately 1 in 1000 to 1 in 3000 women. This disease is typically associated with cholelithiasis, but can also be caused by estrogen-related elevated triglyceride levels.[24] Severe pancreatitis is described as sudden inflammation of the pancreas that causes abdominal pain, nausea, and dehydration. The primary differential diagnosis is hyperemesis gravidarum—the most common misdiagnosis in pregnancy. Pancreatitis is diagnosed by documentation of increases in levels of serum amylase, lipase, and calcium.[24] Preterm birth occurs in approximately 20% of women with severe pancreatitis, pointing to the importance of making a timely referral to an emergency department or specialist. Research has recently linked this disorder to mutations of the cystic fibrosis genes.[24]

Hematologic Disorders in Pregnancy

The hematologic disorders that are the most likely to affect pregnant women include anemias, hemoglobinopathies, and coagulation disorders. A midwife's ability to diagnosis and collaborate in managing these disorders can significantly improve outcomes and help prevent morbidity and mortality for both the pregnant woman and her fetus/infant.

Anemia: An Overview

Anemia is the most common nutritional deficiency worldwide.[25] Anemia in pregnancy is defined as hemoglobin less than 11 g/dL and hematocrit less than 33% in the first and third trimesters.[26] In the second trimester, the criteria for anemia are hemoglobin less than 10.5 g/dL and hematocrit less than 32% (**Table 23-4**).[27-29] The prevalence of anemia in pregnant women globally is approximately 35% to 56%.[28] In low-resource nations, anemia is also frequently a comorbidity of infection (e.g., malaria) or a hemoglobinopathy.

Table 23-4 **Diagnostic Values for the Diagnosis of Anemia in Pregnant Women**

	Hemoglobin (g/dL)	Hematocrit (%)
Trimester		
First trimester	11	33
Second trimester	10.5	32
Third trimester	11	33
Adjustment for Black Race		
First trimester	< 10.2	< 31.0
Second trimester	< 9.7	< 30.0
Third trimester	< 10.2	< 31.0
Adjustment for Living at High Altitude		
First trimester	< 11.2–13.0	< 33.5–39.0
Second trimester	< 10.7–12.5	< 32.0–38.0
Third trimester	< 11.2–13.0	< 33.5–39.0
Adjustment for Smoking		
0.5–0.9 pack/day	+ 0.3	+ 1.0
1.0–1.9 pack/day	+ 0.5	+ 1.5
2.0 or more pack/day	+ 0.7	+ 2.0

Based on American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 95: anemia in pregnancy. *Obstet Gynecol.* 2008;112:201-207[27]; Committee on Nutritional Status During Pregnancy, Food and Nutrition Board, Institute of Medicine. *Nutrition During Pregnancy and Lactation: An Implementation Guide.* Washington, DC: National Academy Press; 1992[28]; Chao C, O'Brien KO. Pregnancy and iron homeostasis: an update. *Nutr Rev.* 2013;71(1):35-51.[29]

Consequences of anemia during pregnancy include increased vulnerability to infection, reduced peripartum blood loss reserves, increased cardiovascular burden, and increased risk for transfusion. Anemia is also associated with an increase in maternal mortality—an association that is strongly influenced by postpartum hemorrhage. Moreover, women who are anemic are at increased risk for preterm birth, fetal growth restriction, low birth weight and prematurity, fetal/infant infection, and infant mortality.[25],[27] In addition, fetal iron stores may be compromised when a pregnant woman is anemic, and suboptimal iron stores in the neonate are associated with cognitive impairments in the child.[29] Most importantly, treatment of women with anemia during pregnancy improves these outcomes.[30],[31]

Differential Diagnosis and Initial Treatment of Anemia

Normocytic anemia is diagnosed when the hemoglobin and hematocrit are low but the mean corpuscular volume (MCV) is in the normal range of 80–100 fL; microcytic anemia refers to small red blood cells wherein MCV is less than 80 fL; and macrocytic anemia refers to large pale red blood cells wherein the MCV is larger than 100 fL. These definitions, and the causes of the various types of anemia, are noted in **Table 23-5**.[26] Anemia is a symptom of many different disorders, and multiple algorithms for evaluation of anemia are available, based on a particular population and the most likely possible diagnoses. However, because most pregnant women with anemia have iron-deficiency anemia, the usual practice is to presumptively treat with iron and then reassess the hemoglobin and hematocrit levels before performing a detailed evaluation of iron status. If iron supplementation is not successful, further evaluation is indicated. One algorithm for evaluating essentially healthy pregnant women who have anemia is presented in **Figure 23-1**.

Table 23-5 **Causes of Anemia by Mean Corpuscular Volume**

Normocytic Anemia: MCV 80–100 fL	Microcytic Anemia: MCV < 80 fL	Macrocytic Anemia: MCV ≥100 fL
Chronic disease	Chronic disease	Folic acid deficiency
Early iron deficiency	Iron deficiency anemia	Drug-induced hemolytic anemia
Hemorrhage	Lead poisoning	Liver disease and/or alcohol abuse disorder
Hemolytic anemia	Thalassemias	Vitamin B_{12} deficiency
Hypothyroidism		

Abbreviations: MCV, mean corpuscular volume; fL, femtoliter (which is 10^{-15} liters).

Note: This table is not comprehensive, rather these are the most common differential diagnoses for anemia that are likely to occur in women seen for primary care services or maternity care.

Based on American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 95: anemia in pregnancy. *Obstet Gynecol.* 2008;112:201-207.[27]

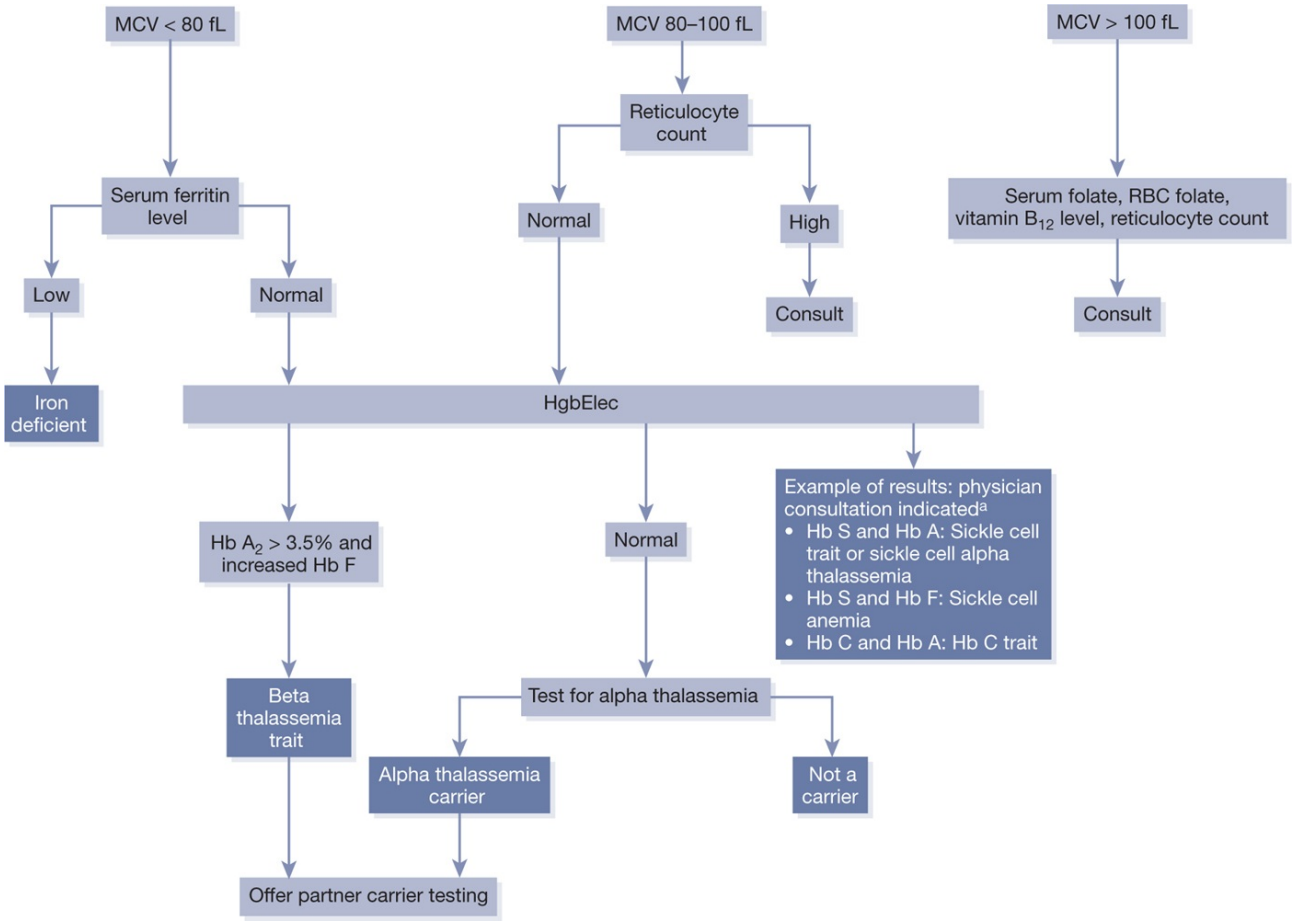

Figure 23-1 Morphologic evaluation of anemia.

Abbreviations: Hb A, hemoglobin A; Hb A_2, hemoglobin A_2; Hb C, hemoglobin C; Hb F, hemoglobin F; Hb S, hemoglobin S; Hb SC, hemoglobin SC; HgbElec, hemoglobin electrophoresis; MCV, mean corpuscular volume; RBC, red blood cell.

Note: The hemoglobin electrophoresis reports the type and percentage of different types of hemoglobin. Possible interpretations include sickle cell trait, sickle cell disease, sickle beta-thalassemia, and Hb SC disease, among others. Physician consultation is recommended for detailed interpretation, diagnosis, and management.

[a] This figure is an example of an algorithm for a population of essentially healthy pregnant women who are not at risk for other comorbid conditions or infections.

Microcytic Anemias

The most common anemia in pregnant women is iron-deficiency anemia. However, the thalassemias and sickle cell disease are also associated with a microcytic anemia.

Iron-Deficiency Anemia

In the United States, approximately 18% of pregnant women are anemic overall, but this rate varies by trimester from 6.9% to 14.3% to 29.5% in the first, second, and third trimesters, respectively.[25] Worldwide, the prevalence of iron-deficiency anemia is much higher. Approximately 40% of women begin pregnancy with low or absent iron stores.[32,33] Increased

risks for iron-deficiency anemia include multifetal gestation, multiparity, short interval between pregnancies, anemia prior to pregnancy, poor nutrition, and poor socioeconomic status.

As a preventive measure, research supports offering iron supplementation to all women in pregnancy. A Cochrane review including 27,402 women in pregnancy found that daily supplementation significantly reduced risks for maternal anemia, iron deficiency at term, and low-birth-weight infants.[31] Interestingly, intermittent supplementation (1 to 3 times per week) has been shown to be as effective as daily supplementation and has fewer side effects. This may be secondary to the regulation of iron absorption in the duodenum.

Iron deficiency is a continuum that ranges from depletion of iron stores to overt anemia. Hemoglobin and hematocrit levels do not begin to decrease until stored iron is depleted, so a pregnant woman may have normal hemoglobin and hematocrit values yet also be iron depleted. For this reason, iron supplementation is recommended for all pregnant women.

Serum ferritin levels are the most sensitive measure for diagnosis of iron-deficiency anemia, as ferritin is the storage form of iron. Serum iron levels and total iron-binding capacity can also be obtained but both have diurnal variations, with higher concentrations noted later in the day. Values for hemoglobin, MCV, serum iron, and total iron-binding capacity (TIBC) in iron-deficient states are listed in **Table 23-6**.[26,34]

Table 23-6 Laboratory Tests Indicative of Iron Deficiency, by Degree of Severity

	Normal Values	Iron Deficient Without Anemia	Iron Deficient with Anemia	Iron Deficient with Severe Anemia
Hemoglobin (Hgb), g/dL	12–13	Normal (> 12)	9–12	6–7
Mean corpuscular volume (MCV), fL	80–100	80–100	< 80	< 80
Red blood cell (RBC) morphology	Normal	Normal	Normal or slight hypochromia	Hypochromic, microcytic
Serum ferritin (ng/dL)	10–150	< 40	< 20	< 10
Serum iron (SI), mcg/dL	40–175	60–150	< 60	< 40
Total iron-binding capacity (TIBC), mcg/dL	216–400	300–390	350–400	> 410
Transferrin saturation (TSAT), %	16–60	30	< 15	< 10
Free erythrocyte protoporphyrin (FEP), mcg/dL	< 3	30–70	> 100	100–200

Based on American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 95: anemia in pregnancy. *Obstet Gynecol.* 2008;112:201-207[27]; Haider BA, Olofin I, Wang M, Spiegelman D, Ezzati M, Fawzi WW; Nutrition Impact Model Study Group (Anaemia). Anaemia, prenatal iron use, and risk of adverse pregnancy outcomes: systematic review and meta-analysis. *BMJ.* 2013;346:f3443.[34]

When iron-deficiency anemia is present, the recommendation is to supplement with 30 to 120 mg per day of elemental iron. The amount of elemental iron varies among supplements as described in the *Nutrition* chapter. The most common side effects of oral iron preparations include bloating, constipation, and black stools. These side effects can be mitigated with smaller doses of elemental iron and spaced dosing to every other day. Given iron absorption can be saturated in the intestine, smaller doses and spaced dosing may be as effective as higher daily doses. A follow-up complete blood count is performed 3 to 4 weeks after

supplementation is initiated. Reticulocytosis should be apparent by 7 to 10 days, and the hemoglobin and hematocrit levels should rise within a few weeks.[26]

Parenteral forms of iron are available and may be of value for women who do not respond to oral supplementation and/or women who have comorbid conditions associated with hemolysis or malabsorption. For example, women who have undergone bariatric surgery have diminished capacity to absorb oral formulations. Historically, parenteral forms of iron were considered a choice of last resort because of the risk of anaphylaxis associated with intravenous iron administration. Newer formulations of low-molecular-weight iron dextran are much less likely to have adverse effects, however, and can be used safely when needed.[35] Intravenous administration of iron will occur in a hospital setting. Several formulations with different doses and protocols are available.

Hemoglobinopathies

When a woman has microcytic anemia and normal iron indices, the next step is to screen for hemoglobinopathies. Normal hemoglobin is made of two pairs of polypeptide chains (two alpha and two beta), each of which has a heme–iron complex attached. More than 100 variant forms of hemoglobin exist.[36] Hemoglobinopathies are genetic synthesis disorders of hemoglobin, of which there are two types: thalassemias and sickle cell disease. Thalassemias are disorders of reduced synthesis of alpha- or beta-globin chains, whereas structural abnormalities of hemoglobin cause sickle cell disease. Both thalassemias and sickle cell disease cause microcytic anemia. Depending on the genetic inheritance, the individual may be homozygous or heterozygous for one of these disorders. The resulting phenotypes vary and are based on the percentage of different hemoglobin variants, and in the case of thalassemias, which globin genes are affected and how many are affected.

Diagnosis and treatments for hemoglobinopathies are determined by hemoglobin electrophoresis, as reviewed in the *Common Conditions in Primary Care* chapter. Implications for pregnancy and care for affected individuals during pregnancy are presented in this chapter.

Alpha-Thalassemia

Alpha-thalassemia is classified on the basis of how many of the four globin chains are affected, as described in **Table 23-7**.[37] Individuals with alpha-thalassemia trait have microcytic anemia and a normal hemoglobin electrophoresis, and DNA testing is done to detect the alpha-globin gene deletions. The primary purpose of detecting alpha-thalassemia carrier status is to identify couples who are at risk for having a fetus with hemoglobin Bart's hydrops fetalis. Prenatal counseling is likely of value for these individuals.[37]

Table 23-7 Classification of Alpha-Thalassemias

Number of Globin Genes	Genotype	Clinical Implications

0	**- -/- -**	Hemoglobin “Bart’s”: incompatible with life. The fetus develops hydrops.
1	α **-/- -**	Hemoglobin H disease. Mild to moderate hemolytic anemia.
2	α **-/**α **- -** **or** α α**/- -**	Homozygous: alpha-thalassemia trait. Mild microcytic anemia that is asymptomatic. This person is a carrier.
3	α **-/**α α	Heterozygous: silent carrier state; not clinically detectable.
4	α α**/**α α	Normal: no thalassemia present.

Beta-Thalassemia

Beta-thalassemia is the result of insufficient or absent production of the beta-globin chains.[38] This disorder is subclassified as minor, intermedia, or major depending on the amount of beta-globin chains produced. Women with beta-thalassemia major (Cooley’s anemia) or beta-thalassemia intermedia have an increased risk of diabetes and cardiovascular disease during pregnancy. Women with beta-thalassemia minor usually have uncomplicated pregnancies; because they are generally asymptomatic, this hemoglobinopathy may be first diagnosed in pregnancy.

Beta-thalassemia trait is diagnosed by hemoglobin electrophoresis, which will reveal more than 3.5% of hemoglobin A_2 and increased levels of hemoglobin F. Once diagnosed, partner testing can be offered. Prenatal diagnosis for beta-thalassemia major is available.

Sickle Cell Disease

Sickle cell disease is characterized by intermittent, painful “sickle cell crisis,” especially during viral infections. Sickle cell disease and trait are highly prevalent in India, the Mediterranean, the Middle East, and sub-Saharan Africa because this hemoglobin variant is protective against malaria. Sickle cell disease is a multiple-organ disorder associated with hemolytic anemia and microvascular obstruction by red blood cell agglutination. Persons who have sickle cell disease can experience intensely painful crises, particularly due to interference with oxygenation of vessels and organs. In addition, they can accumulate iron and become iron overloaded despite having microcytic anemia. Women with sickle cell disease have an increased risk for spontaneous abortion, preterm labor, preeclampsia, stillbirth, fetal growth restriction, prematurity, and low birth weight.[39] These women need specialized care during pregnancy.

Women with sickle cell trait have an increased risk for urinary tract infections during pregnancy secondary to increased levels of free iron in the urine and increased monitoring through periodic urine cultures during pregnancy can reveal asymptomatic bacteriuria. Additionally, iron does not accumulate in these women, so they can become iron deficient in pregnancy and need iron supplementation.

If a pregnant woman has sickle cell disease or sickle cell trait, screening of the father of the fetus is offered, along with genetic counseling, to determine inheritance patterns and the chance that the fetus will have the trait or disease. Sickle cell trait follows a Mendelian autosomal

recessive inheritance pattern. Thus, if the woman has sickle cell trait and the father of the fetus does not, there is a 50% chance in each pregnancy that her fetus will have the trait. If the woman and father of the fetus both have sickle cell trait, there is a 25% chance that the fetus will have sickle cell disease and a 50% chance that the fetus will have sickle cell trait.

Macrocytic Anemia

Macrocytic anemia can be secondary to glucose-6-phospate dehydrogenase (G6PD) deficiency, vitamin B_{12} deficiency, alcoholism, folate deficiency, or medications such as those used to treat human immunodeficiency virus (HIV). Macrocytic anemia is not common in pregnant women.

Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is an inherited defect in a red blood cell enzyme that protects the red blood cell from oxidative injury. This disorder can range from severe hemolytic anemia to asymptomatic. Women with a G6PG deficiency rarely manifest symptoms, and it is unusual for G6PD deficiency to adversely affect the course of pregnancy. The primary maternal risk associated with G6PD deficiency is severe hemolysis as the result of use of medications such as nitrofurantoin and sulfa derivatives, infection or surgery, and ingestion of certain foods such as fava beans.

Infants born with G6PD deficiency may present with severe jaundice and kernicterus. If a pregnant woman has G6PD deficiency or a family history of this condition, the pediatric providers for the newborn will need to be aware that the fetus may have this disorder to treat the newborn appropriately.[40] Neonatal screening for G6PD is not universal in the United States.

Thrombocytopenia

Physiologic changes in pregnancy include a reduction in the platelet count, especially in the third trimester. Thrombocytopenia is defined as a platelet count less than 150,000 cells/mL. Pregnancy-related thrombocytopenia includes gestational thrombocytopenia and thrombocytopenia related to severe preeclampsia or HELLP syndrome. Types that evolve from causes unrelated to pregnancy but may first manifest during pregnancy include immune thrombocytopenia, antiphospholipid syndrome, and thrombotic thrombocytopenia. Initial screening involves evaluating the platelet count and the white blood cell count in routine prenatal lab tests.

Gestational thrombocytopenia typically develops in the second trimester and the platelet count is rarely less than 70 cells/mL. This disorder is not associated with fetal thrombocytopenia and generally resolves within days to a few months. In contrast, immune thrombocytopenia can occur at any time during pregnancy and platelet counts can be quite low. Neonatal thrombocytopenia is possible because the maternal autoantibodies cross the placenta.

Due to the serious clinical consequences associated with different forms of thrombophilia, an early response to abnormal platelet counts, diagnosis, and treatment and/or referral is

extremely important.[41,42]

Coagulation Disorders: Venous Thromboembolism and Thrombophilias

Thromboembolic events are one of the leading causes of maternal mortality. Although the absolute incidence is low, a woman's risk of developing a venous thrombolic event (VTE)—either deep vein thrombosis (DVT) or pulmonary embolism (PE)—is four-fold higher during pregnancy than when she is not pregnant.[43] Pregnancy, as a hypercoagulable state, is a significant risk factor for VTE. Additional risk factors include previous VTE, family history of VTE, inherited thrombophilia, diabetes, autoimmune inflammatory disorders, age greater than 35 years, body mass index (BMI) greater than 30 kg/m^2, varicose veins, multifetal gestation, and hospitalization.[44]

Symptoms of DVT include pain, tenderness, swelling, palpable cord, and changes in color and limb circumference. Calf pain may also be present. Homan's sign is no longer used for assessing DVTs because it is neither adequately sensitive nor specific. Nearly 90% of DVTs that develop in pregnant women occur in the left lower extremity, perhaps due to compression of the left iliac artery by the gravid uterus. Women with a PE may present with dyspnea, tachypnea, tachycardia, cough, pleuritic chest pain, fever, anxiety, cyanosis, and hemoptysis. Women with symptoms of a DVT or PE require physician evaluation.

A DVT is diagnosed via compression ultrasound. Antepartum management includes increased surveillance and anticoagulant treatment with low-molecular-weight heparin.[45,46]

Care during pregnancy for women with a history of a VTE depends on several factors. VTEs are classified as provoked or unprovoked. A provoked VTE occurs in persons who have a clinical risk factor such as surgery, bone fracture, or bedrest. A VTE is determined to be unprovoked if no risk factor is identified. If a pregnant woman has a history of a VTE, anticoagulant prophylaxis may be indicated depending on whether the VTE was provoked or unprovoked:

- Women with a history of an unprovoked VTE prior to pregnancy are tested for inherited thrombophilias and it is recommended that they receive anticoagulant therapy prophylactically during pregnancy.
- Women with a history of provoked VTE are generally not at increased risk for reoccurrence. However, if the woman has an underlying thrombophilia, her risk for developing a VTE in pregnancy is significant. Therefore, women with a history of provoked VTE and a first-degree relative with a history of high-risk thrombophilia should be screened for thrombophilia and offered prophylactic anticoagulant therapy if a thrombophilia is diagnosed.[47,48]

Thrombophilias and Risk for Venous Thromboembolism

Inherited thrombophilias are genetic conditions that increase the risk for thromboembolism. Approximately 50% to 60% of women who develop a VTE during pregnancy have an inherited thrombophilia,[44,45] such as factor V Leiden (FVL) deficiency, prothrombin G20210A gene

mutation, protein S deficiency, or protein C deficiency. Most women with thrombophilias are asymptomatic and undiagnosed; thus, one of these disorders may be first identified in a woman who develops a VTE during pregnancy.

Routine screening of pregnant women for inherited thrombophilias is not recommended. However, as noted above, testing for thrombophilias is offered to pregnant women who have either a history of an unprovoked VTE or a first-degree relative who has a known history of a high-risk thrombophilia or a history of VTE that occurred before the age of 50 years.[48]

Thrombophilias and Risk for Adverse Pregnancy Outcomes

The risk for adverse pregnancy outcomes associated with thrombophilias is controversial. Some thrombophilias, such as FVL, are associated with increased risks of preeclampsia, whereas others do not appear to adversely affect the course of pregnancy. Furthermore, some thrombophilias are associated with a higher frequency of VTE than are others. Care of women who have an inherited thrombophilia depends on the type of thrombophilia as well as her personal and family history of VTE; thus, women with a known inherited thrombophilia are referred for physician consultation to establish a plan of care.[48] Although routine screening for thrombophilias is not recommended at this time, current research on pregnancy outcomes associated with specific thrombophilias may identify risks that will change this recommendation.[47],[48]

Hepatic Disorders

Hepatic (liver) disorders that are specific to pregnancy include hyperemesis gravidarum and intrahepatic cholestasis. These conditions are reviewed in the *Pregnancy-Related Conditions* chapter. Preeclampsia, HELLP syndrome, and acute fatty liver of pregnancy are considered both hypertensive and hepatic disorders, are reviewed later in this chapter. Other liver diseases that may adversely affect the course of pregnancy include hepatitis, cirrhosis, autoimmune liver disease, Wilson's disease, and drug-induced hepatotoxicity. Diagnosis and treatment of hepatitis are reviewed in the *Common Conditions in Primary Care* and *Reproductive Tract and Sexually Transmitted Infections* chapters. Physician consultation is indicated for women with signs or symptoms of hepatitis or liver dysfunction.

Acute viral hepatitis during pregnancy increases both maternal and fetal morbidity. Hepatitis A is generally self-limited and management is supportive. Nevertheless, this form of hepatitis may be associated with preterm labor or premature prelabor rupture of membranes if the woman becomes ill during the second or third trimester.

The more common hepatic condition that may occur in women cared for in midwifery practice is positive carrier status for hepatitis B or hepatitis C. The risk of vertical transmission of hepatitis B is as high as 90% when the woman has this infection, and infants who acquire hepatitis B via vertical transmission at the time of birth are likely to become chronic carriers. Thus, screening for hepatitis is recommended for all pregnant women. Testing for the degree of viral load is recommended for women who are identified as carriers of hepatitis B. These women are referred for physician consultation because antiviral medication may be recommended to decrease the risk of vertical transmission at birth.

Hypertension During Pregnancy

Hypertensive disorders of pregnancy are classified into four conditions: (1) gestational hypertension, (2) preeclampsia–eclampsia, (3) chronic hypertension, and (4) chronic hypertension with superimposed preeclampsia–eclampsia.[49] Preeclampsia is further subcategorized as preeclampsia with or without severe features.[49] A severe constellation of hemolysis, elevated liver enzymes, and low platelets—that is, HELLP syndrome—is a variant of preeclampsia that occurs in a small subset of women who develop preeclampsia. The nomenclature for hypertensive disorders of pregnancy has a long history and has changed several times in the past. The 2013 American College of Obstetricians and Gynecologists (ACOG) Taskforce on Hypertension in Pregnancy Report provides an important perspective on the current nomenclature for clinical management.[49] Preeclampsia and eclampsia are not distinct pathologies, but rather disorders that exist on a continuum.[49] Preeclampsia was once thought to be a unique pregnancy-related condition that resolved postpartum. However, just as gestational diabetes is associated with future development of type 2 diabetes, it is now evident that hypertensive disorders of pregnancy are also a continuum linked to long-term adverse cardiovascular outcomes. Thus, it is of value to consider these conditions as a group.

In the United States, 3% of pregnant women develop preeclampsia and 5% to 10% of pregnant women have other hypertensive disorders.[50] Approximately 7.4% of pregnancy-related maternal deaths are attributable to these disorders.[51,52] A recent analysis by the World Health Association found that 14.0% of maternal deaths worldwide were attributable to hypertension, second only to deaths from hemorrhage (27.1%).[53] Hypertension is defined as either a systolic blood pressure of 140 mm Hg or greater *or* a diastolic blood pressure of 90 mm Hg or greater *or* both observed on two occasions at least 4 hours apart.[49] During pregnancy, hypertension is classified as mild/moderate (systolic, 140–159 mm Hg or diastolic, 90–109 mm Hg) or severe (systolic, ≥ 160 mm Hg or diastolic, ≥ 110 mm Hg). Severe hypertension is a medical emergency that is diagnosed when two measurements meeting the criteria are noted within 15 minutes.[50] Blood pressure should always be obtained after the woman is at rest for at least 10 minutes and seated with an appropriately sized cuff positioned at the level of her heart.

Differentiating between the types of hypertensive disorders of pregnancy is not always straightforward and requires a clear understanding of specific diagnostic components. **Table 23-8** provides an overview of the diagnostic criteria for each condition.

Table 23-8 Diagnostic Criteria for Hypertensive Disorders in Pregnancy

Condition	Onset of Hypertension	Diagnostic Criteria
Gestational hypertension	≥ 20 weeks of pregnancy	Hypertension (systolic, ≥ 140 mm Hg and/or diastolic, ≥ 90 mm Hg) in a previously normotensive woman without proteinuria or diagnostic features of preeclampsia
Preeclampsia[a]	≥ 20 weeks of pregnancy	New-onset hypertension plus proteinuria (≥ 300 mg per 24-hour urine collection, or > 1+ dipstick if other quantitative methods are not available,

		or protein/creatinine ratio > 0.3 mg/dL) If no proteinuria, new-onset hypertension with any of the following: Thrombocytopenia (platelet count < 100,000 cells/mcL) Impaired liver function (elevated liver transaminases to twice normal) Renal insufficiency (serum creatinine > 1.1 mg/dL or doubling of serum creatinine in the absence of other renal disease) Pulmonary edema Cerebral or visual disturbances
Preeclampsia with severe features	≥ 20 weeks of pregnancy	Same diagnostic criteria as for preeclampsia but with the addition of at least one of the following: Systolic blood pressure ≥ 160 mm Hg and/or diastolic blood pressure ≥ 110 mm Hg measured twice at least 15 minutes apart Thrombocytopenia (platelet count < 100,000 cells/mcL) Impaired liver function: transaminases 2 times the normal level; severe right upper quadrant or epigastric pain Renal insufficiency: in the absence of other renal disease, serum creatinine > 1.1 mg/dL or twice the baseline level Pulmonary edema New-onset cerebral or visual disturbances
Eclampsia	After or with preeclampsia	Preeclampsia plus new-onset grand mal seizures
Chronic hypertension	Prior to pregnancy or < 20 weeks of pregnancy	Hypertension that predates pregnancy, occurs before 20 weeks of pregnancy, or persists after pregnancy
Chronic hypertension with superimposed preeclampsia/eclampsia	Prior to pregnancy or < 20 weeks of pregnancy	Worsening hypertension with new development of any of the following: proteinuria, elevated liver enzymes, thrombocytopenia, pulmonary edema, cerebral or visual disturbances, renal insufficiency

[a] An atypical form of preeclampsia that occurs before 20 weeks' gestation is associated with hydatidiform mole and antiphospholipid syndrome.

Based on American College of Obstetricians and Gynecologists, Task Force on Hypertension in Pregnancy. Hypertension in pregnancy: report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. *Obstet Gynecol*. 2013;122(5):1122-1131.[49]

Women who have a hypertensive disorder of pregnancy are at increased risk for subsequent cardiovascular disease and mortality as well as for future hypertension and diabetes.[54] The American Heart Association guideline for the prevention of cardiovascular disease in women recognizes preeclampsia, eclampsia, and pregnancy-induced hypertension (gestational hypertension) as independent risk factors for cardiovascular disease, such that assessment of pregnancy history is one of the critical components in determining a woman's cardiovascular risk.[54]

Because of the potential for lifelong adverse effects following hypertensive disorders of pregnancy, educating women and their families during the perinatal period is essential. This health education includes discussing the importance of informing all subsequent healthcare providers of the disorder during pregnancy, addressing the importance of health behaviors to ameliorate modifiable risks, and providing ongoing clinical follow-up and, in some cases,

specialty referral.[54] It is important to recognize that much of the evidence that associated hypertensive disorders of pregnancy with a woman's future health is relatively new. Additional clinical implications of these findings will become evident as research continues.

Gestational Hypertension

The distinguishing characteristics of gestational hypertension are two-fold. First, the woman does not have proteinuria or meet the other diagnostic criteria for preeclampsia/eclampsia. Second, gestational hypertension resolves by 12 weeks after birth. If there is a continuation of the hypertension beyond this period, the diagnosis is changed to chronic hypertension. Approximately 46% of women with gestational hypertension will develop preeclampsia.[55] Often, what initially appears to be gestational hypertension is, in fact, preeclampsia in the process of developing. The likelihood of developing preesclampsia increases in women who develop gestational hypertension before 30 weeks' gestation. If diagnostic criteria arise that are consistent with preeclampsia/eclampsia, the diagnosis is changed to preeclampsia.

Management recommendations include evaluation for signs or symptoms of preeclampsia (e.g., urinary protein excretion; liver enzyme levels; fetal well-being via nonstress test or ultrasound, or both). If preeclampsia is ruled out, women are encouraged to monitor blood pressure at home and are seen once or twice weekly. The fetus is monitored via fetal movement counts and weekly fetal surveillance testing. An ultrasound for fetal growth may be obtained. Women are informed of danger signs and have a plan for whom to call and when to call.[49] The optimal gestational age for birth depends on the severity of the disorder and the status of the fetus. In women with uncomplicated gestational hypertension, induction of labor is generally recommended after 37 to 38 weeks' gestation.[49]

Preeclampsia–Eclampsia

Approximately 2% to 8% of women experience preeclampsia during pregnancy worldwide.[50] In the United States, the current incidence is approximately 3.8%—which represents an increase since 1990, when the incidence was approximately 2%.[51]

Pathophysiology of Preeclampsia

Although the primary feature of preeclampsia is hypertension that usually appears late in pregnancy, preeclampsia is actually a multisystem disorder that begins early in pregnancy. Placental tissue is key to this disorder; that is, placental tissue must be present but a fetus does not need to be. Thus, women with a hydatidiform mole have a risk for developing signs of preeclampsia early in pregnancy. Furthermore, the disease resolves spontaneously only after the placenta is delivered.

Preeclampsia is characterized by abnormal placentation and failed remodeling of the spiral arteries, which usually occurs early in gestation in two distinct phases.[56] In a normally developing placenta, cytotrophoblast cells extend into endothelial lining of the decidual segment of the spiral arteries first; later in a second wave, cytotrophoblast cells invade the

myometrial portion of the arteries. This process causes the spiral arteries to be remodeled so they become large, low-resistance vessels that can accommodate increased blood flow.[57] Failure of this process causes hypoperfusion, hypoxia, and ischemia within the developing placenta.

The second phase of the development of preeclampsia reflects the maternal inflammatory response to the initial abnormal placentation and subsequent placental hypoxia. As a result of maternal systemic endothelial activation, hypoxia and subsequent oxidative stress cause endothelial cell dysfunction in the maternal spiral arteries. The release of cytokines and other substances then results in systemic inflammation, vascular endothelial dysfunction throughout the vascular system, and a prothrombotic condition.[58,59] This process is characterized by hypertension and, in more severe cases, organ damage, including damage to the kidneys, liver, and brain.[59] The kidney and liver both filter blood, which may partly explain why these two organs are especially vulnerable to the abnormal function of the endothelial cells that line all blood vessels. Early-onset preeclampsia (diagnosis before 34 weeks' gestation) is associated with more severe adverse maternal and fetal outcomes as well as increased risk for future cardiovascular morbidity and mortality. The pathophysiology of preeclampsia and clinical findings are described in **Table 23-9**.[60,61]

Table 23-9	Abnormal Findings in Preeclampsia/Eclampsia
Pathophysiology	**Organ System Findings**
Renal	
Release of placental protein leads to endothelial edema and hypertrophy, reducing the glomerular filtration rate and increasing tubular reabsorption	Proteinuria ↑ Serum creatinine ↑ Serum uric acid ↑ Blood urea nitrogen (BUN) ↓ Creatinine clearance Oliguria
Cardiovascular	
Excessive inflammation and endothelial dysfunction cause hyperreactivity of vessels	Hypertension
Fluid shifts from intravascular to extracellular spaces, causing edema	Peripheral edema
Endothelial blood vessel damage leads to fluid leakage into alveoli; most frequently occurs postpartum	Pulmonary edema
Hepatic	
Damage to lining of small blood vessels leads to hemolysis, elevated liver enzymes, and increased fibrin deposits	↑ Aspartate transaminase (AST) ↑ Alanine transaminase (ALT)
The preceding effects can lead to tissue necrosis and infarction; pain is caused by vasospasm	↑ Right upper quadrant or epigastric pain
Central Nervous System	

Endothelial damage allows fluid to leak into brain tissue, leading to cerebral edema Increased vasospasm can result in ischemia	Headaches, visual disturbances Seizures Stroke Hyperreflexia
Hematologic	
Fluid shifts from intravascular to extracellular spaces, decreasing serum levels and causing edema Reduction in plasma volume results in hemoconcentration	↑ Hemoglobin and hematocrit
Inappropriate activation of leukocytes, complement, and clotting factors depletes platelets and increases clotting time, leading to hemolysis	Thrombocytopenia ↓ Fibrinogen Fibrin split products Prolonged prothrombin time (PT) Prolonged partial prothrombin time (PPT)
Placental Function	
Inadequate remodeling of spiral arteries leads to vasoconstriction and reduced placental perfusion	Intrauterine growth restriction ↓ Amniotic fluid index Nonreactive nonstress test Placental abruption

Based on American College of Obstetricians and Gynecologists, Task Force on Hypertension in Pregnancy. Hypertension in pregnancy: report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. *Obstet Gynecol*. 2013;122(5):1122-1131[49]; Snydal S. Major changes in diagnosis and management of preeclampsia. *J Midwifery Womens Health*. 2014;59(6):596-605[60]; Warrington JP, George EM, Palei AC, Spradley FT, Granger JP. Recent advances in the understanding of the pathophysiology of preeclampsia. *Hypertension*. 2013;62(4):666-673.[61]

Preeclampsia is associated with placental abruption, pregnancy loss, stroke, organ failure, and maternal death. For the fetus, adverse effects of this disorder include preterm birth, fetal growth restriction, stillbirth, and neonatal death. Women who develop preeclampsia have a two-fold increase in the risk for cardiovascular disease and mortality from ischemic heart disease, heart failure, or stroke.[62-64] The likelihood of having hypertension after the perinatal period is increased more than three-fold when a woman develops preeclampsia. Factors that affect the increased risk for cardiovascular disease include multiparity, prematurity and severity of the hypertensive disorder.[62-64]

Risk Factors for Preeclampsia

Risk factors for preeclampsia are listed in **Table 23-10**. A history of preeclampsia in a prior pregnancy increases the risk of preeclampsia by seven-fold compared to women without a history of preeclampsia. The U.S. Preventive Services Task Force and other professional associations recommend that women with high risk factors are for preeclampsia take low dose aspirin (81 mg) daily, starting in the second trimester, in subsequent pregnancies.[49,64] Low-

dose aspirin among these women reduces the risk for preeclampsia by 24% (relative risk [RR], 0.76; 95% confidence interval [CI], 0.62–0.95).[64]

Table 23-10 **Risk Assessment for Preeclampsia Based on Medical History**

Risk Level	Risk Factors	Recommendation
High[a]	Autoimmune disease (SLE, APA) Chronic hypertension History of preeclampsia, especially if accompanied by an adverse outcome Multifetal gestation Renal disease Type 1 or 2 diabetes	Recommend low-dose aspirin if the woman has ≥ 1 of these high-risk factors
Moderate[b]	Age ≥ 35 years BMI ≥ 30 kg/m^2 Family history of preeclampsia in mother or sister Nulliparity Personal history risk factors (e.g., low birth weight, small for gestational age, previous adverse pregnancy outcome, > 10 year pregnancy interval) Sociodemographic characteristics (African American race, low socioeconomic status)	Consider low-dose aspirin if the woman has several of these moderate-risk factors

Abbreviations: APA, antiphospholipid antibody; SLE, systemic lupus erythematosus.

[a] Single risk factors that are consistently associated with the greatest risk for preeclampsia. The incidence of preeclampsia in pregnant women with ≥ 1 of these risk factors is approximately ≥ 8%.

[b] A combination of multiple moderate-risk factors may be used to identify women at high risk for preeclampsia. These risk factors are independently associated with preeclampsia, some more consistently than others. These risk factors vary in their association with an increased risk for preeclampsia.

Diagnosis of Preeclampsia

Preeclampsia may slowly progress over a period of weeks, or it may develop in a fulminant manner over a few hours. Prior to the appearance of diagnostic symptoms of preeclampsia, some clinical findings warrant close observation and follow-up. Fetal growth restriction or new-onset proteinuria in the second half of pregnancy without hypertension may precede development of diagnostic criteria for preeclampsia. While not diagnostic, an elevation of blood pressure late in the pregnancy (above baseline levels from the first trimester) that exceeds 15 mm Hg diastolic or 30 mm Hg systolic is sometimes seen in women who go on to

develop preeclampsia. Recent research has investigated using certain biomarkers and uterine artery Doppler studies to help predict preeclampsia. At this time, no screening method for the disorder is recommended other than taking a complete medical history to assess for known risk factors.[49]

Historically, edema, proteinuria, and hypertension were the classic triad of symptoms that defined preeclampsia. Edema is relatively common in pregnancy, however, so it is no longer considered a diagnostic criterion. Proteinuria is a common manifestation of reduced renal function, but symptoms of other target organ damage may manifest before proteinuria appears, and this condition is sometimes absent in women with preeclampsia. Preeclampsia without proteinuria was previously called "atypical preeclampsia." Today, when hypertension exists but proteinuria is absent, other factors are used to confirm diagnosis, as noted in **Table 23-8**. When a woman with hypertension develops systemic organ involvement or severe hypertension (blood pressure ≥ 160 mm Hg systolic and/or 110 mm Hg diastolic on two occasions), the diagnosis becomes preeclampsia with severe features. Early-onset preeclampsia (diagnosis before 34 weeks' gestation) is associated with more adverse effects for both the woman and the fetus as well as increased risk for future cardiovascular morbidity and mortality.[65]

Although preeclampsia is the most common cause of hypertension and end-organ dysfunction, it is important to remember the differential diagnoses that can mimic preeclampsia:

- Acute fatty liver of pregnancy: In addition to having symptoms of preeclampsia, women with acute fatty liver of pregnancy present with anorexia, nausea and vomiting, and low-grade fever. Liver dysfunction is more severe, and the woman may develop disseminated intravascular coagulation.
- Thrombotic thrombocytopenic purpura or hemolytic uremic syndrome: Women with this syndrome have microangiopathic hemolytic anemia, thrombocytopenia, neurologic and renal abnormalities, and fever.
- HELLP syndrome: HELLP syndrome (discussed later in this section) is considered a severe form of preeclampsia, but women with HELLP syndrome may not present with hypertension or proteinuria. The presentation of HELLP is variable although the most common symptoms are abdominal pain and mid-epigastric or right upper quadrant tenderness. Nausea and vomiting and malaise may be present, causing this condition to be mistaken for hepatitis. Jaundice, visual changes, and ascites can develop.

These disorders are severe illnesses associated with a high incidence of maternal and fetal morbidity. Prompt assessment by a physician or maternal–fetal medicine specialist is indicated for women who have symptoms that suggest a disorder other than preeclampsia is present.

Treatment of Women with Preeclampsia

The role of the midwife in caring for women who develop hypertension during pregnancy focuses on meticulous screening, early identification, referral or consultation, ongoing

assessment, and participation in a collaborative model of care as appropriate. Inpatient care is reviewed in more detail in the *Complications During Labor and Birth* chapter.

The definitive treatment of preeclampsia is delivery of the placenta. Expectant management requires consideration of the health of the woman and the health of her fetus. If birth is not indicated for fetal well-being, then the goal of treatment is to treat the woman's symptoms to allow the fetus to have more time in utero.

Antihypertensive medication is not recommended for women with preeclampsia unless she has severe features.[49] Increased surveillance includes weekly blood pressure measurements, daily fetal movement counting, assessment of maternal symptoms, and monitoring platelet counts and liver enzyme levels.

Management of Women with Severe Hypertension

Severe hypertension (systolic blood pressure ≥ 160 mm Hg and/or diastolic blood pressure ≥ 110 mm Hg) is an acute emergency. Evidence-based guidelines for treating severe hypertension produced by the National Partnership for Maternal Safety,[66] and endorsed by other professional associations, state that women with severe hypertension be evaluated within 15 minutes and treated within 30 minutes. Treatment of severe hypertension is reviewed in the *Complications During Labor and Birth* chapter.

Eclampsia

Eclampsia may present in the antepartum, intrapartum, or early postpartum period. Eclampsia occurs in 2% to 3% of women who have preeclampsia with severe features who are not treated with antiseizure medication and in 0.6% of women with preeclampsia without severe features.[67] Seizures are often preceded by hypertension, severe headache, hyperreflexia, visual disturbances, and right upper quadrant or epigastric pain. Approximately 25% of women who have eclampsia do not have previous symptoms.[49]

During the tonic–clonic seizure associated with eclampsia, a fetal bradycardia typically develops that generally lasts 3 to 5 minutes. The fetal heart rate pattern usually improves after the seizure resolves. Complications of eclampsia include brain hemorrahge, permanent neurologic morbidities, and stroke. In addition, placental abruption may occur if the seizure is prolonged.[67] Treatment of eclampsia is reviewed in the *Complications During Labor and Birth* chapter.

Chronic Hypertension

Chronic hypertension affects more than 5% of all pregnant women, and the incidence is expected to rise as the incidence of obesity increases. Most chronic hypertension is of primary etiology, but in as many as 10% of women chronic hypertension occurs secondary to underlying renal or endocrine disease.[49] Approximately 20% of women who have chronic hypertension will develop preeclampsia, although this risk is higher among those women with more severe hypertension.[68] Factors that increase a woman's risk for superimposed

preeclampsia include having secondary hypertension, diabetes, obesity, and preeclampsia in a previous pregnancy.

Complications associated with chronic hypertension include preterm birth, fetal growth restriction, placenta abruption, and superimposed preeclampsia. Women who have chronic hypertension are referred to a physician for management for prenatal care. Midwives may be involved in prenatal care visits once a plan of care is established.

When a woman with chronic hypertension first presents for prenatal care, an initial history, physical examination, assessment of current medications, and baseline testing of renal function are performed. Specific tests include serum creatinine, electrolytes, uric acid, liver enzymes, platelet count, and a quantitative measure of urine protein.

Assessing for the possibility of secondary hypertension is important, because women with secondary hypertension may require additional management. Chronic renal disease is the most common etiology of secondary chronic hypertension. Resistant hypertension, hypokalemia, elevated serum creatinine, and a family history of renal disease should raise the index of suspicion for secondary hypertension, and providers may consider a referral to a kidney specialist if suspected.[49]

Proteinuria is often present in women with renal complications of hypertension, and it is particularly important to establish a baseline for this condition. New-onset or worsening proteinuria is an indicator of the development of superimposed preeclampsia in a woman with chronic hypertension. Therefore, knowledge of the baseline value of proteinuria present at the onset of care is necessary to detect worsening renal function. Early diabetes screening should also be considered for women with chronic hypertension. An echocardiogram may be recommended for women who have a history of prolonged severe chronic hypertension (> 4 years).

Management of Women with Chronic Hypertension

Several different classes of medication can be used to treat chronic hypertension. All antihypertensive medications cross the placenta. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), mineralocorticoid receptor antagonists (e.g., spironolactone [Aldactone]), and direct renin inhibitors are contraindicated in pregnancy because they are associated with fetal malformations and renal abnormalities.[69,70] Statins are also contraindicated during pregnancy, as they may have teratogenic effects.[49] Because of these contraindications, a review of current medications can be a critical assessment at a preconceptional or an initial prenatal visit. An urgent physician consultation is indicated if a pregnant woman presents for prenatal care and is using one of these classes of medications.

Treatment of chronic hypertension depends on the severity of the hypertension and the presence or absence of comorbidities. Women with mild elevations in blood pressure (systolic, 140–150 mm Hg; diastolic, 90–100 mm Hg) but no other comorbid disorders may be monitored without use of medication, whereas women with mild hypertension who have comorbid diseases such as diabetes may require medication. Some women with mild chronic hypertension can discontinue medication during pregnancy or delay starting medication because the normal physiologic decline in blood pressure during the first half of pregnancy can

result in normal blood pressure values. Women with higher degrees of hypertension are offered antihypertensive medication.[49] Agents recommended for antihypertensive therapy in pregnancy include labetalol (Normodyne), nifedipine (Procardia), and methyldopa (Aldomet). For women with previous, early-onset preeclampsia and preterm birth, daily low-dose aspirin (60–80 mg) can be started late in the first trimester.[49]

Home blood pressure monitoring can be helpful for some women. "White coat hypertension"—that is, elevated blood pressure when present with a healthcare provider—may increase blood pressure readings in the clinical setting above those experienced at home.[71] Home monitoring will also allow for comparing measurements in different environments to ensure accurate diagnosis. Because preeclampsia typically develops after 20 weeks' gestation, increased frequency of blood pressure checks in the second half of the pregnancy is recommended. For women who are accustomed to engaging in exercise and have well-controlled blood pressure, moderate exercise is recommended during pregnancy. Salt-restricted diets and weight loss are not recommended for management of chronic hypertension in pregnancy.

Serial fetal growth ultrasounds help to monitor for fetal growth restriction when women have chronic hypertension. Depending on the severity of maternal disease, weekly or biweekly antenatal fetal testing and amniotic fluid assessment may be recommended starting in the early third trimester. Timing of birth is based on maternal and fetal indications.

Chronic Hypertension with Superimposed Preeclampsia

Initial management of women with chronic hypertension and superimposed preeclampsia follows the same guidelines recommended for women with preeclampsia, including assessment of severity, baseline laboratory values, fetal well-being, and gestational age. When the superimposed preeclampsia has severe features, administration of parenteral magnesium sulfate is indicated during the intrapartum and postpartum periods. Decisions about the timing of birth are driven by consideration of disease severity, the rate at which the disease is progressing, and close assessment of maternal and fetal well-being.

HELLP Syndrome

HELLP syndrome, is characterized by **h**emolysis, **e**levated **l**iver enzymes, and **l**ow **p**latelets. The etiology of this syndrome is unclear. It is usually considered a severe form of preeclampsia, although some experts suggest that HELLP may be a separate autoimmune disorder, especially because as many as 20% of women with this condition do not have hypertension or proteinuria. HELLP occurs in approximately 0.9% of pregnant women.[72] It most commonly arises during the antepartum period, but may emerge postpartum. Risk factors include previous hypertensive disorder of pregnancy, previous HELLP syndrome, and nulliparity.

HELLP syndrome is characterized by abnormal vascular tone, vasospasm, and coagulation defects.[72] Affected women may report cerebrovascular symptoms of severe headache (predominantly frontal), blurred vision, or scotomata and/or right upper quadrant pain or

persistent epigastric pain. Diagnosis is based on the triad of abnormal coagulopathy, liver dysfunction, and thrombocytopenia. The more abnormal the lab findings, the more severe the disease.

The presence of HELLP syndrome increases a woman's risk for eclampsia, disseminated intravascular coagulation, acute renal failure, liver hematoma, placental abruption, fetal growth restriction, preterm birth, neonatal respiratory distress syndrome, and perinatal death. Management focuses on stabilization of blood pressure and assessment of fetal well-being to determine the optimal time for delivery.[73] In general, immediate birth for women who are 34 weeks' gestation or more is recommended. If the woman is less than 34 weeks' gestation, a delay is recommended to allow for administration of corticosteroids to help fetal lung development as long as both the woman and the fetus are stable.[49,72,73]

Infectious Diseases

Several infectious diseases can cause congenital anomalies, fetal harm, or fetal death. TORCH is an older acronym for toxoplasmosis, other, rubella, cytomegalovirus (CMV), and herpes. Although a single test for TORCH antibodies is available. specific tests for individual infections based on risks, exposure, or maternal/fetal signs have become more widely used, as knowledge and testing modalities have expanded.

Midwives are often involved in screening, diagnosis, counseling about prevention, and obtaining physician consultation as needed. The *Reproductive Tract and Sexually Transmitted Infections* chapter reviews prenatal considerations for women who are exposed to or develop syphilis, hepatitis B, herpes, human immunodeficiency virus (HIV), human papillomavirus (HPV), and Zika virus. This section reviews the other clinically significant infections associated with adverse perinatal outcomes.

Cytomegalovirus

Cytomegalovirus, a member of the herpesvirus family, is the most common cause of infection-related congenital disorders. Transmission of CMV occurs by sexual contact and direct contact with body fluids. Toddlers are the most frequent source of infection. CMV is ubiquitous in the environment, and approximately 50% to 80% of reproductive-age women in the United States have experienced an asymptomatic infection and already possess antibodies.[74] However, an initial in utero infection with CMV can cause congenital anomalies, such as fetal growth restriction, microcephaly, hepatosplenomegaly, and thrombocytopenia. Hearing loss, vision impairment, and learning disabilities are the most common sequelae. Approximately 1 in 200 newborns are born with congenital CMV infection but only about one-fifth of them will have health problems related to the infection.[74]

Women with CMV are typically asymptomatic. Routine screening for this virus is not recommended because serologic tests for CMV are not specific. Thus, the first indication of CMV infection is usually signs of fetal compromise identified on ultrasound.[75] Congenital infection can be confirmed via culture or polymerase chain reaction (PCR) analysis of amniotic fluid. Diagnosis of CMV infection in the pregnant woman may be confirmed via PCR analysis of blood, urine, or saliva, although serology is the most commonly used approach. Serum samples collected 3 to 4 weeks apart are tested in parallel for anti-CMV immunoglobulin G (IgG). A four-fold increase or seroconversion from negative to positive will confirm the diagnosis.

There is currently no treatment for CMV infection. Women with suspected CMV infection are referred to a maternal–fetal medicine specialist for care.[75] Women concerned about CMV are counseled to wash hands carefully when around children and when handling body fluids from children.

Listeriosis

Listeria monocytogenes is an intracellular facultative Gram-positive bacterium that grows in

contaminated meat, dairy products, and cheese.[76] The source of the infection is usually soil and decaying vegetable matter that contaminates nonpasteurized products or processed food after pasteurization. Although *Listeria* outbreaks are uncommon in the United States, the rate of infection in pregnant women is 13 times higher than that in the general population.[76]

Listeriosis is generally a mild, self-limited illness. When symptoms are noticed, they generally take the form of gastrointestinal complaints and diarrhea followed by flu-like symptoms. The incubation period for this infection is 24 hours to 10 days after exposure to the pathogen. Fetal risks include miscarriage, preterm labor, and stillbirth, because the bacterium has a predilection for the placenta and fetal central nervous system.[76-78] The perinatal mortality rate following in utero infection is 29%.[77] Prevention is the primary strategy for protecting pregnant women from listeriosis. Foods that have a high risk of being contaminated are listed in the *Prenatal Care* chapter.

Treatment of women with suspected listeriosis is based on presumptive exposure and symptoms. If the woman has a presumptive exposure but no symptoms, no testing or treatment is recommended. If she has a presumptive exposure, management is based on whether she is febrile. Expectant management is offered to women who are not febrile, and blood cultures may be considered. For women who are febrile, blood cultures and treatment with intravenous ampicillin are recommended.[79]

Parvovirus B19

Parvovirus B19 is a single-stranded DNA virus that is responsible for the childhood infection known as “fifth disease”—also called “slap-cheek fever” because the hallmark of this infection is bright red erythema that develops on both cheeks. Seasonal outbreaks occur in early winter. Approximately 50% to 60% of pregnant women are immune to parvovirus B19. The primary source of infection is young children who contract the illness, and the virus is transmitted via respiratory secretions or hand to mouth contact. Approximately 20% to 30% of susceptible women exposed to parvovirus B19 in a nursery school or school classroom will become infected. The incubation period is 4 to 14 days (but can be as long as 20 days) after exposure; during this time, the infected individual is contagious.[80]

Parvovirus causes a mild flu-like illness in women, but may also be asymptomatic. The rate of maternal-to-fetal transmission ranges from 17% to 33%.[80] This virus crosses the placenta and the virus attaches to an antigen on fetal red blood cell precursors and invades them. When the fetus is infected in the first trimester, the risk of death is approximately 10%. When this illness is contracted in the second trimester, the fetus can develop severe anemia, hydrops, high-output cardiac failure, and liver damage. Fetal hydrops secondary to parvovirus accounts for approximately 10% to 25% of all fetuses identified with non-immune hydrops.[80]

Universal screening for parvovirus B19 or targeted screening in low-risk women is not recommended. Women should be counseled to report any exposure to this virus as soon as possible. Management of women who are exposed to parvovirus B19 starts with documenting the date of exposure and obtaining a serologic test for anti-parvovirus antibodies. Immunoglobulin G and M (IgG and IgM) titers should be obtained as soon as possible. If these initial titers are negative, follow-up titers should be drawn to determine whether

seroconversion has occurred. If the woman has positive IgG and negative IgM tests within the first few days after exposure, she can be reassured that she is immune and not at risk for transplacental transmission.[75] Interpretation of laboratory tests for this disorder are outlined in **Table 23-11**.

Table 23-11 **Interpretation of Lab Results for Maternal Parvovirus B19 Serology**

IgG	IgM	Interpretation	Clinical Management
Negative	Negative	Nonimmune and no infection	Repeat tests in 14 days[a]
Negative	Positive	Current active infection	Weekly ultrasound to monitor for fetal hydrops
Positive	Negative	Past infection with immunity and fetal infection very unlikely	Ultrasound to determine whether this was a recent infection in which the IgM has dissipated but the fetus was infected
Positive	Positive	Current active infection	Weekly ultrasound to monitor for fetal hydrops

Abbreviations: IgG, immunoglobulin G; IgM, immunoglobulin M.

[a] There is a window of 7 days immediately after infection during which both IgG and IgM are negative.

If the fetus has not developed hydrops by 8 weeks after exposure, infection is highly unlikely. Thus, the fetus is monitored with serial ultrasounds every 1 to 2 weeks for

approximately 8 to 10 weeks after exposure.[75] Fetal infection can be confirmed via PCR analysis of amniotic fluid.

Rubella

The rubella virus—a single-stranded RNA virus—is the organism responsible for "German measles," or what was once called "three day measles" in contrast to rubeola. Population-level immunization has virtually eliminated maternal rubella infection and congenital rubella syndrome in the United States, but this risk should not be forgotten and outbreaks can and do still occur.

Rubella is transmitted via droplets from infected humans. The incubation period is approximately 12 to 23 days. Viremia is present approximately 7 days before and 7 days after the infection, during which time the individual is contagious. Prodromal symptoms including fever, malaise, and adenopathy, especially in the postauricular nodes, appear first. The characteristic rash is a maculopapular eruption and persists for 1 to 3 days. Approximately 25% to 50% of children with rubella will have a subclinical or asymptomatic course. In adults, the disease is more symptomatic, with 70% developing arthralgia or arthritis in addition to the other symptoms.

Fetal infection rates vary over the course of pregnancy, being high in the first and third trimesters (80% and 100%, respectively) and somewhat lower in the second trimester (25%).[81] Rubella spreads through the circulatory system of the fetus, causing damage to all organs. Deafness, cataracts, and cardiac defects are the classic triad of congenital anomalies referred to as *congenital rubella syndrome*, but the infection is systemic and can affect almost all fetal organs; thus, miscarriage, preterm birth, fetal growth restriction, and stillbirth are possible. The severity of the disease depends on the time of infection, with the highest risks occurring with infection before 18 weeks' gestation.[81]

A pregnant woman who is nonimmune and potentially exposed to rubella is referred for physician consultation. The diagnosis of rubella may be confirmed if the woman is symptomatic and pharyngeal samples are obtained when the virus is present. Interpretation of serology is complicated.

- The presence of IgM is not used for detection of this viral illness. IgM first appears approximately 5 days after the rash develops, but may be falsely positive, as it can appear in response to other infections.
- When IgG is not detected, susceptibility to infection is established and subsequent testing occurs 2 to 3 weeks later to determine whether infection has occurred.
- The presence of IgG does not indicate whether the infection was recent or remote. Specialized reference laboratories can conduct avidity testing, which measures the strength of the antibody response—this strength increases over time. These results can aid in establishing the timing of infection.
- A four-fold increase in IgG is diagnostic.

Fetal infection can be confirmed via culture of amniotic fluid, but ultrasound findings are not

specific. Depending on the gestational age, timing of infection, risk of fetal infection, and maternal desires, pregnancy termination may be offered.

Population-level vaccination in the United States has made rubella infection during pregnancy rare. Occasionally, a woman will receive the vaccine for rubella during pregnancy before she is aware of the pregnancy. Rubella vaccine is a live-attenuated vaccine, so there is a theoretical risk that the vaccine could cause infection. Nevertheless, there are no documented cases of rubella infection or congenital rubella infection following rubella vaccination during pregnancy. Women should be counseled about the theoretical risks, but rubella vaccination is not considered a reason to terminate the pregnancy.[82] In any case, the best prophylaxis for rubella is universal vaccination, if not long before pregnancy, at least during the postpartum period.

Toxoplasmosis

Toxoplasma gondii is an obligate intracellular protozoan parasite that infects humans and usually remains dormant in neural or muscle tissue for the lifetime of the infected individual. Exposure to infection occurs via contact with contaminated cat feces, water, fruits and vegetables, and gardening in affected soil. A population study in the United States reported that 85% of women of childbearing age are susceptible to infection. Vertical transmission in pregnancy is possible and most likely to occur during primary infection. The transmission rate increases from 10% in the first trimester to 25% in the second trimester, and then to 60% in the third trimester.[75]

Maternal infection is usually asymptomatic and most newborns are asymptomatic at birth. Unfortunately, 90% of children infected with *T. gondii* in utero will subsequently develop visual impairment, hearing loss, and developmental delay. Women with a potential exposure to toxoplasmosis are referred for physician consultation.

Interpretation of serology for toxoplasmosis is difficult and standard assays are not available in all laboratories.

- Negative IgM and IgG tests indicate absence of infection or recent infection prior to seroconversion. In this case, a repeat evaluation in 2 to 3 weeks is indicated.
- If IgM is present, the timing of infection cannot be determined because the protozoa can remain in sera in high levels for several months or years. IgM can also be falsely positive. However, if the IgM test is positive and the IgG test is negative initially, and the IgG appears in a test performed 2 weeks later, recent infection can be reliably confirmed.
- The presence of IgG and no IgM indicates that infection has occurred but does not establish the timing of infection. A reference laboratory can perform avidity testing to determine whether the infection was recent or remote.
- The presence of both IgG and IgM does not determine the timing of infection. IgG develops rapidly in the case of toxoplasmosis, and IgM may be detectible for a long time.

Additional specialized tests are available for detection of maternal infection. Ultrasound may show early fetal effects, and amniotic fluid culture can establish the diagnosis of

congenital toxoplasmosis.[75] Routine screening for toxoplasmosis is not recommended in the United States because the prevalence is low and standardized serologic assays are not available. In parts of Europe, serial testing for susceptible women is cost-effective and a standard component of care; in contrast, the low prevalence of toxoplasmosis in the United States does not make this testing a cost-effective prevention strategy.

Treatment of infected women involves administration of spiramycin (Rovamycine), a macrolide antibiotic and antiparasite that is not commercially available in the United States but can be obtained at no cost from the U.S. Food and Drug Administration or special toxoplasmosis testing laboratories. If fetal transmission has not yet occurred, the woman can take spiramycin for the rest of the pregnancy to reduce transmission. If maternal seroconversion develops after 18 weeks' gestation or if fetal infection is confirmed, a complex regimen of specialized antibiotics may reduce the severity of disease in the neonate. Monthly monitoring is indicated throughout pregnancy. Primary prevention counseling is a standard component of routine prenatal care.

Varicella

The varicella zoster virus causes chickenpox and shingles. In the United States, approximately 90% of women of childbearing age are immune to varicella. The incubation period is 10 to 21 days following exposure to an infected individual. The characteristic rash appears as vesicles on the face, trunk, and extremities following a prodromal period of fever, malaise, and myalgia.

The diagnosis of varicella is made clinically, based on the characteristic rash. The viral DNA can be detected via PCR testing of skin at the base of vesicles. Serology interpretation can be difficult, however.

Primary infection in pregnancy is associated with severe maternal disease that can be either uncomplicated or complicated. The complicated form includes pneumonia, which has a mortality rate as high as 40% and is considered a medical emergency.[75] Women with varicella during pregnancy are offered antiviral medication (acyclovir [Zovirax] 800 mg 5 times per day for 7 days), which should be initiated as quickly as possible. Women with complicated varicella infection require hospitalization and specialized care.

The risk of vertical transmission of varicella virus to the fetus is highest in the first trimester of pregnancy, but decreases thereafter; overall, the risk of vertical transmission is approximately 2%. If women develop varicella infection 1 to 4 weeks before giving birth, as many as 50% of newborns will acquire the infection. The mortality rate in infected infants is approximately 30%.[83] Fetal effects of in utero infection include fetal growth restriction, low birth weight, skin lesions, limb hypoplasia, abnormalities such as microcephaly and hydrocephaly, and cognitive impairment.[83]

If a pregnant woman reports exposure to varicella, the first step is to determine if she has a history of vaccination or disease. If she has been vaccinated or has contracted varicella, she is immune and the fetus is not at risk. If her immunity is not known, the second step is to assess the degree of exposure—defined as a household contact, face-to-face contact for more than 5 minutes with an infected individual, or sharing the same hospital room with a contagious

person. If the woman does not have a known history of vaccination or disease, a varicella titer should be obtained. Nonimmune women who are exposed to varicella during pregnancy should receive varicella zoster immune globulin (VZIG), which can be administered up to 10 days after exposure.[75]

Neurologic Conditions

Numerous neurologic conditions may precede or develop during pregnancy. Midwifery care of women includes diagnosing and treating neuropathies such as carpal tunnel syndrome and Bell's palsy, as well as caring for women with migraine headaches during pregnancy.[84] A neurologic examination and interpretation of findings are within the midwifery scope of practice. Women who have complex neurologic illnesses such as multiple sclerosis or seizure disorders require physician care during pregnancy.

Migraine Headache

Headaches are common and can be a symptom of a wide range of disorders, some of which are benign and some of which can be life threatening. As a first consideration, whenever a woman presents with a headache in pregnancy, preeclampsia should be ruled out. Women with headaches that are atypical or concerning warrant prompt physician evaluation.

Migraines are a complex neurovascular brain disorder that affects approximately 18% to 20.2% of women during their childbearing years.[85,86] Many nonpregnant women experience an increase in migraine symptoms in conjunction with their menstrual cycle. The physiologic state of pregnancy with its sustained hormone levels—versus the variability in hormone levels seen during the menstrual cycle—can reduce the frequency of migraines. Many women who have migraine headaches report that the migraines improve or cease during pregnancy. A small proportion experience no change in frequency, and approximately 7% experience new onset of migraines during pregnancy. Improvement is most likely in the second and third trimesters.[87]

Migraine headaches are usually unilateral and may be associated with photophobia or phonophobia, nausea, and vomiting. These headaches are often induced by triggers such as sleep deprivation, stress, or certain foods.[85,86] Migraines do not adversely affect the course of pregnancy, although some studies suggest women who have migraines may have an increased risk for preeclampsia and low-birth-weight infants.[87]

Care of women with migraines during pregnancy starts with avoidance of migraine triggers, adequate fluid and rest, and use of acetaminophen. Formulations that include butalbital, acetaminophen, and caffeine are considered safe for short-term use (4–5 days per month). Triptans have vasoconstrictive effects that could theoretically cause vasoconstriction in the placenta, but sumatriptan (Imitrex) has been studied in pregnant women and not found to be associated with adverse effects.[85,86,88] Ergotamine (Cafergot) is contraindicated during pregnancy due to fetal hypoxia and potential oxytocic type effects. Women who need other medications or additional therapy are best cared for by a physician.

Peripheral Neuropathies

Pathology of the nerve roots may be acquired or inherited. Incidence of peripheral neuropathies during pregnancy is infrequent, especially in women without diabetes. The most common neuropathies that occur in pregnant women include Bell's palsy, carpal tunnel syndrome, and sciatica.

Bell's Palsy

Bell's palsy—a peripheral neuropathy affecting the face unilaterally—is more common among women than men, and is three times more common among pregnant women than among nonpregnant women. This condition is most likely to occur in the third trimester.

Symptoms of Bell's palsy may include pain behind the ear, increased perception of loudness, altered or lost taste of food, drooling, and difficulty with smiling or eye movement. The condition is painful; reports of dry eye (because the eyelid does not completely close), oversensitive hearing, changes in taste, and headache are common. On examination, the face is smooth and the affected side of the mouth droops. One test is to ask the woman to wrinkle her forehead, which she cannot do if Bell's palsy is present.

Management in pregnancy is limited to supportive treatment, and occasionally use of corticosteroids. Physician consultation can aid in making a plan for care, and referral to a neurologist may be of benefit. The eyelid may not close so keeping it moist and protected is important.

Carpal Tunnel Syndrome

Pregnancy is a known risk factor for carpal tunnel syndrome. Increased fluid retention and effects of relaxin have been reported to play a role in the increased frequency of this condition among pregnant women.[89] The presentation of carpal tunnel syndrome includes nocturnal or activity-related hand paresthesias, with nearly two-thirds of women reporting concurrent pain.[89],[90] The condition is more likely to be bilateral in pregnancy when compared to the nonpregnant population.

Treatment consists of wrist splints and local anesthesia injections as indicated. Surgery during pregnancy may be appropriate but generally is reserved for severe cases. Physical therapy can be recommended for additional support with carpal tunnel syndrome.[89]

Meralgia Paresthetica

Meralgia paresthetica is caused by compression of the lateral cutaneous femoral nerve. In pregnancy, it is associated with weight gain, obesity, diabetes, or a large fetus.[90] Affected women may complain of burning, uncomfortable pain, tingling, and numbness over the lateral thigh. Diagnosis is usually possible with careful examination and does not require unnecessary testing.[90] Protective measures include frequent position changes, along with avoidance of prolonged hip flexion or rotation and thigh abduction. Symptom relief may be accomplished by abdominal binders and avoiding tight clothing. Symptoms are typically self-limiting and resolve postpartum. Meralgia paresthesia is not a contraindication for regional anesthesia.[90]

Pelvic Girdle Pain: Sciatica and Symphyseal Separation

Low back pain, symphyseal pain, and sacroiliac joint pain are all common in pregnancy. These conditions are related to musculoskeletal changes of pregnancy and pressure on pregnancy-involved joints, although peripheral nerves can be entrapped and cause pain that radiates down

the back of the buttocks or legs. Pelvic girdle pain can include low back pain, or it may present as isolated pain over one of the pelvic joints. Sciatic pain may occur secondary to hormonal influences during pregnancy or secondary to a herniated disc. In most cases, the various presentations of pelvic girdle pain resolve spontaneously after birth, although low back pain can persist.

Muscle relaxation, rest with legs flexed, avoiding prolonged standing, and abdominal girdles may provide some relief. If the woman has severe pain or difficulty moving, physical therapy may be helpful. Women who have severe pain or other neurologic symptoms should be referred to a physician for consultation.

Epilepsy

Seizure disorders have a range of manifestations and causes, but are collectively called epilepsy.[91] Epilepsy is one of the most common neurologic conditions encountered during prenatal care.[92] In this disorder, abnormal electrical activity in the brain causes altered sensation, lapses in attention, or seizures. Seizure activity may be stimulated by brain trauma, infection, tumors, or specific triggers such as bright lighting.[91] Although epilepsy is most often treated with medications, other treatments include surgical excision of the brain seizure foci, ketogenic diets, and implantable brain neurostimulators.[91]

Ideally, women with epilepsy would seek preconceptional counseling that focuses on medication optimization. Women without a personal or family history of neural tube defects are advised to begin 400 mcg of oral folic acid daily and continue this dose during pregnancy.[93] Daily folic acid is increased to 4 mg orally starting one month before conception for women with a personal or family history of neural tube defect. This dose is also recommended by some clinicians when women use antiepileptic drugs associated with neural tubes defects, including valproic acid (Depakote, Convulex) and carbamazepine (Tegretol).[93]

Infants born to women with epilepsy have a 4% to 14% risk of having a major congenital malformation. Epilepsy-associated malformations include cleft lip and palate, ventricular septal defect, neural tube defects, hypospadias, club foot, and facial abnormalities such as flattened nasal bridge.[93,94] This increased risk of congenital anomalies is likely secondary to the effects of antiepileptic drugs, but the disorder itself may account for some of the increased risk.

One million women of childbearing age are estimated to have epilepsy, with approximately 24,000 infants born to these women annually.[93] Although some antiepileptic drugs are known teratogens, more than 90% of women with epilepsy give birth to healthy newborns. Valproate (Depakote, Convulex) and phenobarbital, which are known to increase the risk of congenital malformations and cognitive impairments, should be avoided when possible during pregnancy.[94,95] Lamotrigine (Lamictal) and levetiracetam (Keppra) have not been associated with congenital malformations.[94] Adjustment of preconception medication to monotherapy (instead of polytherapy) is preferred, because polytherapy is associated with a higher risk of congenital malformations and long-term cognitive deficits in offspring.[92-94] Antiepileptic drugs are cleared more quickly during the second and third trimesters, so serum levels of these

agents are monitored regularly during pregnancy.[93] Midwives are encouraged to participate in the Antiepileptic Drug Pregnancy Registry, which is listed in the Resources section at the end of this chapter.

Estrogen and progesterone affect neuronal excitability, thereby changing seizure thresholds. Approximately 15% to 32% of women with epilepsy will have changes in seizure type, frequency, or severity during pregnancy, although at least half of women experience no change in seizure activity.[93] The best predictor of remaining seizure free during pregnancy is having been seizure free for 9 months prior to pregnancy.[93] Compared to women without epilepsy, women with epilepsy during pregnancy are at higher risk for spontaneous miscarriage, preterm labor, preeclampsia, small-for-gestational-age newborns, fetal growth restriction, induction of labor, cesarean birth with prolonged hospital stay, and excessive postpartum bleeding.[92-95]

Respiratory Conditions

Asthma

Asthma affects as many as 8% of pregnant women in the United States and is often undertreated in adults. The course of asthma during pregnancy is variable, with approximating one-third of women experiencing exacerbations, one-third having fewer episodes, and one-third not experiencing any difference in asthma symptoms or frequency.[96] Overall, acute exacerbations during pregnancy occur in 20% to 36% of women with asthma.[97] The more severe or poorly controlled a woman's asthma is in the year prior to pregnancy, the higher the risk she has of worsening disease and hospital admission during pregnancy.[98]

The effect of asthma on pregnancy is not fully established. However, it appears to be associated with a small increase in various pregnancy complications such as low birth weight, preeclampsia, and preterm birth, but it is not clear if these risks are secondary to asthma, an underlying condition that affects both asthma and pregnancy, or the effects of medications used to treat asthma.

Research consistently demonstrates undertreatment of asthma by providers as well as underutilization of asthma medications by women during pregnancy. In addition, pregnant women with asthma who visit emergency departments for this disease are less likely to have appropriate medications prescribed than are nonpregnant individuals with asthma who receive emergency department care. Effective management of asthma during pregnancy requires vigilance, and multidisciplinary collaborative care is the optimal model for care for achieving this goal.[98]

When initially evaluating a woman who has asthma, it is important to determine the classification of the woman's asthma (see the *Common Conditions in Primary Care* chapter) based on current National Asthma Education and Prevention Program guidelines.[98] Assessment includes obtaining data about the severity, number of episodes, hospitalizations, and medications used in the prior year. Management goals are to (1) prevent chronic symptoms, (2) maintain optimal pulmonary function to support normal levels of activity, (3) prevent exacerbation, (4) maintain fetal oxygenation by preventing maternal hypoxic episodes, and (5) use treatment with no or minimal side effects.[97,98]

Evaluation of asthma during pregnancy is based on clinical evaluation and peak expiratory flow measurements. A stepwise approach is recommended for treating women with asthma, as described in **Table 23-12**.[98] Treatment should be stepped up when control is not achieved and stepped down if the woman has experienced resolution of symptoms for 3 months or more.

Table 23-12 Management of Asthma During Pregnancy

Asthma Classification	Step Therapy for Treating Women with Asthma During Pregnancy
Mild intermittent	No daily medications Albuterol inhaler as needed
Mild persistent	Low-dose inhaled corticosteroid

Moderate persistent	Low-dose inhaled corticosteroid and salmeterol (Advair) or medium-dose inhaled corticosteroid is preferred
Severe persistent	High-dose inhaled corticosteroid and salmeterol (Advair); oral corticosteroid if needed

Note: Alternative therapies are available for each step. If an alternative medication is needed, physician consultation should be obtained.

Based on National Asthma Education and Prevention Program. Working group report on managing asthma during pregnancy: recommendations for pharmacologic treatment. Available at: https://www.nhlbi.nih.gov/files/docs/astpreg_qr.pdf. Accessed November 4, 2017.[98]

While some women may be concerned about using asthma medication out of fear of fetal harm, a fetus needs oxygenation. Therefore, it is safer for pregnant women to be treated for asthma than to have asthma symptoms and complications in pregnancy. There are no documented adverse side effects of the medications for asthma, although only limited data are available on the use of antihistamines in pregnancy.[97,98]

Women with asthma in pregnancy will benefit from health education and preventive health strategies, including information on how to avoid triggers, how to take their medications, cessation of smoking, danger signs of worsening disease, and the importance of fetal movement counts.

Tuberculosis

When pregnancy and tuberculosis coexist, poor outcomes may result.[99] Pregnancy suppresses the pro-inflammatory response, which increases both susceptibility to new infection and reactivation of tuberculosis. Thus, pregnant women are at increased risk for active tuberculosis, and those with latent tuberculosis infection are more likely to progress to active tuberculosis. Outcomes of the disease in pregnancy vary, making the course of the disease difficult to predict. The prevalence of tuberculosis in pregnancy is estimated to be between 0.06% and 0.25% in high-resource countries.[100]

Risk factors for tuberculosis are reviewed in the *Common Conditions in Primary Care* chapter. Individuals with active infection may be asymptomatic. Symptoms include a prolonged, productive cough; fatigue; fever; chills; and night sweats.[101] Compared to pregnant women without tuberculosis, those with the disease have an increased risk of maternal morbidity, anemia, preterm birth, cesarean birth, low-birth-weight infants, birth asphyxia, and perinatal death.[101] Active tuberculosis is also associated with maternal mortality, with the highest rates of death occurring in women coinfected with tuberculosis and HIV. Infants born from women with tuberculosis can contract congenital tuberculosis; in such a case, they may either be asymptomatic or have birth defects.[100]

The Centers for Disease Control and Prevention (CDC) recommends screening pregnant women who are at high risk for tuberculosis, including women with known or suspected contact with a person who has tuberculosis, recent residence in an area where tuberculosis is prevalent (e.g., homeless shelters, countries with a high prevalence of tuberculosis), work in a high-risk setting such as a correctional facility or a hospital, use of injectable drugs, HIV, or immunosuppression.[102,103] Tuberculosis screening during pregnancy may be done with either

the intradermal tuberculin screening test (TST; also referred to as purified protein derivative [PPD]) or the interferon-gamma release assay (IGRA), which uses a serum sample. Both the TST and the IGRA are recommended by the CDC, both measure the body's response to tuberculin, and both are used in pregnancy. For the TST, population factors affect the measurement for determining positivity, whether the woman is pregnant or not (as noted in the *Common Conditions in Primary Care* chapter). When either test is positive, it usually means the woman has been infected with tuberculosis, but a differential diagnosis of latent tuberculosis or active tuberculosis remains to be made.[102,104]

An important confounder in the diagnosis of tuberculosis is the tuberculosis vaccine used in other countries, called bacillus Calmette-Guerin (BCG), which can potentially confer a lifelong positive response to tuberculosis tests. Women who have received BCG can still acquire tuberculosis. Tuberculin testing of women who have received BCG is acceptable if indicated and a positive result requires follow-up to confirm the diagnosis.

When a tuberculosis test is positive, a posterior–anterior chest X ray using shielding can be performed to detect the presence of tuberculosis lesions in the lung. A negative finding rules out active disease, and a diagnosis of latent tuberculosis is then made. Another option is obtaining a sputum for a culture. If the culture is positive for *Mycobacterium tuberculosis*, tuberculosis is confirmed.

Treatment of active tuberculosis in pregnancy is the same as treatment for nonpregnant women.[105,106] Previously, treatment of latent tuberculosis infection was delayed until 3 months postpartum. Currently, it is recommended that treatment be initiated at the time of diagnosis for women with either active or latent tuberculosis, although women with latent tuberculosis infection who do not have recent infection or immunocompromise may delay treatment until after birth.[102,103,106] The CDC recommends 9 months of isoniazid (Nydrazid) with pyridoxine (vitamin B_6 supplement). Either a daily or twice-weekly regimen may be used. Treatment with rifampin (Rifadin, Rimactane), either in combination with isoniazid or alone, is not recommended in pregnancy. Women with tuberculosis are best cared for by physicians with specialist training.

Upper Respiratory Infections

The diagnosis and management of upper respiratory infections (URIs) are described in detail in the *Common Conditions in Primary Care* chapter. In general, symptoms and the course of care for individuals with URIs are the same for pregnant women as for those who are not pregnant. The hormonal shifts and changing body mechanics of pregnancy can affect respiratory function, reducing lung volume and increasing activity in mucosal membranes. Thus, pregnant women may experience more intense symptoms or have a longer delay before health is restored. Although pregnant women may experience dyspnea, tachypnea is never a normal sign of pregnancy. Most importantly, women who are pregnant with a URI are more likely to progress from a cold, bronchitis, or influenza to pneumonia. The differential diagnoses when women have symptoms of URI include the common cold, influenza, bronchitis, sinusitis, and pneumonia.

Common Cold

Pregnant women are as susceptible to the common cold as nonpregnant women. Symptoms include rhinitis, sore throat, cough, and malaise, but adults rarely have a fever. The only difference in progression of this disorder during pregnancy is that a cough may take several days longer to resolve in pregnant women. Treatment focuses on mitigating symptoms. Decongestants, both oral and nasal sprays, are the usual treatment for women who have a URI and are not pregnant. Studies have failed to identify strong teratogenic effects associated with these agents; however, many midwives suggest nonpharmaceutical treatments and use of drugs only when the former fail to provide relief. Dextromethorphan, which is available under many brand names, is an effective antitussive and can be used to treat a woman with a cough.

Sinusitis

Pregnancy-related hormonal effects on the nasal passages increase a woman's risk for developing sinusitis following a common cold. Most cases of sinusitis are viral in origin. Symptoms include nasal congestion, faciomaxillary pain, headache, and facial pain or pressure that is worse when the woman bends forward. During pregnancy, symptoms of sinusitis may be atypical but often appear as a worsening of symptoms of a common cold that was resolving. This disease is generally self-limiting and will resolve in 7 to 10 days. Antibiotic therapy can be initiated if symptoms worsen or do not resolve. The first-line agent is amoxicillin–clavulanate (Augmentin) 875 mg/125 mg administered twice daily assuming the woman is not allergic to penicillin. A higher-dose formulation is available for women with severe infection or risk factors for developing pneumonia.

Bronchitis

Acute bronchitis often follows a common cold and should be considered if a cough persists more than 5 days. Bronchitis is an inflammation of the bronchi generally caused by a viral infection. Women with bronchitis will have clear lungs during auscultation but may have purulent sputum. The color of the sputum does not indicate the presence of bacteria. The differential diagnoses include pneumonia, asthma, and pertussis. Treatment is based on symptoms and antibiotics are not recommended.

Influenza

Annual influenza vaccination is recommended for all adults, including pregnant women. Use of the injectable trivalent inactivated vaccine does not cause harm to women or their fetuses.[107] In addition, maternal vaccination reduces the incidence of infection among one of the highest-risk populations—namely, infants younger than 1 year of age. Influenza can be a serious respiratory disease in pregnant women and is associated with increased risk of morbidity and mortality for both the woman and fetus.[107] The symptoms of influenza are similar to the symptoms of the common cold, but are more severe and include a fever. Hyperthermia is associated with some congenital anomalies in the fetus.[108],[109] The diagnosis is usually made on the basis of clinical

findings but laboratory tests are available.

Treatment should be instituted as quickly as possible when influenza is suspected. Oral oseltamivir (Tamiflu) can be safely used during pregnancy and is preferred because it is systemically absorbed.[109] Acetaminophen to reduce fever is an important component of care. Adjunct medications to treat symptoms such as rhinitis are safe and can be used concomitantly with oseltamivir.

Pneumonia

The symptoms of community-acquired pneumonia among pregnant women are similar to those experienced by nonpregnant women, and include cough, shortness of breath, sputum production, chest pain, fever, and malaise. Tachypnea and tachycardia may be present. On examination, lung consolidation, elevated temperature, tachypnea, and signs of respiratory distress may be evident. Women with suspected pneumonia should have a chest X ray, a complete blood count (CBC), metabolic panel (electrolytes, blood urea nitrogen, creatinine, glucose), and blood gases. Because of the likelihood of rapid disease progression and fetal compromise from decreased oxygenation, hospitalization is often necessary when pneumonia occurs during pregnancy, especially during the third trimester.

In addition to the maternal morbidity directly related to infection, pregnant women with pneumonia have an increased risk of developing preeclampsia. Fetal risks include preterm premature rupture of membranes, fetal growth restriction, prematurity, low birth weight, and small-for-gestational-age infants, as well as morbidity from hypoxemia.

Women who have symptoms of pneumonia during pregnancy are referred for physician evaluation and consideration for hospitalization. Antimicrobial therapy is chosen based on the microorganism although treatment with macrolide and beta-lactam antibiotics is recommended. Fluoroquinolones and clarithromycin (Biaxin) should be avoided.

Thyroid Disorders

Thyroid disorders are common in women of childbearing age. Hyperthyroidism, which is characterized by increased levels of free thyroxine (T_4) and low levels of thyroid-stimulating hormone (TSH), is present in 0.5% of pregnant women. *Graves' disease* accounts for 95% of hyperthyroidism in pregnant women.[111]

In settings where iodine deficiency is rare, the prevalence of hypothyroidism, which is characterized by high TSH levels and low free T_4 levels, is approximately 0.3% among pregnant women.[110] Most hypothyroidism in pregnancy is a result of autoimmune thyroiditis, also called *Hashimoto's disease*.[110] Thyroid storm, a life-threatening condition of severe hyperthyroidism, is rare but often precipitated by an acute event such as parturition, trauma, or surgery. Caused by an excess of thyroid hormone, this condition develops abruptly and can lead to multiple-organ decompensation.

Maternal and fetal complications associated with hyperthyroidism and hypothyroidism are listed in **Table 23-13**.[110-112] In general, overt hyperthyroidism is associated with more severe fetal effects than is overt hypothyroidism. In addition, medications used to treat hyperthyroidism can cause congenital defects, whereas thyroid replacement medications are not associated with adverse fetal effects.

Table 23-13 **Complications of Hyperthyroidism and Hypothyroidism During Pregnancy**

Pregnancy Complications	Hyperthyroidism	Hypothyroidism
Maternal	Gestational diabetes	Abruptio placenta
	Heart failure	Gestational hypertension
	Liver injury secondary to propylthiouracil	Preeclampsia
	Preeclampsia	
	Thyroid storm	
Fetal	Congenital anomalies secondary to thyroid medication	Cretinism
	Fetal hypothyroidism secondary to thyroid medication (fetal goiter)	Lower IQ and psychomotor delay after birth
	Fetal hyperthyroidism secondary to fetal exposure to thyroid-stimulating receptor antibodies	Fetal growth restriction
	Fetal growth restriction	Low birth weight
	Hydrops	Miscarriage
	Low birth weight	Preterm birth
	Neonatal autoimmune hyperthyroidism (neonatal Graves' disease)	Stillbirth
	Preterm birth	
	Stillbirth	
	Tachycardia	
	Thyrotoxicosis	

Based on Stagnaro-Green A. Overt hyperthyroidism and hypothyroidism during pregnancy. *Clin Obstet Gynecol*. 2011;54(3):478-487[110]; Korevaar TIM, Medici M, Visser TJ, Peeters RP. Thyroid disease in pregnancy: new insights

in diagnosis and clinical management. *Nat Rev Endocrinol*. 2017;13(10):610-622[111]; Alexander EK, Pearce EN, Brent GA, et al. 2017 guidelines of the American Thyroid Association for the diagnosis and management of thyroid disease during pregnancy and the postpartum. *Thyroid*. 2017;27(3):315-389.[112]

Pregnancy-Related Changes in Thyroid Function

Diagnosis of thyroid disorders during pregnancy requires an understanding of the physiologic changes that occur in thyroid function under the influence of pregnancy hormones (see the *Anatomy and Physiology of Pregnancy* chapter). Serum levels of two thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3), increase by 20% to 50%; TSH decreases; and thyroxine-binding globulin (TBG) increases substantially. Several interactions cause these changes. The alpha subunit of human chorionic gonadotropin (hCG) is structurally very similar to TSH and has thyroid-stimulating activity. As T_4 levels rise in response to the hCG stimulation of the thyroid gland, the pituitary releases TSH in response to the normal negative feedback between thyroxine levels and TSH. This creates a transient but physiologic hyperthyroidism. Estrogen induces a two-fold increase in TBG levels during pregnancy. Thyroxine bound to TBG is not active, so to maintain a euthyroid state, total T_4 must also increase.[113] Total T_4 increases in the first trimester and then falls in the second and third trimesters. Under normal conditions, the concentrations of free T_3 and T_4 do not actually change. T_3, the metabolically active hormone, is mostly made via conversion of T_4 in tissue.

Three other aspects of thyroid physiology changes are important considerations in clinical practice:

- The fetal thyroid does not produce T_4 until after 12 weeks' gestation, and does not produce enough to support fetal growth during the first half of gestation. Thus, the fetus depends on transplacental passage of maternal thyroxine until after the fetus is fully formed. T_4 is critical for early brain development, fetal growth, and bone maturation. There are critical windows during gestation for development of tissues that require thyroid hormone. Treatment of pregnant women with overt thyroid disorders is critical, therefore, and is best managed by a combination of specialists familiar with thyroid endocrinology.
- Iodine clearance increases during pregnancy. Iodine is essential for the production of T_4, so its intake needs to increase by approximately 50% in pregnancy. Although rare in the United States, where iodine supplementation in many basic food sources is common practice, iodine deficiency is an important cause of mental impairment worldwide.[113] This aspect of thyroid physiology can be an important consideration for women who have recently resided in an area where iodine deficiency exists. The recommended iodine intake during pregnancy is 220 micrograms per day. In the United States, most women achieve sufficient iodine intake via diet. Because iodine sufficiency is not universal, however, the American Thyroid Association recommends a daily supplement of 150 micrograms of potassium iodide; this amount is found in most (but not all) prenatal vitamins.
- When evaluating thyroid tests, the reference ranges for TSH and T_4 are trimester specific and population based, as there is significant geographic and ethnic diversity in TSH

concentrations during pregnancy. If local reference ranges are not available, the upper limit for TSH should be 4.0 mU/L (range: 0.1–4 mU/L).[112]

An overview of thyroid hormone levels during pregnancy in women with hyperthyroidism, hypothyroidism, and hyperemesis gravidarum is presented in **Table 23-14**.

Table 23-14 Overview of Thyroid Hormone Values During Pregnancy in Women with Thyroid Dysfunction

Thyroid Hormone	Normal Pregnancy	Overt Hyperthyroidism in Pregnancy	Overt Hypothyroidism in Pregnancy	Hyperemesis
Thyroid-stimulating hormone (TSH)	Normal	Suppressed or undetectable	High	
Thyroid-binding globulin (TBG)	Increased	Increased	Normal	Normal or low
Total thyroxine (T_4)	Increased	Increased	Low	Increased
Free thyroxine (FT_4)	Normal	Increased	Low	Increased
Total triiodothyronine (T_3)	Increased	Increased	Low	Normal or increased
Free triiodothyronine (FT_3)	Normal	Increased	Low	Increased

Hyperthyroidism

Table 23-15 presents an overview of management of thyroid disorders during pregnancy. Symptoms of hyperthyroidism are reviewed in the *Common Conditions in Primary Care* chapter. Women who have symptoms of hyperthyroidism or a history of hyperthyroidism should have thyroid function tests performed, but routine screening is not recommended.[114,115] Secondary to stimulation by hCG, approximately 2% to 15% of women will have laboratory values consistent with hyperthyroidism in the first trimester, and this finding is more frequent in women with hyperemesis gravidarum or severe nausea and vomiting. Sometimes called gestational transient hyperthyroidism, this condition resolves after the hCG levels normalize. It is not associated with adverse pregnancy outcomes and does not require treatment.

Table 23-15 Overview of Treatment of Thyroid Disorders in Pregnancy

	Hyperthyroidism	Hypothyroidism
Recommended treatment	PTU in first trimester Methimazole (Tapazole) after first trimester	Levothyroxine (Synthroid)
Monitoring during pregnancy	TSH, FT4 monthly With PTU: liver function tests monthly	TSH monthly through second trimester and once at beginning of third trimester
Postpartum evaluation	TSH, FT4	TSH, FT4

Abbreviations: FT_4, free thyroxin concentration; PTU, propylthiouracil; TSH, thyroid-stimulating hormone.

When hyperthyroidism is first diagnosed during pregnancy, referral for physician management is indicated. The more common scenario that midwives encounter in maternity care settings is one of a woman who has the diagnosis of Graves' disease and is being treated with propylthiouracil (PTU) or methimazole (Tapazole).

PTU has potential adverse effects for the pregnant woman, and methimazole has potential adverse effects for the fetus. PTU can cause a life-threatening hepatotoxicity but is more strongly protein-bound than is methimazole and does not cross the placenta as easily.[114,115] Methimazole is associated with a small increased risk for congenital anomalies, such as choanal atresia, tracheo-esophageal fistula, and omphalocele. Thus, it is recommended that women with Graves' disease use PTU in the first trimester and then switch to methimazole after the first trimester.[112,114,115] Once medication is started, thyroid function is monitored every 2 to 4 weeks by following serial free T_4 levels and adjusted as needed.

Hypothyroidism

Hypothyroidism is more common than hyperthyroidism in pregnant women. Subclinical hypothyroidism, defined as an elevated TSH with normal free T_4 levels, is present in 2% to 5% of women during pregnancy.[115] A few retrospective studies, published in the 1990s, found that subclinical hypothyroidism during pregnancy was associated with impaired neurodevelopment in the child. These findings supported the call for universal screening for hypothyroidism during pregnancy. The data supporting the association between subclinical hypothyroidism and adverse neonatal outcomes were not conclusive, however, and universal screening remained controversial until 2012, when the Controlled Antenatal Thyroid Screening Study (n = 21,846) was completed.[116] This randomized trial screened women for subclinical hypothyroidism and followed women in two groups: One group was treated, while the other group received usual care without treatment. The study found no difference in neurocognitive development at age 3 years in the offspring when the children from both groups of women were compared.[116] Thus, the call for universal screening for hypothyroidism during pregnancy was quelled, and this practice is no longer recommended. Currently, the American College of Obstetricians and Gynecologists recommends screening women who have symptoms, a personal history of thyroid disease, or the finding of a goiter or thyroid nodules on physical examination.[115] The American Thyroid Association has a longer list of recommended criteria for screening as noted in **Table 23-16**.[112,117]

Table 23-16	Factors That Increase the Risk of Thyroid Disease in Pregnancy
Living in an area with known moderate to severe iodine insufficiency	
Family history of thyroid disease	
Past Medical History	
Autoimmune disorder	

Elevated thyroid peroxidase antibodies
Infertility
Irradiation of head or neck or multiple dental X rays
Multiple miscarriages
Pregnancy loss or unexplained preterm birth
Type 1 diabetes mellitus
Thyroid antibody positivity
Thyroid disease or thyroid surgery
Treatment with lithium (Lithobid), amiodarone (Cordarone), or recent administration of a radiologic contrast agent
Physical Examination Findings
Symptoms or clinical signs of thyroid disease
Goiter
Age ≥ 30 years
Body mass index (BMI) ≥ 40 kg/m^2

Based on Alexander EK, Pearce EN, Brent GA, et al. 2017 guidelines of the American Thyroid Association for the diagnosis and management of thyroid disease during pregnancy and the postpartum. *Thyroid*. 2017;27(3):315-389[112]; De Groot L, Abalovich M, Alexander EK, et al. Management of thyroid dysfunction during pregnancy and postpartum: an Endocrine Society clinical practice guideline. *J Clin Endocrinol Metab*. 2012;97(8):2543-2565.[117]

Diagnosis and Treatment of Hypothyroidism

The initial screening test used to establish thyroid dysfunction is TSH level. In many settings, a TSH and free T_4 level will be obtained at the same time because the addition of the free T_4 level is useful to identify the diagnosis of hypothyroidism. The total T_4 level is not a useful measure in pregnancy because of the increased protein binding that occurs during gestation. If the TSH level is higher than 4.0 mU/L or the population-specific upper limit, treatment with levothyroxine is initiated. Levothyroxine is titrated to maintain TSH in the normal range by trimester. For women diagnosed prior to pregnancy, an increase in the dose by as much as 30% may be needed early in pregnancy. Laboratory monitoring of TSH levels should be performed every 4 weeks until the second half of pregnancy, and then at least once at the beginning of the third trimester.[112]

If the TSH level is higher than 2.5 mU/L but less than 4.0 mU/L and the woman is euthyroid (i.e., free T_4 level in the normal range), a blood test to determine the absence or presence of thyroid autoantibodies (TBOAb) may be recommended. Some studies have found that women with subclinical hypothyroidism (i.e., euthyroid but moderately high TSH levels plus thyroid autoantibodies) have an increased risk for adverse outcomes, but evidence that treatment prevents these outcomes is lacking. Current guidelines from the American Thyroid Association recommend following TSH levels in pregnant women who are euthyroid with positive TBOAb every 4 weeks through mid-pregnancy. Treatment is not recommended in general,[112] but physician consultation is appropriate because guidelines differ by region, population, and individual clinical circumstances.

Recommendations for evaluation of thyroid nodules in pregnancy include serum TSH testing

and a neck ultrasound. Women with abnormal findings may be referred to a specialist.[112]

Urinary Disorders

Women, relative to men, have an increased risk for developing urinary tract infections (UTIs). Such infections, which are common in pregnancy, include asymptomatic bacteriuria, cystitis, recurrent UTI, and pyelonephritis. In addition to pregnancy itself, other risk factors for UTIs include low socioeconomic status, sickle cell disease, previous UTI, and pregestational diabetes. Pregnancy-related changes to the urinary tract predispose women to pyelonephritis once a UTI is present.[118] Diagnostic criteria for urinary disorders are presented in the *Common Conditions in Primary Care* chapter.

Asymptomatic Bacteriuria

The incidence of asymptomatic bacteriuria is similar in pregnant and nonpregnant women, with prevalence rates ranging from 2% to 13%. The pathogen most likely to cause this infection is *Escherichia coli*, which accounts for 63% to 85% of such infections. The combination of having no overt symptoms commonly associated with symptomatic UTI and a clean-catch urine culture that has isolated 100,000 (10^5) colonies or more of no more than two microorganisms is diagnostic for asymptomatic bacteriuria.[119]

Untreated asymptomatic bacteriuria is associated with a 30% to 40% risk for becoming a symptomatic UTI, including pyelonephritis. Treatment of asymptomatic bacteriuria reduces these risks significantly.[120]

When bacteriuria or a symptomatic UTI occurs secondary to group B *Streptococcus* (GBS) infection, the diagnostic criterion for infection is 10,000 (10^4) colonies or more.

Women who have GBS in their urine are presumed to have heavily colonized vaginas. Because GBS is transient, treatment based on a urine culture is not necessarily needed, but these women are subsequently offered prophylactic antibiotics during labor and do not need the routine vaginal/rectal culture at 35 to 37 weeks' gestation.

All pregnant women should be screened for asymptomatic bacteriuria between 12 and 16 weeks' gestation or upon entry to care via a urine culture. Dipstick analysis and microscopy have poor predictive value. If screening for asymptomatic bacteriuria is negative, routine reculture is not indicated or cost-effective in pregnancy. Because there is a 40% false-positive rate with single cultures for asymptomatic bacteriuria, a second culture can be used for confirmation.[119]

The selection of antibiotic to treat asymptomatic bacteriuria is guided by resistance patterns, local costs, availability, and allergy history. Beta-lactams (e.g., ampicillin, penicillin, cephalosporins) are safe when used during pregnancy. Nitrofurantoin (Macrobid, Macrodantin), sulfonamides, and trimethoprim (Bactrim, Septra) may also be used, albeit with some caution.[121] Data regarding an association between these agents and congenital anomalies are conflicting. According to the American College of Obstetricians and Gynecologists, these antimicrobial agents are safe for use as first-line agents during the second trimester, and may be used in the first trimester if other antibiotic choices are not optimal.[121] Sulfonamides and nitrofurantoin are contraindicated for women with G6PD deficiency. Some authors recommend avoiding trimethoprim–sulfamethoxazole in the first and third trimesters because trimethoprim

is a folic acid antagonist and sulfonamides displace bilirubin from plasma-binding sites in the newborn, which theoretically increases the risk for newborn jaundice. Fluoroquinolones, tetracycline, and doxycycline are contraindicated in pregnancy.

In studies, treating asymptomatic bacteriuria for 7 days has proved superior for achieving bacteriologic cure over shorter treatment periods.[122] Commonly used antibiotic regimens for asymptomatic bacteriuria and other UTIs are presented in **Table 23-17**.

Table 23-17 **Commonly Used Antibiotic Regimens for Treatment of Asymptomatic Bacteriuria, Acute Cystitis, and Recurrent Urinary Tract Infections During Pregnancy**

Drug: Generic (Brand)	Dose	Clinical Considerations
Amoxicillin (Amoxil), Ampicillin (Principen)	500 mg orally 3 times/day or 875 mg orally 2 times/day for 3–7 days	Not considered a first-line agent. Beta-lactams may be less effective than other agents due to high rates of resistance. Adverse effects include allergies, candidal overgrowth, and pseudomembranous colitis.
Cephalexin (Keflex)	500 mg 4 times/day for 3–7 days	Not active against enterococci. Risks include allergies and hepatic dysfunction.
Fosfomycin (Monurol)	Single 3-gm oral dose	Lower efficacy than 3 days of other agents, but resistance is rare in the United States. This agent may be an option for women with multiple allergies. Does not reach a therapeutic dose in the kidney, so should not be used if pyelonephritis is suspected.
Nitrofurantoin (Macrobid)	100 mg orally twice daily for 3–7 days	First-choice for uncomplicated UTI. Resistance is unlikely, but bactericidal in urine only; poor penetration into tissues. Does not reach a therapeutic dose in the kidney, so should not be used if pyelonephritis is suspected. Administer with meals to improve absorption. Side effects include gastrointestinal upset, peripheral neuropathy, and pneumonitis.
Trimethoprim–sulfamethoxazole (Bactrim, Septra, Septra DS)	800 mg/160 mg (one double-strength tablet) orally twice daily for 3 days	First-choice agent if resistance in the local area is less than 20%. Avoid during first and third trimesters unless it is the only or best choice. Contraindicated for women with glucose-6-phosphate dehydrogenase deficiency. Allergic reactions are common; serious skin reactions and blood dyscrasias may occur.
Suppressive Therapy		
Nitrofurantoin (Macrobid)	50–100 mg orally once daily at bedtime	May be used daily or postcoital if UTI is sexually related.
Cephalexin (Keflex)	250–500 mg orally once daily at bedtime	May be used daily or postcoital if UTI is sexually related.

Abbreviation: UTI, urinary tract infection.

A test of cure culture is recommended 1-2 weeks after antibiotic treatment is complete, as a significant portion of women with asymptomatic bacteriuria do not clear the infection. If the woman experiences a second recurrence of either asymptomatic bacteriuria or develops a symptomatic UTI, continuous suppressive therapy should be initiated.[119]

Acute Cystitis

Acute cystitis is an infection in the bladder that develops in approximately 15% to 20% of pregnant women. Symptoms in pregnancy include urgency, frequency, dysuria, hematuria, and suprapubic pressure. Fever, chills, flank pain, and costovertebral angle tenderness suggest possible pyelonephritis. In addition to an increased risk for pyelonephritis, studies have found an increase in both preterm birth and low-birth-weight infants in women who develop acute cystitis during pregnancy. The diagnosis of a symptomatic UTI is based on urine culture results but women may be treated presumptively before culture results are available.[119] If the woman has persistent dysuria or dysuria without bacteriuria, testing for sexually transmitted infections is indicated.

Antibiotic regimens are based on culture results and microorganism sensitivities. Either a 3-day or 7-day course is recommended, depending on the severity of symptoms and individual clinical circumstances. A repeat urine culture for test of cure is recommended once the therapy is completed.

Recurrent Urinary Tract Infections

Recurrent UTI is distinguished from relapse or reinfection.

- A woman is considered to have *recurrent UTIs* if she has two or more infections within one year.
- A *relapse* (persistent infection) occurs when subsequent infections are found to be caused by the same organism as the original infection and occur within 2 weeks of the completion of treatment.
- *Reinfection* is defined as a UTI caused by a new organism more than 2 weeks after a negative test of cure.

Women who have recurrent UTIs are offered continuous daily suppressive therapy (**Table 23-17**).

Pyelonephritis

During pregnancy, women with bacteriuria have a 20- to 30-fold increase in their risk of developing pyelonephritis. This infection, which typically manifests in the second or third trimester, is often the consequence of undiagnosed or inadequate treatment of a UTI. Maternal age, nulliparity, sickle cell anemia, diabetes, nephrolithiasis, illicit drug use, and a history of pyelonephritis are all risk factors.

Signs and symptoms of pyelonephritis include low back pain, flank pain, fever, chills,

nausea, vomiting, costovertebral angle tenderness, and pyuria (white blood cells in the urine). Dysuria is less common. Pyelonephritis is a risk for sepsis, septic shock, adult respiratory distress syndrome, anemia, renal insufficiency, preterm birth, and low-birth-weight infant. The differential diagnoses for women with these symptoms are kidney stones, intra-amniotic infection, preterm labor, and placental abruption. Pyuria and bacteriuria will be present in women with pyelonephritis but do not occur in women with kidney stones, intra-amniotic infection, or abruption.

Inpatient management is usually recommended for women with pyelonephritis during pregnancy. Antibiotics are administered parenterally until the woman is afebrile for 24 to 48 hours. These agents are initiated empirically and changed as needed when the urine culture results are available. Once the acute symptoms have resolved, oral medications can be instituted and the woman is discharged from the hospital. Antibiotics are administered for 10 to 14 days and suppressive therapy is begun thereafter.

Outpatient management has been proposed for some women and may be appropriate when medical follow-up is available. Candidates for outpatient management include women less than 24 weeks' gestation who do not have severe symptoms and are healthy (i.e., no comorbid conditions).

Conclusion

Midwifery can be of great benefit for women whose pregnancy is medically complicated. Careful history taking, thorough physical examination, and an understanding of differential diagnoses and danger signs can help assure that women receive the correct diagnosis—the first step in mitigating adverse effects of these disorders, some of which can have lifelong effects. The decision to consult with, collaborate with, or refer to a specialist for ongoing care will be based on the severity of the woman's condition, practice policies, and the resources available. A multidisciplinary, team-based approach can provide the woman and her fetus with optimal care when she experiences complications during her pregnancy, birth, postpartum, and throughout their lives.

PART V

Intrapartum

NANCY K. LOWE

"Not just another day in a woman's life." This conclusion by Penny Simkin,[1,2] childbirth educator and doula extraordinaire, should play itself over and over in the midwife's mind when with or thinking about a woman in labor. They are simple words, yet profound in their description of the importance and permanence of a woman's memory of the day she gives birth. As Simkin's research showed, women remember with exquisite detail and accuracy the words and actions during labor of their providers and partners 15 to 20 years later. What the midwife does and says during labor may affect not only the physiology of the labor process, but also the woman's memory of the important day when she gave birth and welcomed a new child into her life and family. The chapters in this section present the components of midwifery care of women during the labor process.

The midwife is the guide, consultant, and collaborator for a woman and her family during labor and birth. The midwife helps to ensure a safe physical, psychological, and spiritual place for labor and birth, while functioning in the milieu of the specific birth setting, whether in the home, birth center, or hospital. The midwife serves as the buffer between the laboring woman and whatever system of care surrounds her. It is the midwife's responsibility to ensure a protected space where labor and birth can evolve as the unique process that it is for each woman and each infant she carries. The philosophy of midwifery care includes "watchful waiting and non-intervention into normal processes."[3]

There are few other times during the reproductive cycle when inappropriate or ill-timed interventions can have the dire consequences that are possible during labor and birth. The ill-timed amniotomy with a high fetal head can turn an otherwise normal labor into an emergency when a loop of umbilical cord drops into the midwife's hand and the fetal head descends against it. Tachysystole and fetal bradycardia from injudicious exogenous oxytocin administration can trigger a cascade of additional interventions that create anxiety and further disrupt and perhaps even stop the normalcy of labor. While the availability of medical and

surgical interventions during labor can help assure an appropriate safety net for problems that may occur, their injudicious use not only produces more harms than benefits for mother and infant, but also unnecessarily increases the cost of health care.

The midwife is the vigilant protector who ensures safety for a woman and her infant during labor and birth. This vigilance requires an exquisite understanding of the physiology and psychology of human parturition, as well as the scientific basis for midwifery practice during this vulnerable period of transition. The expert midwife is a lifelong student of labor, its many aberrations, and the scientific literature that helps deepen our understanding and expand our expertise.

Although labor is a normal physiologic and developmental process, it is also a period of vulnerability for both mother and infant, during which problems can arise requiring the midwife's expert action through timely identification based on comprehensive assessment, treatment, and collaboration with and potential referral to other members of the healthcare team. Regardless of the problem or the treatment regimen required, the laboring woman and respect for her autonomy and self-determination remain the center of the midwife's care.

An adaptation of a writing by Lao Tzu on leadership and being a midwife (Do you think of your role as a midwife as a role of leadership?) summarizes the midwife's role during the intrapartum period well:

> *Imagine that you are a midwife; you are assisting at someone else's birth. Do good without show or fuss. Facilitate what is happening rather than what you think ought to be happening. If you must take the lead, lead so that the mother is helped, yet still free and in charge. When the baby is born, the mother will rightly say: "We did it ourselves!"*[4(p33)]

CHAPTER

24

Anatomy and Physiology During Labor and Birth

CINDY M. ANDERSON AND MELISSA D. AVERY

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

Providing care that supports the normal physiologic process of labor and birth requires an understanding of the physiology of this unique period. The anatomy and physiology of the female reproductive system and changes during pregnancy are described in the *Anatomy and Physiology of the Female Reproductive System* and *Anatomy and Physiology of Pregnancy* chapters, respectively. This chapter focuses on the anatomic and physiologic changes that occur during labor and birth in both the woman and the fetus. The uterine changes that proceed from contraction inhibition during pregnancy to uterotropin-associated activation and uterotonin-associated stimulation during latent and active labor are highlighted. *Uterotropins* such as estrogen and progesterone are hormones that cause an effect on the uterus and *uterotonins* such as prostaglandins and oxytocin induce uterine contractions. A review of the anatomic relationships between the fetus and the maternal pelvis during the process of birth follows.

Traditionally, the processes involved in labor and birth have been conceptualized as those that affect the power (uterus), the passenger (fetus), and the passage (pelvis). A fourth "P" is often included in this rubric—the psyche—and will be addressed in this chapter. However, many more complex adaptations also occur during labor and birth. It is important to appreciate that labor and birth involve normal physiologic processes best supported through limited intervention.[1] During labor and birth, interventions have the potential to disrupt complex hormonal regulation, thereby prompting a cascade of additional interventions with potential for further disruption of physiologic processes.[2] Interventions during labor such as administration of synthetic oxytocin, prelabor rupture of membranes, and continuous electronic fetal heart-rate monitoring may have unintended risks and interfere with physiologic processes in low-risk women in spontaneous labor.[2,3] With this knowledge, midwives are prepared both to appreciate and support the normal physiologic processes of labor and birth, and to recognize situations when labor does not progress as anticipated, requiring alternative management strategies.

Premonitory Signs and Symptoms of Labor

At term, the transition leading to labor results from the combined physiologic and hormonal responses of mother and fetus.[2] Premonitory signs and symptoms of impending labor may occur 1 or 2 weeks before active labor starts, as the uterus slowly shifts from a quiescent state to active ongoing contractions.

Maternal Adaptations to Fetal Descent

Lightening—that is, the descent of the fetus into the true pelvis—may occur as early as 4 weeks prior to the onset of labor. The movement of the fetus into a lower position in the true pelvis, referred to as *engagement*, is more common among nulliparous women than multiparous women. The anatomic change in fetal position, which may be measured objectively by a decrease in fundal height, is accompanied by characteristic signs and symptoms in the mother, including partial relief of pressure on the diaphragm, leading to greater ease of breathing and decreased reflux. In turn, pressure on structures adjacent to the pelvis increases, with symptoms such as urinary frequency, pelvic pressure, leg cramps, and dependent edema in the lower extremities becoming more evident. Partial obstruction by the fetal presenting part on the femoral veins reduces venous return to the maternal heart, particularly when the woman is standing. As blood pools in her lower leg veins, increased intravascular pressure promotes fluid movement out of the vessels and into the surrounding interstitial tissue, resulting in edema. When the woman is supine, venous return is enhanced and intravascular pressure is reduced, resulting in improvement of lower extremity edema. Tilting a woman to her left side further improves venous return by reducing pressure on the inferior vena cava, which lies slightly to the right of center. The reduced capacity of the maternal bladder due to anatomic pressure of the engaged fetal presenting part, coupled with increased venous return when recumbent, contributes to increased frequency of urination, which can lead to interrupted sleep in the last weeks of pregnancy.

Cervical Ripening, Effacement, and Dilation

Our understanding of cervical changes during pregnancy, labor, and birth is largely the result of animal studies. Thus, knowledge of human physiology has not yet been fully elucidated with regard to timing and molecular processes. It is known that the cervix undergoes four phases of remodeling over the course of pregnancy, labor, and birth, as described in the *Anatomy and Physiology of Pregnancy* chapter.

Cervical connective tissue changes are central to the significant remodeling that characterizes the third stage of cervical ripening that occurs prior to and during labor. The rearrangement of collagen is the primary change that causes cervical ripening, with realignment of elastin and smooth muscle fibers playing a more minor role in the process.[4,5] The anatomic changes modulated by inflammatory and hormonal influences are accompanied by an increase in water content that leads to softening of the cervix,[6] setting the stage for the full effacement and dilation that precede birth during active labor.

The triggers that promote these cervical changes include increases in inflammation, oxytocin, and prostaglandin activity.[2] The ripening and softening of the cervix, which are essential for effacement and dilation, reflect the enhanced collagen breakdown and elastin remodeling mediated by matrix metalloproteinases (enzymes that break down peptide bonds) that were previously inhibited by progesterone during uterine quiescence.[7] The tight collagen bundles in the nonpregnant cervix respond to hormonal changes by becoming less dense and more loosely packed at midpregnancy. In later pregnancy and during labor, an increase in water content creates a softer consistency, which is also associated with separation of collagen fibrils promoted by the proteoglycan decorin and a reduction in the fibronectin level.[4] Increased levels of enzymes that break down connective tissue, including collagenase and elastase, contribute to the process of cervical remodeling.

Effacement is the result of the lengthening of the muscle fibers at the internal os, which stretch the endocervix upward into the lower uterine segment. This change is evaluated clinically in terms of actual centimeters of length or percentage of the original length, where no effacement is described as 0% and complete effacement is described as 100%. The trend is toward documenting the cervix in actual centimeters of length. However, when a woman is at term and her cervix is being assessed to determine how likely she is to have a vaginal birth, cervical length may be reported as a percentage of the original length noted before the process of effacement begins. Effacement as a percentage remains one of the parameters in determining the Bishop's score, a measure that is discussed in more detail in the *Complications During Labor and Birth* chapter.

Some cervical dilation may occur prior to labor, with effacement and dilation continuing over the course of labor. Nulliparous women may experience some cervical softening and effacement prior to labor, or they may enter labor with the cervix not yet soft or effaced. In nulliparous women, effacement typically precedes dilation. In contrast, parous women often enter labor with some effacement and dilation having already taken place, and these processes continue to occur simultaneously as labor progresses.

Dilation is the widening of the external os, with this structure expanding from an opening of a few millimeters to one that allows the passage of the fetus during birth. The force of contractions, coupled with the hydrostatic action of the amniotic fluid, creates a force that promotes dilation of the low-resistance cervix. In the case of ruptured membranes, the pressure of the presenting fetal part on the cervix also promotes progressive dilation. Dilation is clinically evaluated by measuring the diameter of the cervical opening digitally in centimeters, with 0 centimeters describing a closed external cervical os and 10 centimeters defining complete dilation. The 10-centimeter measure of complete dilation is based on the suboccipitobregmatic diameter of the fetal head, which is approximately 9.5 centimeters at term; it is the widest anterior–posterior diameter of the flexed head during the normal mechanisms of labor when the fetus is in a cephalic presentation. Fetal head diameters are reviewed in detail later in this chapter.

In addition to placing traction on the cervix to promote ripening, uterine contractions may increase in frequency and lead to discomfort before the onset of labor. Historically referred to as "false labor," these early Braxton Hicks–like contractions do not occur in a regular pattern, nor do they cause the progressive cervical dilation and effacement seen during active labor.

They are not “false,” however, because premonitory uterine contractions probably reflect changes within the uterine musculature that occur with advancing gestation and preparation for labor. The hormonal milieu that stimulates cervical ripening, combined with anatomic pressure of the presenting part on the cervix and the traction generated by uterine contractions, also causes the premonitory sign of the passing of the cervical mucus plug. This blood-tinged mucus is expelled from the cervical canal after the cervical changes associated with labor have started. The passage of the mucus plug may occur all at once or, more commonly, over a period of 1 to 2 days. In the absence of trauma or injury to the cervix (e.g., during aggressive vaginal examination), the passing of the mucus plug often indicates impending labor within 48 hours.

Factors That Influence the Onset of Labor

The onset of labor is classically defined as the occurrence of regular painful contractions that promote dilation of the cervix. Contractions that occur at regular intervals with increasing frequency, duration, and intensity are the hallmark of labor.[8,9] The primary basis of our understanding of the process of labor onset is evidence from animal studies, which have been extrapolated to explain the human condition. The onset of labor is likely the result of a complex interplay between biochemical and mechanical influences originating in both the maternal and fetal systems and the complex interactions of hormonal systems regulating one another's activity.[2] In essence, the wide individual variations in the chronology of events associated with labor onset reflect the variability of the human experience.

The influence of genetic (maternal and fetal) and race/ethnicity factors in the timing of labor onset provides some evidence for genetic influences of labor onset.[10-12] Gene–environment interactions that occur as a result of maternal, fetal, and intrauterine factors illustrate the complexity of outcomes, including labor onset.[13,14] Genetic polymorphisms in the maternal genome suggest many factors may influence the duration of pregnancy and timing of onset of labor, including stress[15] and inflammation.[16-18]

Endocrinology of Labor: Parturition Cascade

The onset of labor is likely the result of interactions among the maternal, fetal, and placental units.[19] This process involves a cascade of events that include multiple redundant loops—perhaps the reason why researchers have failed to find a single initiating factor for labor. Two primary mechanisms that are known "players" are a change from progesterone dominance and uterine quiescence to estrogen-stimulated uterotropin activation and placental production of corticotropin-releasing hormone. The overall process of parturition proceeds through four phases (**Figure 24-1**):[9,20,21]

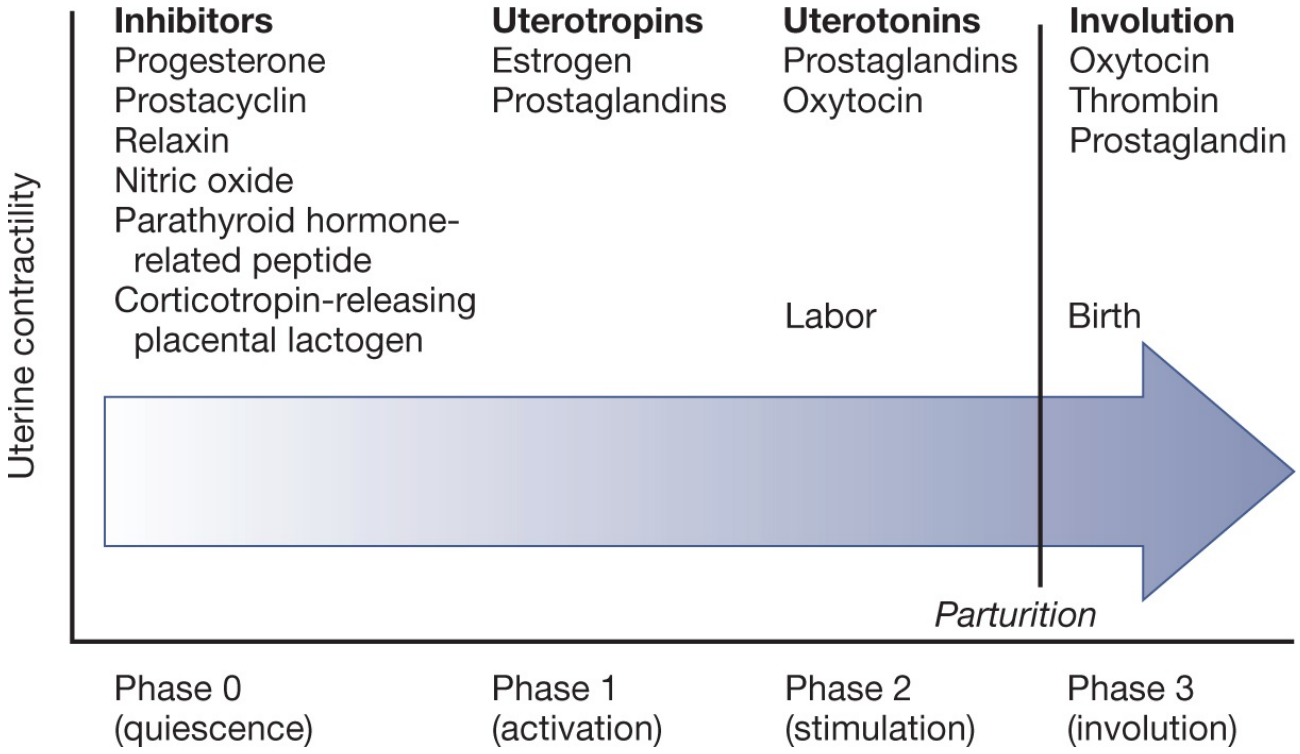

Figure 24-1 Phases of parturition.

Phase 0, Quiescence: Period in late pregnancy of uterine quiescence. Inhibitors of uterine contractions include progesterone, prostacyclin, relaxin, nitric oxide, and other hormones.

Phase 1, Activation: Uterotropins (e.g., estrogen) stimulate upregulation of myometrial receptors for oxytocin and prostaglandins, and activation of gap junctions between myometrial cells.

Phase 2, Stimulation: Uterotonins (e.g., oxytocin and prostaglandins) promote labor progression.

Phase 3, Involution: Uterine involution after birth is mediated by oxytocin and possibly thrombin.

Phase 1: Activation

Increases in myometrial excitability, spontaneous activity, and responsiveness to substances

that stimulate uterine contraction are the primary changes that the uterus undergoes in the transition from quiescence to activation.[22] The activation phase of parturition is characterized by loss of progesterone dominance. The uterus has two forms of progesterone receptors, which have opposing functions. Progesterone primarily binds to the progesterone receptor-B (PR-B) during pregnancy; this binding suppresses inflammation and induces uterine quiescence. During activation, the shortened progesterone receptor-A (PR-A) preferentially binds to progesterone, promoting the dominant pro-inflammatory effects associated with labor.[23] The increased concentration of PR-A relative to PR-B causes a functional progesterone withdrawal without altering the circulating progesterone concentrations.[24-27] Similarly, progesterone stimulates nitric oxide synthesis, which inhibits smooth muscle contraction. When these effects of progesterone, prostacyclin, relaxin, and nitric oxide—which are present during the quiescent period cease, increased uterine activity ensues.

Under the influence of estrogen, uterine myometrial cells express receptors for prostaglandins and oxytocin and develop gap junctions that allow direct communication between muscle fibers. *Gap junctions* are transmembrane proteins that create a pore—that is, a line of communication—between two adjacent myocytes. The action potentials that initiate contraction activity propagate through gap junctions, resulting in synchronous uterine contractions characterized by generation of force along a short distance at low velocity.

Prostaglandins facilitate uterine contractions, increase myometrial sensitivity to oxytocin, and stimulate formation of gap junctions. In labor, PGE_2 favors the prostaglandin EP3 receptor over the prostaglandin EP1 receptor, thereby stimulating uterine contractility through binding to the EP3 receptor.[28]

Role of the Placenta in Labor Initiation

The declining influence of progesterone and nitric oxide also contributes to increased production of corticotropin-releasing hormone (CRH) by the placenta.[23,29] Placenta-derived CRH levels peak at the time of birth, which suggests the placenta has an important role in the timing of labor onset and birth. Placental CRH is transported to the fetus, where it stimulates the fetal hypothalamic–pituitary–adrenal axis, promoting cortisol production by the fetal adrenal gland. Cortisol-induced maturation of fetal lungs triggers increased pro-inflammatory surfactant and phospholipid production, thereby serving as a fetal mechanism for inducing maternal uterine contractions mediated in part by stimulation of prostaglandin synthesis in the intrauterine tissues.[19] CRH also stimulates fetal adrenal production of dehydroepiandrosterone sulfate (DHEA-S), which serves as a substrate for estrogen production, enhancing the fetal influence on the onset and progression of labor. Fetal membranes, which represent the maternal–fetal interface, serve as a vehicle for communication of these hormones between the fetal and maternal systems to stimulate labor.[30,31]

CRH influences the transition from progesterone to estrogen dominance in labor through stimulation of fetal adrenal activity, which increases the fetal production of DHEA-S. The placenta, in turn, converts DHEA-S to estrogens that oppose the function of progesterone. Contractile activity is also modulated by CRH through the promotion of fetal membrane production of the stimulatory prostaglandins $F_2\alpha$ and E_2 and through uterine smooth muscle cell

signaling that increases calcium availability.[32]

Role of Inflammation in Labor Initiation

The activation and stimulation stages of labor are characterized by a heightened state of inflammation. At the onset of labor, leukocytes invade the myometrium, cervix, chorio-decidua, and amnion.[33] Pro inflammatory cytokines released by activated leukocytes promote calcium entry into uterine smooth muscle cells and increased prostaglandin production, enhancing uterine contractions. Neutrophils release enzymes that further degrade extracellular matrix proteins, including fetal fibronectin and collagen, to allow for progressive dilation. Inflammatory cytokines and degrading matrix metalloproteinase enzymes are likewise increased in the fetal membranes, contributing to their weakening and eventual rupture.

Phase 2: Stimulation of Uterine Myometrial Activity

The onset of regular, progressive uterine contractions characterizes the stimulation phase of parturition. The influence of oxytocin becomes especially pronounced during the stimulation phase of labor. Produced in the hypothalamus and secreted via the posterior pituitary, oxytocin is released into the maternal circulation in a pulsatile fashion, reaching peak levels during fetal expulsion.[34] Estrogen dominance also initiates expression of oxytocin genes in the chorio-decidua, providing a local source of oxytocin. Binding of oxytocin to myometrial oxytocin receptors stimulates the smooth muscle contractions that characterize active labor through a calcium-dependent pathway. Prostaglandin production in the maternal decidua is also stimulated by oxytocin-receptor binding; thus, the relationship between prostaglandins and oxytocin is bidirectional.[35,36]

Changes in oxytocin receptor number and sensitivity—rather than the production and release of oxytocin itself—serve as a primary influence on the strength and frequency of uterine contractions during active labor.[29] This relationship has important clinical implications. First, the affinity of oxytocin for its receptor in the uterine fundus increases,[37] maximizing the effect of this hormone even without an increase in the oxytocin plasma concentration. Second, the number of oxytocin receptors present on the myometrial cell membranes peaks in early labor, reflecting an increase of up to 200-fold from the number of such receptors present on myometrial cells in the nonpregnant state. The plasma level of oxytocin does not change from prelabor levels during the first stage of labor, but does increase and peak in the second stage of labor, possibly enhanced by fetal oxytocin synthesis, release, and transport to the maternal side of the placenta.[38] Labor and mechanical stretch also increase expression of oxytocin receptors in the uterine myocytes, further enhancing the potential for oxytocin-receptor binding.[36,39]

Similar to the case for other related G-protein–coupled receptors, desensitization of the oxytocin receptor can be induced by exposure of the receptor to increased concentrations of oxytocin in the maternal circulation. This can occur as the result of increasing plasma levels of oxytocin or prolonged exposure to oxytocin administered for induction or augmentation of labor.[40] Prolonged or repeated stimulation of the oxytocin receptors then contribute to downregulation, which reduces the number of receptors available for oxytocin binding. Uterine

contractions become less forceful and less frequent as a result of attenuation of cell signaling and reduced calcium release, potentially leading to impaired labor progress or uterine atony after birth.

Along with oxytocin, the influence of prostaglandins on the myometrium predominates during the stimulation phase. Produced by the amnion, chorion, and decidua, prostaglandins work in a paracrine fashion to promote uterine contractile activity. Prostaglandin production is also stimulated by inflammatory cytokines. Recent evidence suggests additional effects of these changes may include decreased collagen content and area covered by connective tissue, providing a potential explanation for the higher vaginal delivery rates, tachysystole, and uterine rupture noted with administration of PGE_1 in labor.[41]

Mechanism of Uterine Contraction

Contraction of uterine smooth muscle is a phenomenon unique to labor. The uterine myocyte is an excitable smooth muscle cell type that has contractile ability. Triggers for uterine myocyte contraction include mechanical stretch (myogenic) and hormone-receptor binding. Prostaglandins produced by activated myocytes work in a paracrine fashion, stimulating nearby myocytes to depolarize in a wave of contraction,[19] with action potentials being propagated to adjacent myocytes via gap junctions between muscle groups.[9]

Uterine smooth muscle contractions are intermittent, which allows for reperfusion of the uterine muscle, placenta, and fetus between contractions. Each contraction builds in intensity, reaches its peak, and then decreases in intensity until the muscle returns to a state of relaxation, which persists until the next contraction begins. This pattern is often referred to as the increment, acme, and decrement phases of contraction.

The smooth muscle (myometrium) in the uterus is anatomically different from other types of smooth muscle. Located between the decidua and the perimetrium, the myometrium consists of four muscle layers, each of which produces a distinct response to substances that promote or inhibit contractions. The inner circular muscle layer runs perpendicular to the long axis of the uterus in a spiral fashion, while the two outer layers run parallel to this axis. The middle layer has blood vessels running throughout the interlacing fibers. The uterine myocytes are organized in a bundle, contributing to the generation of tension under local stimulation by uterotonic hormones. The uterine muscle is thickest in the fundus, which demonstrates the greatest contractile strength. The fundal portion of the uterus becomes the active segment (**Figure 24-2**).[42] Uterine muscle becomes thinner toward the lower uterine segment in the isthmus; this thinner lower uterine segment forms the muscular tube through which the fetus passes.

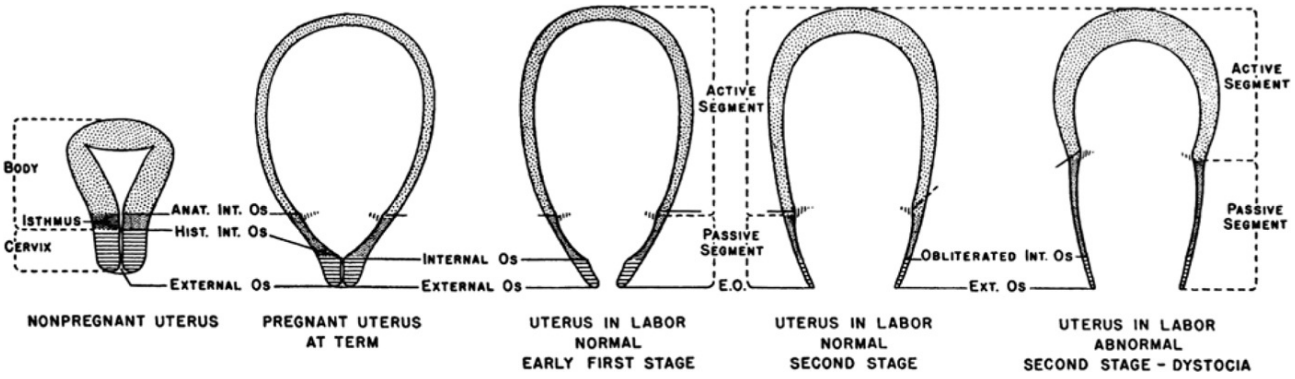

Figure 24-2 Sequence of development of the segments and rings in the uterus in pregnant women at term and in labor. Note the comparison between the uterus of a nonpregnant woman, the uterus at term, and the uterus during labor. The passive lower segment of the uterine body is derived from the isthmus; the physiologic retraction ring develops at the junction of the upper and lower uterine segments. The pathologic retraction ring develops from the physiologic ring.

The propagation of the contraction wave is often called the triple descending gradient of fundal dominance, wherein contractions (1) start in the fundus, (2) last longer in the fundus, and (3) progress from the fundus toward the isthmus. Fundal dominance is essential for effective cervical dilation but has not been definitively proved to exist. Nonetheless, the muscle bundles in the uterine fundus progressively shorten with each contraction, causing the upper portion of the uterus to thicken and gradually become a smaller cavity. This reduced fundal capacity, in turn, promotes descent of the fetus toward the more passive lower uterine segment. The lower uterine segment muscle bundles become longer in response to contractions in the fundus, creating a distensible structure that is able to accommodate the fetus, a process that promotes fetal descent. The line of demarcation between the active and passive segments is termed the *physiologic retraction ring*. When labor is obstructed, the active segment becomes so much thicker and shorter that one can sometimes see the line between the two uterine segments when observing the abdomen—the so-called *pathologic retraction ring* or *Bandl's ring*.

At the cellular level, contractile units made of myosin and actin that are found in uterine smooth muscle myocytes promote the generation of tension that leads to synchronous smooth muscle contraction. The interaction between the thin actin and thick myosin filaments is central to the generation of force (**Figure 24-3**).[43] Myosin is arranged in two heavy chains and two light chains, with a globular head attached to a tail that protrudes from the heavy chains at regular intervals. The myosin head also contains a site that binds to actin, generating force that is carried along the myosin tails. Entry of calcium into the myocyte in response to specific stimuli prompts intracellular release of additional calcium from a reservoir in the sarcoplasmic reticulum through binding of inositol triphosphate (IP_3) to sarcoplasmic reticulum receptors. Calcium binding to the smooth muscle protein calmodulin causes activation of the myosin light-chain kinase (MLCK) enzyme. In turn, MLCK phosphorylation of

the light chain on the myosin head leads to establishment of a structural link between actin and myosin, catalyzed by myosin adenosine triphosphatase (ATPase) enzyme activity on the myosin head. Energy release from myosin ATPase activity causes the structural cross-bridge to shorten the muscle. At this point, the myosin head rotates and pulls on actin, which generates force and shortening. The action potentials that pass through gap junctions facilitate contraction of adjacent uterine smooth muscle bundles, which results in a coordinated wave of uterine contraction. Decreased intracellular calcium concentrations and the action of myosin light-chain phosphatase enzymatically reverses the actin–myosin linkages through removal of a phosphate from the myosin light chain, prompting smooth muscle relaxation.

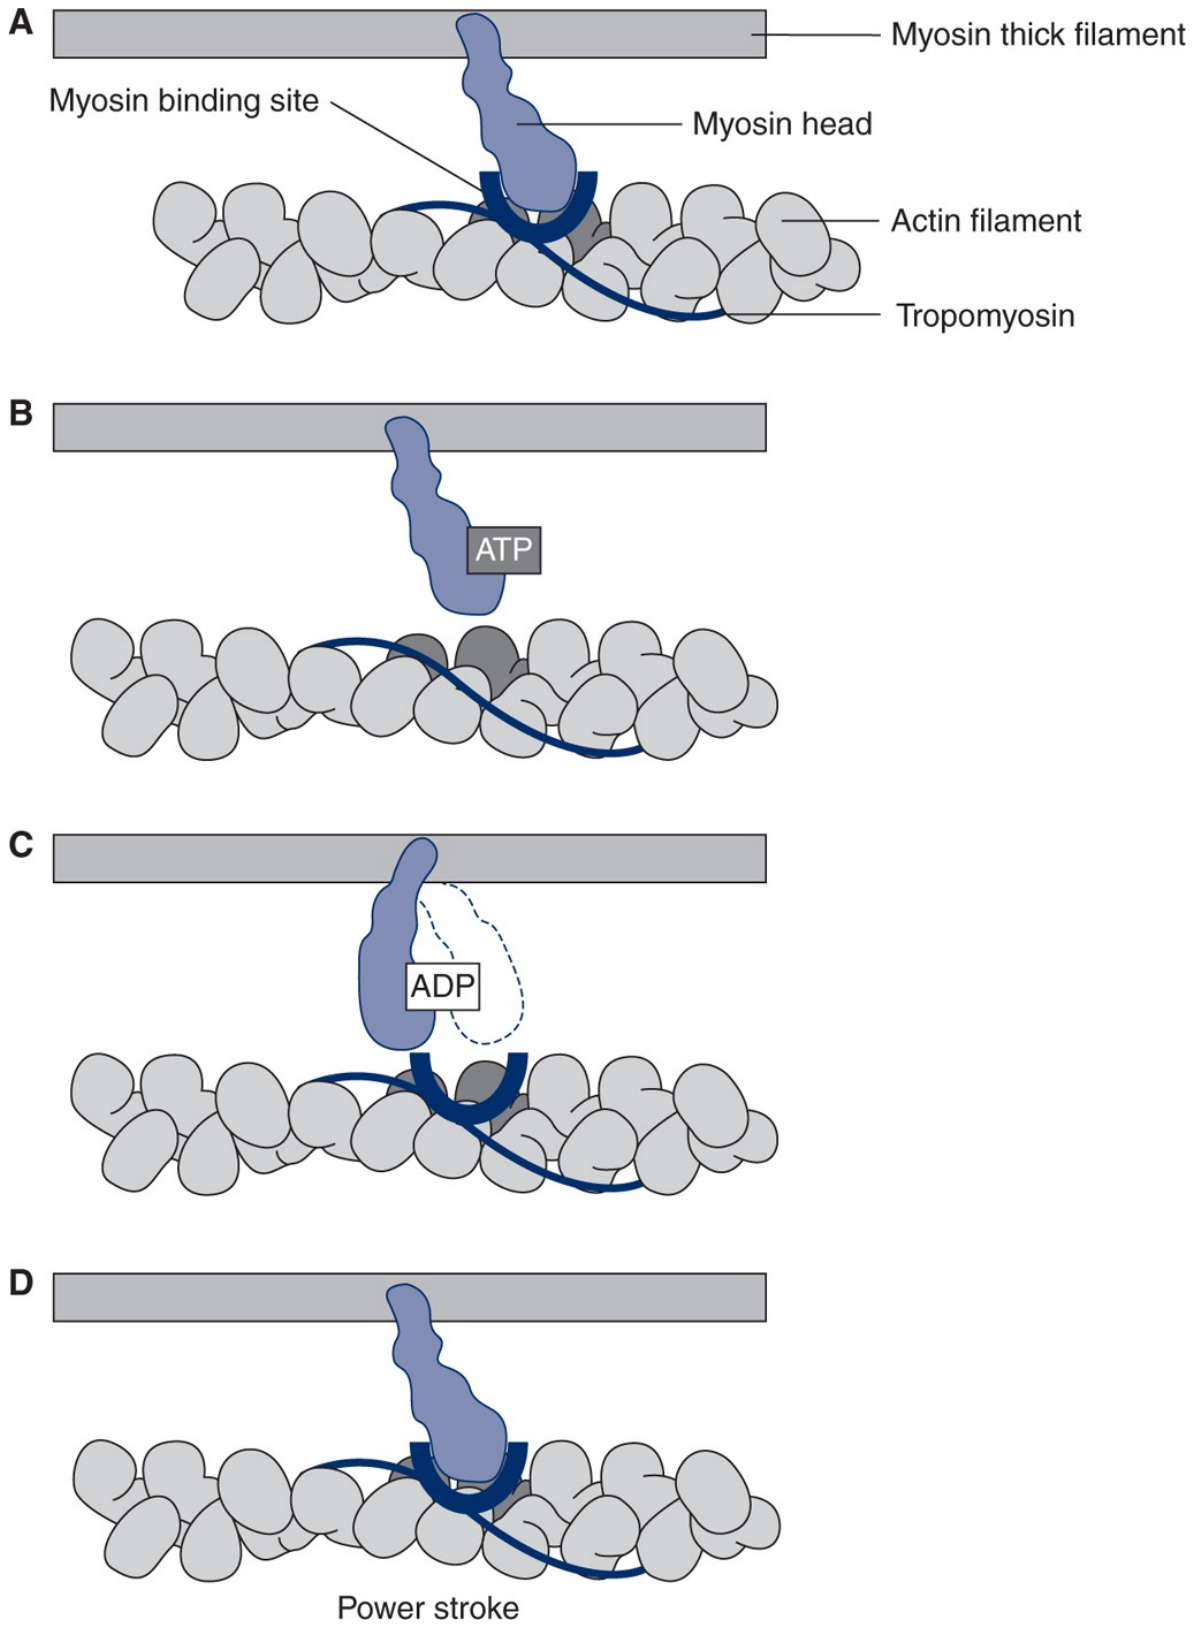

Figure 24-3 Uterine muscle contraction. **A.** Attached: At the start of the cycle, the myosin head is attached to the myosin binding site on the actin filament. **B.** Recharging: A molecule of ATP binds to a large cleft at the back of the myosin head, which causes a slight change in the conformation of the myosin binding site, which reduces the affinity the myosin head has for the myosin binding site. **C.** Cocked: The cleft on the myosin head closes around the ATP, which causes a large shape change so that the head is displaced along the actin filament by a distance of approximately 5 nm. **D.** Force-generating: As ATP is hydrolyzed to ADP, the myosin head once again binds tightly to the next myosin

binding site on the actin filament and in this process the myosin head essentially ratchets along the actin filament, creating the muscle contraction.

Relaxation involves the removal of contractile stimuli or action of factors that inhibit contractions. Factors that may inhibit this process—and, therefore, that may be used to treat preterm labor contractions—include drugs that stimulate the β-adrenergic signaling pathway (e.g., terbutaline [Brethine]), drugs that inhibit inflammatory pathways (e.g., indomethacin [Indocin]), calcium-channel blockers (e.g., nifedipine [Procardia]), and agents that inhibit the myosin light chain (e.g., magnesium sulfate). In addition, progesterone is used to prevent recurrent preterm labor in women who have experienced a previous preterm birth.

Role of Oxytocin

Oxytocin, a potent uterotonic, is a small nine-amino acid peptide. The word *oxytocin* is derived from the Greek *oxys*, which means "quick," and *tokos*, which means "birth." Many organs have oxytocin receptors, including the uterus, breast, kidney, and central nervous system. Although the primary source of oxytocin is the hypothalamus, oxytocin is also synthesized in the uterus, placenta, corpus luteum, and fetus. Along with exerting uterotonic effects, oxytocin stimulates contraction of myoepithelial cells in the lactating breast (i.e., the let-down reflex), increases sexual arousal in women and men, and may have profound effects on initial maternal–infant bonding. In animal studies, oxytocin has been shown to regulate many maternal behaviors.

For many years, oxytocin was thought to initiate the stimulatory phase of parturition.[37] It is now known that this peptide plays an important role in maintaining labor but most likely does not initiate labor. Oxytocin is manufactured in the hypothalamus and released from the posterior pituitary in a pulsatile fashion. Between 36 and 39 weeks' gestation, pulsations increase in frequency and amplitude in a diurnal rhythm, with maximum plasma levels occurring at night. Trending oxytocin pulses may play a role in the increased frequency of Braxton Hicks contractions in the final weeks of pregnancy.

During spontaneous labor, oxytocin pulses occur approximately 4 times per 30 minutes in the first stage of labor and 7 times per 30 minutes in the second stage. The biologic half-life of this molecule is approximately 3 to 4 minutes. Plasma levels of oxytocin do not correlate with uterine contractility or cervical dilation. Instead, the number and distribution of oxytocin receptors on the surface membranes of myocytes influence the strength and frequency of uterine contractions in labor. The number of oxytocin receptors in the uterus increases 100-fold during the last weeks of pregnancy, reaching a maximum during labor.[34,35] This increase in receptor density explains the increased sensitivity to oxytocin displayed by uterine myometrial cells. Early in pregnancy, the uterus is not sensitive to oxytocin. Myometrial receptivity starts at approximately 20 weeks' gestation and slowly increases over the last half of pregnancy.

The pivotal role of oxytocin receptors also explains why oxytocin can cause both uterine

contractions and uterine atony. The oxytocin receptors can become saturated after a period of time of constant agonist stimulation and downregulate via endocytosis. Thus, when synthetic oxytocin infusions are used for induction or augmentation of labor, the woman may have an increased risk for uterine atony after birth secondary to downregulation of oxytocin receptors.

Clinical Stages of Labor

Labor and birth are divided clinically into four stages. The *first stage of labor* includes three phases. The *latent phase* is the initial period of time wherein contractions become regular, more painful, and more frequent but little cervical dilation occurs. In the *active phase* of labor, the cervix dilates over a period of hours to complete dilation (i.e., 10 centimeters). Historically, it was believed that the active phase of labor includes a *transition phase* that occurs between 8 and 10 centimeters of cervical dilation, when progress is slower. Recent studies of labor progress have not demonstrated that this phase appears consistently in all women.

The *second stage of labor* refers to the time period from complete dilation to birth of the newborn. During the second stage of labor, the woman actively pushes in concert with uterine contractions. When women do not have regional analgesia, the urge to push or bear down is involuntary and thought to occur secondary to pressure of the fetal head on the vaginal floor and rectum.

The *third stage of labor* is defined by the time between birth of the newborn and birth of the placenta. The *fourth stage of labor* is the first hour after birth. The fourth stage of labor is not always referred to in clinical texts but is considered important clinically because it is the time during which the woman is at highest risk for postpartum hemorrhage.

The normal durations and clinical management of each stage of labor are reviewed in more detail in the *First Stage of Labor*, *Second Stage of Labor and Birth*, and *Third Stage of Labor* chapters.

Maternal Fetopelvic Relationships During Labor

The obstetric pelvic types and fetopelvic relationships are reviewed in the *Anatomy and Physiology of Pregnancy* chapter. Confirmation of the fetal presentation and position is made during a vaginal examination once the cervix is dilated enough to feel the fetal presenting part. Fetal suture lines and fontanels, or portions of the fetal face, breech, external genitalia, or fetal extremities (hands or feet), are palpated. Cephalic vertex presentations are by far the most common, so familiarity with the basic landmarks of the fetal skull is essential for monitoring labor progress. The position of a fetus in a vertex presentation is determined vaginally by feeling the anterior or posterior fontanel (the fontanel shape and number/direction of the sutures leading off the fontanel) and identifying which fontanel is in which side and portion of the maternal pelvis. When identifying the parts of the fetal skull, one starts by finding the sagittal suture, which runs directly between the anterior fontanel at one end and the posterior fontanel at the other end. As the fetus passes through the maternal pelvis, additional measurements that describe the relationship of the fetus to the pelvis during labor are noted and documented in the health record, including station, synclitism, asynclitism, caput succedaneum, and molding.

Station

Station is where the lowermost part of the fetal presenting part resides relative to an imaginary line drawn between the ischial spines of the woman's pelvis (**Figure 24-4**). The line between the ischial spines is called 0 station. Station is measured in terms of the number of centimeters above or below this line between the ischial spines. When the presenting part is above the spines, station is designated as –1, –2, –3, –4, or –5. When the lowermost part of the presenting part (the bone, not swelling or soft tissue) is lower than the level of the ischial spines, the presenting part is at +1, +2, +3, +4, or +5 station. When the fetus is at 0 station, the biparietal diameter is most always descended through the inlet and, thus, is engaged. When the presenting part is at +5 station, it will be visible at the vaginal introitus.

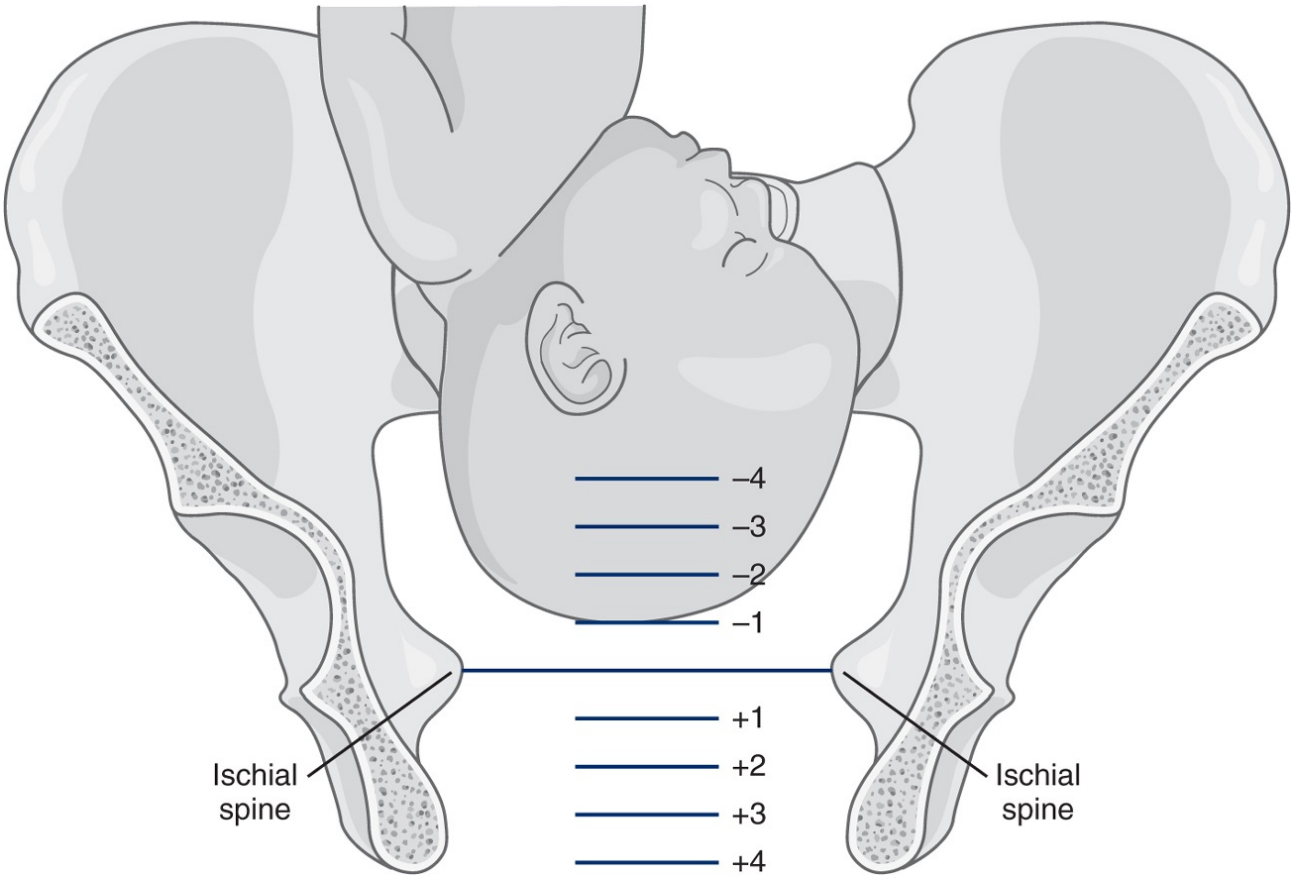

Figure 24-4 Station, or level of descent of the head of the fetus through the pelvis. The location of the forward leading edge (lowest part of the head) is designated in centimeters above or below the plane of the interspinous line.

Synclitism and Asynclitism

Synclitism and *asynclitism* are terms that describe the relationship of the sagittal suture of the fetal head to the symphysis pubis and the sacrum of the maternal pelvis—a relationship determined when the anteroposterior diameter of the fetal head is in alignment with the transverse diameter of the pelvic inlet. This orientation places the sagittal suture line of the fetal skull in the same line as the transverse diameter of the pelvic inlet, and the occiput of the fetal head in the transverse portion of the maternal pelvis. With synclitism, the sagittal suture is located midway between the symphysis pubis and the sacral promontory. With asynclitism, the fetal neck is tilted so that the fetal head leans laterally toward the fetal shoulder somewhat. The alignment of the sagittal suture and transverse diameter of the maternal pelvis are not exact with asynclitism, and the sagittal suture tends to be closer to the symphysis pubis or to the sacral promontory (**Figure 24-5**).

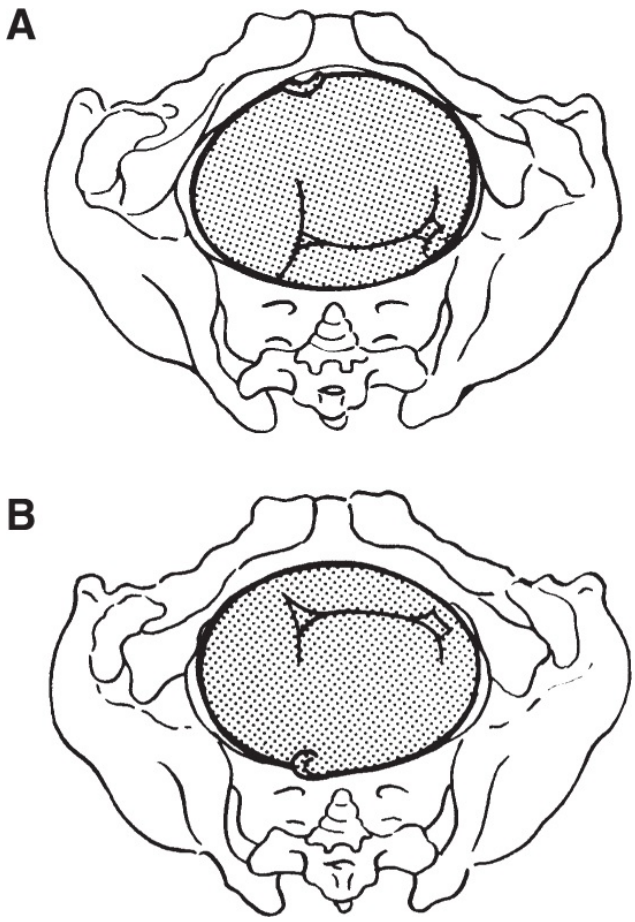

Figure 24-5 Asynclitism. **A.** Anterior. **B.** Posterior.

Determination of anterior asynclitism or posterior asynclitism is based not on the maternal pelvic structure to which the sagittal suture is closer, but rather on which parietal bone is dominant. Therefore, anterior asynclitism occurs when the anterior parietal bone (the one closest to the symphysis pubis) becomes the lowermost or leading part of the presenting part, due to flexion of the head toward the sacral promontory, causing the sagittal suture to lie closer to the sacral promontory. Posterior asynclitism occurs when the posterior parietal bone (the one closest to the sacral promontory) becomes the lowermost part of the presenting part as a result of flexion of the head toward the symphysis pubis, causing the sagittal suture to lie closer to the symphysis pubis. In normal labor, the fetal head usually enters the pelvic inlet with a moderate degree of posterior asynclitism and then changes to anterior asynclitism as it descends farther into the pelvis before the mechanism of internal rotation occurs. This sequential change from posterior to anterior asynclitism facilitates the mechanism of descent; it is an accommodation by the fetus to take advantage of the roomiest portions of the true pelvis.

Molding and Caput Succedaneum

Molding and caput succedaneum are both conditions that result from pressure exerted on the fetal head by the maternal structures of the birth canal during labor and birth. Molding is the change in the shape of the fetal head as a result of the soft skull bones' overriding, or overlapping, one another because they are not yet completely fused, so that movement is

possible at the location of the sutures. Minor degrees of molding occur as the fetal head negotiates the maternal pelvis and are initially considered a normal finding.

The shape of the head depends on the presentation and attitude, which determines the parts of the skull that present first and, therefore, are subjected to pressure. Occiput cephalic presentations are most common, so molding usually occurs as the parietal bones override the occipital bone, which in effect obliterates or minimizes the posterior fontanel. A bony ridge may be palpable where the parietal bones override the occiput. When the parietal bones overlap at the sagittal suture, which is not uncommon, the parietal bone that was anterior in the pelvis overlaps with the "posterior" parietal bone, which was depressed because of pressure from the sacral promontory. Therefore, when a fetus in a right occiput transverse (ROT) position rotates to right occiput anterior (ROA), the left parietal bone overrides the right parietal bone; the reverse is true for a fetus in a left occiput transverse (LOT) position that rotates to left occiput anterior (LOA).

In regard to the overriding of the parietal bones, the location of the left and right parietal bones (either anterior or posterior) should not be confused with anterior and posterior asynclitism. Whether the left or right parietal bone is considered "anterior" is based solely on whether the occiput is to the left or right of the pelvis, which then determines which bone lies closest to the symphysis pubis and which is closest to the sacrum.

Molding involves the entire skull, with overlapping in one area being counterbalanced by movement elsewhere. This creates harmony between the base and the vertex of the skull and prevents destructive tension and possible rupture of the cranial membrane, the dura mater.

Caput succedaneum (commonly referred to as "caput") is the formation of an edematous swelling over the most dependent portion of the presenting fetal head. Pressure around the presenting part by the cervical opening produces congestion and edema of the portion of the fetal head that presents against the cervical opening. If the fetal membranes are ruptured and the fetal head (rather than the membranes) is functioning as the dilating wedge against the cervical opening, a greater amount of caput succedaneum will likely form. If the fetal head is unusually molded or significant caput is present, the head may not be engaged in the pelvis at all, so caput and molding can be clinically quite important. After birth, caput succedaneum can be differentiated from the more serious condition known as cephalohematoma by the fact that caput succedaneum crosses suture lines as a generalized swelling, whereas a cephalohematoma (bleeding beneath the periosteum) may occur over more than one cranial bone but is limited to each individual bone and does not cross any sutures.

The formation of a few millimeters of caput succedaneum is considered normal. A small caput succedaneum may develop during a somewhat prolonged labor resulting from uterine inertia with weak contractions. Formation of extensive caput succedaneum, making the identification of fetal sutures and fontanels impossible, combined with a more severe degree of molding, is usually seen when the pressure has been great and labor prolonged; cephalopelvic disproportion must be suspected in such a case. A sizable caput may also be seen from positional pressure when the fetus was in an occipitoposterior position for a relatively prolonged period. It is important to make sure station is determined based on the level of the fetal skull bone (usually the occiput) and not based on where the caput is in relation to the ischial spine. If caput, which precedes the bone, is used to determine fetal station, the clinician

might mistakenly assume the fetal head is engaged when it is not engaged, or descending when caput is increasing but the head is not descending.

Cardinal Movements of Labor

The *cardinal movements of labor*, also called the mechanisms of labor, describe the movements made by the fetus during labor (**Figure 24-6**) and immediately before birth to negotiate the diameters of maternal pelvis (**Table 24-1**). Understanding the cardinal movements of labor requires knowing the essential average diameters of the fetal head. Although the majority of fetuses enter labor in a cephalic presentation, knowledge of the cardinal movements of labor for each fetal presentation, position, and denominator is essential for the midwife. The cardinal movements are engagement, descent, flexion, internal rotation, extension, restitution, external rotation, and lateral flexion or expulsion.

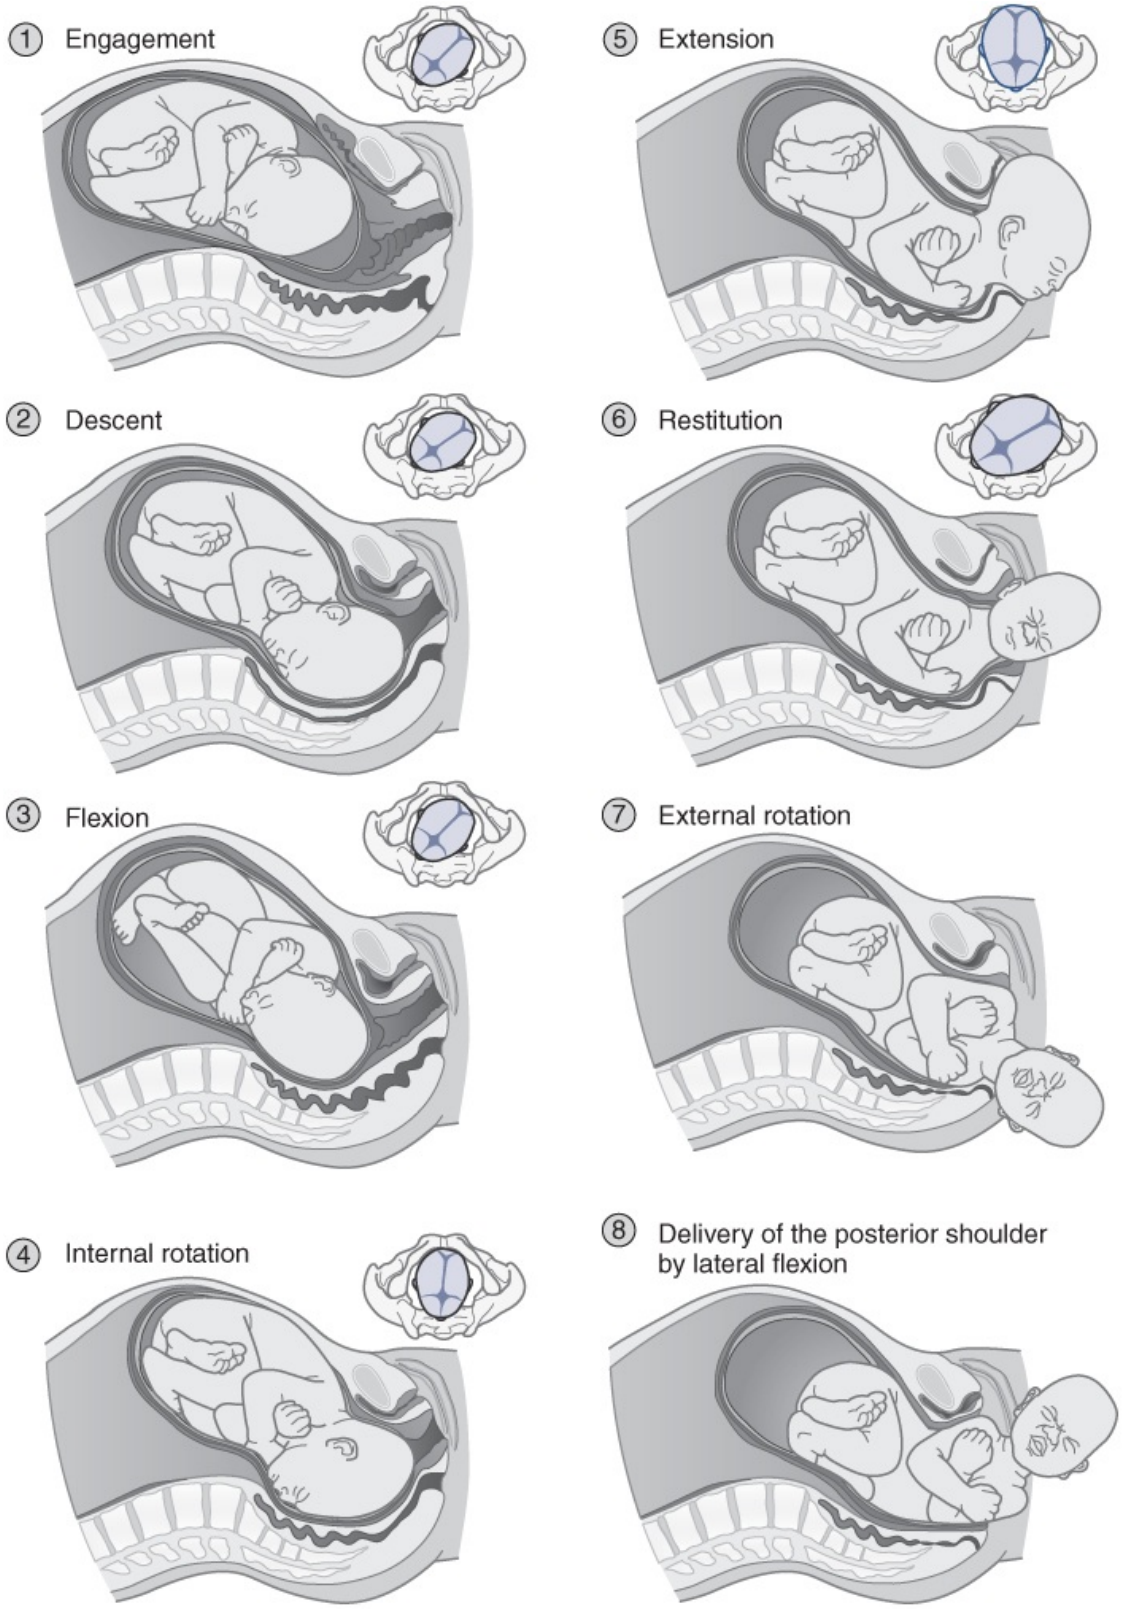

Figure 24-6 Cardinal movements of labor for a fetus in an occiput anterior position.

Table 24-1	Cardinal Movements of Labor for Occiput Anterior and Persistent Posterior Positions

Cardinal Movement	Occiput Anterior	Persistent Posterior

Engagement	ROT or LOT position	Right or left oblique diameter
Descent	Occurs throughout	Occurs throughout
Flexion	Suboccipitobregmatic diameter presenting	Usually less completely flexed
Internal rotation	45° LOA or ROA, 90° LOT or ROT, 135° LOP or ROP to OA	45° LOP or ROP to OP
Extension	Birth of head by extension	Birth of head by first flexion and then extension
Restitution	45° to LOA or ROA	45° to LOP or ROP
External rotation	45° to LOT or ROT	45° to LOT or ROT
Lateral flexion or expulsion	Birth of shoulders by lateral flexion	Birth of shoulders by lateral flexion

Abbreviations: LOA, left occiput anterior; LOP, left occiput posterior; LOT, left occiput transverse; OA, occiput anterior; OP, occiput posterior; ROA, right occiput anterior; ROP, right occiput posterior; ROT, right occiput transverse.

Engagement occurs when the biparietal diameter of the fetal head has passed through the pelvic inlet. *Descent* occurs throughout labor and, therefore, is requisite to and occurs simultaneously with the other cardinal movements. Descent is the result of contractions and maternal pushing efforts during the second stage.

Flexion is essential to further descent once engagement has occurred. During this third cardinal movement, the smaller suboccipitobregmatic diameter becomes the widest fetal head diameter that traverses the maternal pelvis. When the fetal head is flexed so that the fetal chin rests on the thorax, the suboccipitobregmatic is substituted for the larger fetal head diameters that exist when the fetal head is not completely flexed, is in a military attitude, or is in some degree of extension. Flexion occurs when the fetal head meets resistance; this resistance increases with descent and is first met from the cervix, then from the sidewalls of the pelvis, and finally from the pelvic floor. Some degree of flexion, therefore, may occur prior to engagement.

Internal rotation brings the anteroposterior diameter of the fetal head into alignment with the anteroposterior diameter of the maternal pelvis. Most commonly, the occiput rotates to the anterior portion of the maternal pelvis, beneath the symphysis pubis. If internal rotation has not occurred by the time the fetal head has reached the pelvic floor, it takes place shortly thereafter. Internal rotation is essential for vaginal birth to occur, except in unusually small fetuses. The pelvic inlet has a larger transverse diameter than anteroposterior diameter; the midplane and the outlet have larger anteroposterior diameters than transverse diameters. Internal rotation is effected by the V-shape of the pelvic floor musculature and the decreased dimensions of the pelvic cavity. The amount of internal rotation is determined by the distance the occiput must travel from its original position on entering the pelvis to the occiput anterior or occiput posterior position that precedes birth. This distance is expressed in degrees, as it is a portion of the arc of a circle that is being traversed.

When the fetal occiput rotates from an LOP (left occiput posterior), ROP (right occiput posterior), LOT, or ROT position, the shoulders also rotate with the head until the LOA or ROA position has been reached. As the occiput rotates the final 45 degrees into the occiput anterior (OA) position, the shoulders do not continue their rotation with the head, but instead

enter the pelvic inlet in one of the oblique diameters (the left oblique diameter for an LOA and the right oblique diameter for an ROA). The entire cardinal movement, therefore, has the effect of turning the fetus's neck by 45 degrees.

Birth of the head occurs by *extension* (of the fetal head so the chin lifts up from the thorax) in occiput anterior births. This cardinal movement of labor is different when the occiput rotates to an occiput posterior (OP) position, as explained later in this chapter. Extension must occur when the occiput is anterior because of the resistant force of the pelvic floor, which has a curve called the curve of Carus that directs the head upward to the vaginal introitus (**Figure 24-7**). The *curve of Carus* is the lower exiting end of the pelvic curve; the fetus and placenta must follow this curve to be born. The pelvic cavity actually resembles a curved cylinder, such that the direction of either the baby or the placenta coming through it is first downward from the axis of the inlet to just above the tip of the sacrum, and then forward, upward, and outward to the vaginal opening. The suboccipital region impinges under the symphysis pubis and acts as a pivot. At this point, the fetal head is positioned so that further pressure from the contracting uterus and maternal pushing serve to further extend the head as the vulvovaginal orifice opens. Thus, the head is born by extension as the occiput, sagittal suture, anterior fontanel, brow, orbits, nose, mouth, and chin sequentially sweep over the perineum. The suboccipitofrontal diameter is, therefore, the largest anterior–posterior diameter to pass through the vulvovaginal orifice.

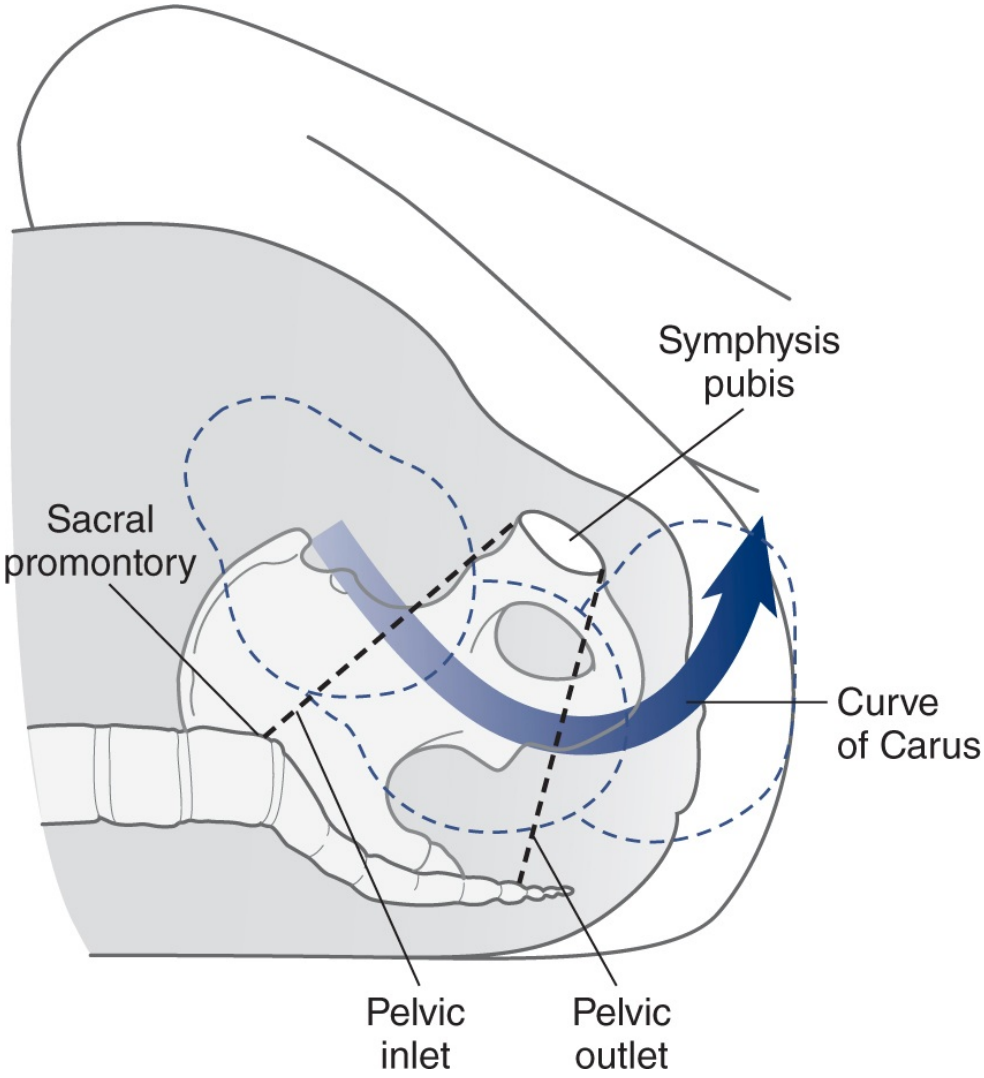

Figure 24-7 Curve of Carus.

Restitution is the rotation of the head 45 degrees to either the left or the right, depending on the direction from which it rotated into the OA or OP position. In effect, in restitution, the neck turns back so that the head is again at a right angle with the shoulders. The sagittal suture is now in one of the oblique diameters of the pelvis, and the bisacromial diameter of the fetus is in the other oblique diameter of the pelvis.

External rotation occurs as the fetus's shoulders rotate 45 degrees, bringing the bisacromial diameter into alignment with the anteroposterior diameter of the pelvic outlet. This causes the head to rotate externally another 45 degrees into the LOT or ROT position, depending on the direction of restitution.

Birth of the shoulders and body occurs by *lateral flexion* to accommodate the curve of Carus. The anterior shoulder comes into view at the vaginal opening, where it impinges under the symphysis pubis; the posterior shoulder then distends the perineum and is born by lateral flexion. After the shoulders are assisted to exit, the remainder of the body follows the curve of Carus and the fetus is readily born.

Cardinal Movements for Occiput Anterior Position

Variations of the eight basic positional movements are determined by the position of the fetus and must be delineated for each movement. When a fetus begins labor in the LOA, LOT, LOP, ROA, ROT, or ROP position and delivers in an occiput anterior position, the cardinal movements are as follows:

1. *Engagement* takes place for the fetus in the LOT and ROT positions, with the fetal sagittal suture in the transverse diameter of the pelvic inlet and the biparietal diameter of the fetus in the anteroposterior diameter of the pelvic inlet. For the LOA, ROA, LOP, and ROP positions, engagement of the fetal head takes place with the sagittal suture in one of the oblique diameters of the pelvis (right oblique diameter for the LOA and ROP positions and left oblique diameter for the ROA and LOP positions). The biparietal diameter, therefore, is in the oblique diameter of the pelvis opposite from the one the sagittal suture is in. The sagittal suture is used as the fetal landmark that determines in which oblique diameter the fetal head enters the pelvis.
2. *Descent* occurs throughout labor.
3. *Flexion* substitutes the suboccipitobregmatic diameter for the diameter that entered the pelvic inlet.
4. *Internal rotation* takes place as follows: 45 degrees (for the LOA and ROA positions), 90 degrees (for the LOT and ROT positions), and 135 degrees (for the LOP and ROP positions—referred to as long arc rotation). The fetal head is now in the OA position in the anteroposterior diameter of the mother's pelvis.
5. Birth of the head occurs by *extension*.
6. *Restitution* is 45 degrees to the LOA or ROA position. The fetal head moves left if the fetus began the cardinal movements of labor with the occiput in the left side of the pelvis; it moves right if the fetus began the cardinal movements of labor with the occiput in the right side of the pelvis.
7. *External rotation* is 45 degrees to the LOT or ROT position. The direction of the rotation of the shoulders is determined by the direction of restitution. External rotation brings the bisacromial diameter of the shoulders into the anteroposterior diameter of the maternal pelvis.
8. Birth of the shoulders and body occurs by *lateral flexion* via the curve of Carus.

Cardinal Movements for Persistent Occiput Posterior Position

A persistent posterior position occurs when the fetus in a left or right occiput posterior position undergoes internal rotation through a short arc of 45 degrees to a direct OP position in the anteroposterior diameter of the maternal pelvis, instead of the more common long arc rotation of 135 degrees to a direct OA position, as described in the previous subsection. Short arc rotation is much less common, occurring approximately 6% to 10% of the time. It is most frequently observed in women with an anthropoid or android type of pelvis.

The cardinal movements of labor for a fetus that begins in the LOP or ROP position and delivers in the OP position are the same as for those fetuses that rotate to an occiput anterior position except as explained here:

1. *Engagement* takes place in the right oblique diameter for the ROP position and in the left oblique diameter for the LOP position.
2. *Descent* occurs throughout.
3. *Flexion* is the same.
4. *Internal rotation* takes place, with the fetal head rotating 45 degrees to an occiput posterior position in the anteroposterior diameter of the mother's pelvis.
5. Birth of the head occurs by the double cardinal movements of first *flexion* and then *extension*. The sinciput impinges beneath the symphysis pubis and becomes the pivotal point for delivery of the head. The head stays flexed as the occiput distends the perineum and is born to the nape of the neck. The remainder of the head is then born by extension, starting with the anterior fontanel and ending with the chin, as the head falls back toward the rectum, with the face looking upward.
6. In *restitution*, the fetal head rotates 45 degrees to the LOP or ROP position, depending on whether internal rotation was from the LOP or ROP position.
7. In *external rotation*, the fetal head rotates 45 degrees to the LOT or ROT position.
8. Birth of the shoulders and body occurs by *lateral flexion* via the curve of Carus.

Persistent posterior position is considered a variation of normal labor. This position may sometimes be maintained for the entire second stage of labor, but not always. A woman with a fetus in a persistent posterior position may experience additional and often severe back pain; alternatively, women who experience severe back pain in labor may have a fetus in an occiput anterior position, so this symptom is not diagnostic for fetal position. Diagnosis of a posterior position is made by abdominal examination and confirmed by vaginal examination or ultrasound. Observation of the contour of the woman's abdomen may give the first clue of a posterior position. A depression in the shape of a saucer is commonly seen at or just below the woman's umbilicus. This depression occurs because the fetus's shoulder is posterior rather than anterior, so there is not a smooth anterior curve but rather what looks like a gap between the cephalic and podalic poles or feet of the fetus. If the head is not engaged, there is a bulge between the symphysis pubis and the saucer-shaped depression.

Maternal Systemic Adaptations in Labor

The adaptations of pregnancy that developed progressively during the quiescent time of gestation provide the essential preparation for the final stages of pregnancy in the intrapartum period. The significant physiologic demands associated with the activation and stimulation phases of labor require maternal adaptations to meet the transient challenges imposed on the maternal and fetal systems.

Cardiovascular Adaptations

The placenta/maternal interface is a low-pressure, high-volume compartment, and blood volume must expand in pregnancy to accommodate this space. The increase in the maternal blood volume reaches its acme of approximately 40% compared to the nonpregnant blood volume in the early third trimester, and is accompanied by a concomitant increase in the cardiac output and left ventricular stroke volume.[44] Oxygen-carrying capacity is supplemented by similar increases in red blood cell (RBC) production, thereby maximizing delivery of oxygen to both the maternal systems and the fetus. Maternal vascular system hypertrophy is promoted by nitric oxide–mediated vasodilation and a progesterone-mediated reduction in vascular tone and resistance, thereby enabling the woman to accommodate the increased blood volume and perfusion requirements of the maternal–placental–fetal unit. The increased plasma volume and decreased viscosity reduce resistance to flow—a phenomenon further supported by decreased vascular resistance; the result is the development of a physiologic arteriovenous shunt that promotes accommodation of increased blood volume and cardiac output.

During labor and birth, additional marked and rapid hematologic adaptations occur secondary to uterine contractions, pain, exertion, loss of the placental compartment at birth, and uterine involution.[45] The woman's systolic and diastolic blood pressures both increase during uterine contractions, returning to baseline between contractions.[44,45] Blood pressure and heart rate may also increase due to pain. Although heart rate often increases, the direction of change is variable, such that both increases and decreases can be observed. The laboring woman's pulse commonly increases during contractions and decreases between contractions. Her cardiac output increases by an additional 10% to 15% in first-stage labor and by as much as 50% in second-stage labor, due primarily to increased stroke volume.[44,46] Cardiac output can also be affected by maternal pain, anxiety, and any anesthetics used.

An inverse relationship exists between myometrial contraction intensity and duration and placental blood flow, with perfusion being reduced during maximal contraction. Restoration of resting tone between contractions provides the opportunity to reestablish perfusion. Approximately 500 to 900 mL of maternal blood flows through the maternal side of the placental site each minute at term.[47,48] Shifts in blood volume that occur during contractions force approximately 300 to 500 mL of blood into the maternal venous system, contributing to increased venous return. Increases in central venous pressure during the second stage of labor can result from pushing efforts, prompting parasympathetic nervous system stimulation during Valsalva maneuvers. Redistribution of blood flow in the maternal system after delivery of the placenta leads to splanchnic circulation vasoconstriction, shunting an additional 500 mL of

blood from the uteroplacental circulation to the maternal circulation. This auto-infusion phenomenon serves to protect the woman when she experiences the usual blood loss of approximately 500 mL after vaginal delivery, by increasing central venous pressure, ventricular preload, and cardiac output. These numbers are not exact, as measurement of blood volume changes during labor is not easily performed.

A woman's cardiac output increases 60% to 80% immediately after birth as the placental site is removed and extra volume is auto-transfused into the maternal circulation. This is followed by a rapid decrease of maternal blood volume within 10 to 60 minutes, but it can take a few months before cardiovascular indices return to their prepregnant levels.[44,49] These remarkable shifts in blood volume, cardiac output, and systemic venous return can be hazardous for women who have preexisting cardiac disorders.

Hematologic Indices During Labor and Birth

Changes in coagulation factors initiated during pregnancy are enhanced during labor, promoting rapid hemostasis after placental separation. Levels of coagulation factors—most notably factor VIII—are markedly increased during active labor. Tissue factor release from the placenta and decidua activates the extrinsic coagulation pathway, promoting clot development. The procoagulant condition reaches its maximal point after placenta separation, with increases in factor V, platelet activation, and fibrin clot formation. Clot development contributes to reduced circulating fibrinogen and platelets, as these components are utilized in the production of fibrin clots. A simultaneous decrease in fibrolytic activity enhances clot development after placental separation, associated with decreased levels of circulating plasminogen.

After birth, clot dissolution is associated with increased production of fibrin degradation products; moreover, d-dimer may promote an anticoagulant effect, potentially interfering with clot development.[50] Uterine contraction and compression of uterine vessels serve to promote accumulation of clotting factors and hemostasis after placental separation, in turn reducing the risk of excessive maternal blood loss.[51] In the event of uterine atony and maternal bleeding, uterine massage and exogenous uterotonics can be administered to promote contraction and intrinsic vasoconstriction. As uterine blood flow contributes to increases in cardiac output ranging from 1% in the nonpregnant woman to 15% at the end of pregnancy, interference with adequate uterine contraction and hemostasis after placental separation can lead to massive maternal hemorrhage.[52]

A slight degree of leukocytosis occurs gradually over the course of pregnancy. During labor the white blood cell count peaks and can be as high as $20 \times 10^3/mm^3$. The etiology of this rise in leukocytes is not known but it is a normal finding and not indicative of infection. Thus, the white blood cell count is not a clinically useful biomarker for infection during labor.

Respiratory Adaptations

Pregnancy adaptations that lead to reduced total lung capacity, residual volume, and functional residual capacity as well as increased tidal volume[53] promote the respiratory system changes that support the woman's increased oxygen requirements during the activation and stimulation

stages of labor. Increased muscular work, metabolic rate, and oxygen consumption can be major challenges to the maternal respiratory system during labor.

Oxygen consumption increases as a woman's muscular activity increases during uterine contractions. Inter-contraction periods of relaxation allow for reperfusion and restoration of oxygen content to the uterine myometrium. Failure to restore oxygenation to uterine muscle cells over time results in anaerobic metabolism, production of lactic acid, and subsequent ischemic pain that is theorized to contribute to the uterine pain felt during labor.

Pain can also lead to an increased respiratory rate and hyperventilation, promoting respiratory alkalosis. During pushing efforts, voluntary muscle activity further contributes to the increased maternal PCO_2 and base deficit, leading to a decline in maternal arterial pH values. A reduction in the woman's respiratory rate in the third stage of labor promotes the return to the usual acid–base balance, which typically normalizes within 24 hours of delivery.

Gastrointestinal Adaptations

The hormonal and anatomic effects on the gastrointestinal system during pregnancy, including delayed motility and reflux, are retained as the quiescent stage transitions into the activation and stimulation stages of labor. The combined effects of decreased gastric motility, relaxation of the gastroesophageal sphincter, and increased intra-abdominal pressure contribute to an increased risk for emesis and aspiration if a laboring woman is sedated or intubated.[53] Transient nausea and vomiting may occur during active labor, particularly during the transition phases.

Nutritional Needs During Labor

Energy demands during the first stage of labor are related to increased cardiac output and work of the respiratory and uterine muscles.[54] The additional work required of voluntary muscles in pushing efforts during the second stage of labor further increases the demand for energy.[55,56] Hypoglycemia due to fasting can lead to use of alternative metabolic pathways that result in accumulation of by-products including lactate and ketones.[57] Strategies that provide energy while limiting risks due to increased volume of gastric contents, including intake of isotonic sports drinks[52,56] and consumption of a light diet,[57] are not associated with any adverse outcomes. Restriction of solid food intake is a common practice that is based on the concern that a woman may aspirate if her stomach is full and she needs to be intubated for an emergency cesarean. However, aspiration is extremely rare and studies have not found either benefit or harm from restriction of food and fluids in laboring women who are at low risk of needing general anesthesia.[58-61]

Pain and Psychobiologic Responses in Labor

Women's experience of pain during labor and methods for mitigating labor pain are reviewed in more detail in the *Support for Women During Labor* chapter and briefly introduced here. Physically, mechanical pressure on anatomic structures, uterine contractions, and cervical

changes are the primary physiologic and anatomic mediators of pain during labor.[62] Pain associated with contractions is conducted from pain receptors (nociceptors) to afferent type A delta and C neurons extending from the uterus to the dorsal spinal cord. The afferent neurons enter the spinal cord via segments of the 10–12 thoracic spinal nerves. Fetal descent induces mechanical pressure on the pelvic floor, vagina, and perineum during the second stage of labor, mediating sensory pain impulses via the pudendal nerve to the 2–4 sacral spinal nerves. Interpretation of pain is achieved when the pain impulse ascends the spinal cord to higher cortical brain centers.[62,63]

The experience of labor pain is, however, a complex dynamic process influenced by multiple factors. For example, anxiety and fear of labor appear to increase the pain of labor.[64] Previous traumatic birth experience, post-traumatic stress disorder, a history of sexual or other abuse, or other unpleasant memories can also worsen the perception of pain during labor.[65–71]

Modulation of pain can be achieved through interruption of the pain pathway (i.e., entry of pain signals into the spinal cord, spinal neurons, and higher brain centers). This knowledge forms the basis for many pain relief strategies.[72-76] For example, decreased transmission of the pain impulse can be promoted through stimulation of inhibitory afferent type A beta pain fibers using interventions such as massage.

Cognitive strategies such as distraction and relaxation techniques can also reduce pain by targeting the woman’s higher cortical brain centers. Attenuation of fear, stress, and anxiety via provision of continuous labor support reduces the perception of pain in labor.[72] Other strategies to promote an optimal psychobiological response to labor include education and anticipatory guidance, support for decision making, and nonpharmacologic methods of pain relief.[72-76]

Fetal Response to Labor

The fetal response to labor is reviewed in detail in the *Fetal Assessment During Labor* chapter. In brief, the primary clinical focus of the fetal experience of labor is maintenance of gas and nutrient exchange across the placenta and through the umbilical cord in the presence of recurrent uterine contractions and fetal descent.

Approximately 40% of fetal cardiac output is located in the fetal–placental circulation. The partial pressure of oxygen at the placental interface is similar to that in the maternal venous system. The fetus maximizes oxygen-carrying capacity via several physiologic parameters, including the presence of fetal hemoglobin, which has a high affinity for oxygen; increased levels of hemoglobin (compared to adult values); a high cardiac output; and a fast heart rate.

Uterine contractions during active labor interrupt delivery of maternal blood to the intervillous space. When researchers used near-infrared spectrometry to measure changes in fetal brain oxyhemoglobin (HbO_2) and deoxyhemoglobin (Hb), they observed a negative change in HbO_2 and a positive change in Hb when the interval between contractions was less than 2 minutes, and a positive change in HbO_2 following longer contraction intervals.[77] Shorter uterine relaxation time, longer contractions, and higher contraction amplitude during labor are more likely to lead to acidosis, as measured by cord blood pH at birth (umbilical artery pH of 7.11 or less), compared to newborns who experience less uterine activity during labor.[78]

When an interruption in the transport of oxygen from the maternal circulation to the fetal circulation occurs that is sufficient to cause a decrease in fetal partial oxygen pressure, the fetus responds with several compensatory mechanisms, including shunting of blood preferentially to vital organs such as the brain, myocardium, and adrenal gland. In addition, the fetus demonstrates a bradycardic response to hypoxia that lowers the metabolic needs of the heart. Failure or exhaustion of compensatory mechanisms that might otherwise ensure fetal oxygen delivery may result in lactic acidemia, cardiac dysfunction, and acidosis.[78]

Conclusion

The physiology of labor is complex, involving hormonal, mechanical, and biochemical events that lead to birth. Endocrine and anatomic changes involving the maternal and fetal systems contribute to the evolution of the phases of labor, including the premonitory signs and symptoms that precede labor and the activation and stimulation phases of uterine activity. Knowledge of the physiology that underlies labor and birth, including a healthy respect for individual normal variations, assures that midwives are in an excellent position to support women during this unique period in their lives.

CHAPTER

25

First Stage of Labor

JEREMY L. NEAL, NANCY K. LOWE, SHARON L. RYAN, AND LINDA A. HUNTER

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

A normal physiologic labor and birth is one that is powered by the innate human capacity of the woman and fetus.[1] Normal labor and birth do not require medical intervention, yet most women in the United States experience childbirth in hospitals, where they labor in bed with intravenous fluids and their fetuses are monitored with continuous electronic fetal heart rate monitoring. Many individuals who have a hospital birth receive synthetic oxytocin (Pitocin) for induction or augmentation. Despite recognition that unnecessary intervention is pervasive in clinical practice, until recently there has been little guidance for eliminating commonly used interventions that are not needed and may, in fact impede, normal labor.

Normal Physiologic Childbirth

There is now a burgeoning movement to recharacterize normal physiologic labor. In 2012, the American College of Nurse-Midwives (ACNM), Midwives of North America (MANA), and National Association of Certified Professional Midwives (NACPM) published a consensus document titled *Supporting Healthy and Normal Physiologic Childbirth: A Consensus Statement by ACNM, MANA and NACPM*.[1] This document defines normal physiologic childbirth and describes essential components and factors that disrupt normal physiologic childbirth (**Table 25-1**). In 2017, the American College of Obstetricians and Gynecologists Committee on Obstetrical Practice released an opinion, *Approaches to Limit Intervention During Labor and Birth*,[2] that has been endorsed by ACNM. This document contains recommendations for obstetrician-gynecologists to support women during labor through use of practices associated with minimal interventions and high patient satisfaction, which is consistent with midwifery practice. Similar documents and resources from other professional associations can be found in the Resources section at the end of this chapter.

Table 25-1	Normal Physiologic Birth
Characteristics of Normal Physiologic Childbirth	
Involves spontaneous onset and progression of labor	
Includes biological and psychological conditions that promote effective labor	
Results in the vaginal birth of the infant and placenta	
Results in physiological blood loss	
Facilitates optimal newborn transition through skin-to-skin contact and keeping the mother and infant together during the postpartum period	
Supports early initiation of breastfeeding	
Factors That Disrupt Normal Physiologic Childbirth	
Induction or augmentation of labor	
An unsupportive environment (e.g., bright lights, cold room, lack of privacy, multiple providers, lack of supportive companions)	
Time constraints, including those driven by institutional policy and/or staffing	
Nutritional deprivation (e.g., food and drink)	
Opioids, regional analgesia, or general anesthesia	
Episiotomy	
Operative vaginal (vacuum, forceps) or abdominal (cesarean) birth	
Immediate umbilical cord-clamping	
Separation of mother and infant	
Any situation in which the individual feels threatened or unsupported	
Factors That Influence Normal Physiologic Childbirth	
Multiple factors influence the ability of a woman to give birth without intervention	
For the Woman	
Her individual health status and physical fitness	
Autonomy and self-determination in childbirth	

Personal knowledge and confidence about birth, including cultural beliefs, norms, and practices and education about the value of normal physiologic birth
Fully informed, shared decision making
Access to healthcare systems, settings, and providers supportive of and skilled in normal physiologic birth
For the Clinician
Education, knowledge, competence, skill, and confidence in supporting physiologic labor and birth, including helping women cope with pain
Commitment to working with women through education to enhance their confidence in birth and diminish their fear of the process
Commitment to shared decision making
Working within an infrastructure supportive of normal physiologic birth

This chapter presents the evidence for the recommendations in the *Supporting Healthy and Normal Physiologic Childbirth* consensus statement and reviews care for essentially healthy women during spontaneous labor.[1] This document provides a roadmap to optimal care for women during labor and birth and, as the U.S. maternity care system begins to step back from the current overuse of unnecessary interventions, the skills and techniques developed in midwifery practice are being recognized as a critical component of this roadmap. Care for women who require induction of labor and those who have medical or obstetric complications is presented in the *Complications During Labor and Birth* chapter.

Definitions of Labor

Labor is the process by which childbirth occurs, requiring uterine contractions of sufficient frequency, duration, and intensity to cause effacement and dilation of the cervix. The mechanisms underlying the onset and progress of spontaneous labor remain largely unknown and labor is a continuum that does not readily lend itself to measurement. Not only is prospectively defining the onset of labor a significant challenge, but the ability to evaluate its progression is limited because cervical examinations are performed only episodically, if at all. Attempts to divide the continuum of labor into stages and phases add to the complexity. In spite of measurement difficulties, understanding and supporting normal first-stage labor allows time for the events of physiologic labor to unfold without unnecessary interventions, while simultaneously observing the woman for situations in which interventions may be needed. Only in this way can safe, state-of-the-science midwifery care be provided.

The *first stage of labor* begins with true labor contractions, as evidenced by progressive cervical change, and ends when the cervix is completely dilated (approximated at 10 centimeters) and ready for passage of the fetal presenting part. It is known as the stage of cervical dilatation. The *second stage of labor*, known as the expulsive stage, follows. The first stage of labor was classically divided into three sequential, albeit rather nebulously defined phases: latent, active, and deceleration. The *latent phase* begins with the onset of regular uterine labor contractions; the *active phase* begins when the rate of cervical dilation increases. A third *deceleration stage* wherein labor progress slows between 8 and 10 centimeters of cervical dilation was identified by Dr. Emanual Friedman in studies conducted in the 1960's but the reality of a deceleration phase is controversial as reviewed later in this chapter. The second stage of labor begins with complete cervical dilatation and ends with the birth of the infant. The *third stage of labor* is the time between birth of the infant and delivery of the placenta. Abnormalities of labor progress are reviewed in the *Complications During Labor and Birth* chapter.

Each stage and phase of the labor is characterized by distinct physical changes and behavioral responses that are distinct. The physical changes—in particular, cervical dilation and fetal station—are used to evaluate labor progress. The woman's behaviors may be used to help estimate labor progress without resorting to a cervical examination, although individual and cultural responses to labor vary significantly. Thus, the midwife needs to know the woman, her goals, expectations, and concerns as well as her cultural framework to assess labor progress via evaluation of her expression and behaviors. Although interpretations of nonverbal behaviors are a common component of midwifery assessment of persons in active labor, individual's express their experiences in markedly varied ways and healthcare provider's implicit biases frequently result in misinterpretation. Thus, a midwife's interpretation of nonverbal behaviors should always be verified with the individual.

Premonitory Signs and Symptoms of Labor Onset

The onset of spontaneous labor cannot be reliably predicted, although many pregnant women experience premonitory signs or symptoms of impending labor. Common signs and symptoms suggestive of physiologic progress toward labor include descent of the fetus, cervical changes, increase in uncoordinated uterine contractions, rupture of membranes, bloody show or increased mucus discharge from the vagina, maternal perception of increased energy, and gastrointestinal distress. Anticipatory guidance for all women in late pregnancy includes reassurance that these signs and symptoms are normal, promotion of comfort measures, and support for watchful waiting.

Descent of the Fetus

Notable descent of the fetus prior to labor, or "lightening," occurs following the gradual softening of the uterine isthmus (lower uterine segment). The fetal presenting part, most commonly the head, descends to or through the inlet of the maternal pelvis (**Figure 25-1**). Although lightening is not synonymous with engagement of the fetal presenting part (i.e., when the widest diameter of the fetal presenting part is at or below the maternal pelvic inlet), engagement may be the result of lightening. A small reduction in fundal height is common following this prelabor fetal descent. Leopold's maneuvers will reveal that the presenting part is no longer ballottable above the symphysis pubis. Cervical examination typically finds the presenting part as "fixed" and not ballottable. Women often subjectively refer to the physical experience of lightening as "the baby has dropped."

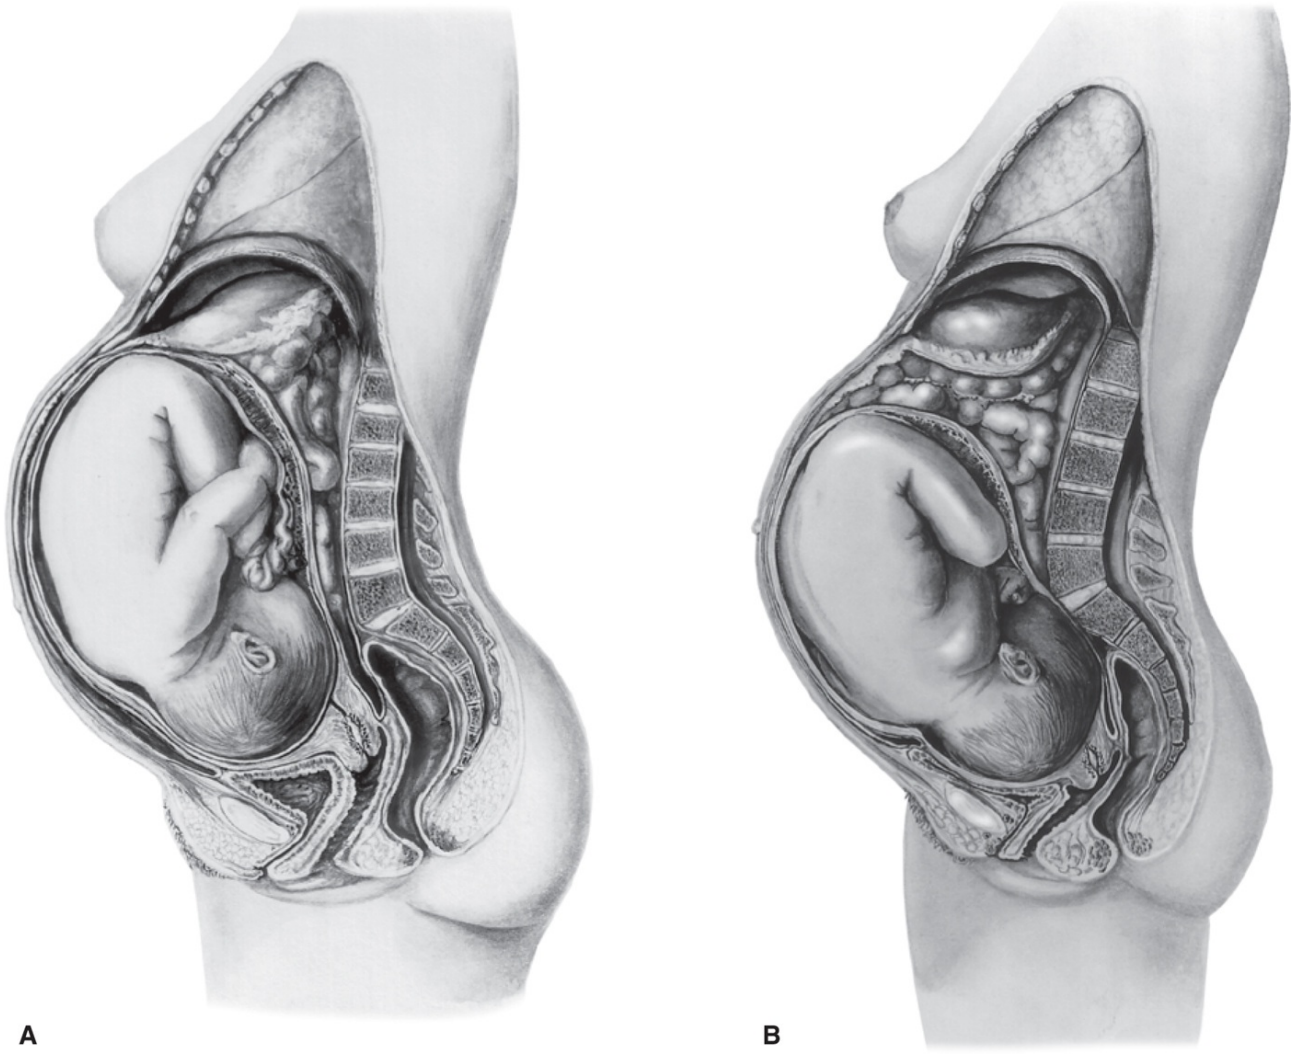

Figure 25-1 **A.** Prelightening. **B.** Postlightening.

© Childbirth Connection. 2013. Used with permission.

Among many, but not all, nulliparous women, prelabor descent of the fetus may occur two or more weeks in advance of labor and is reassuring for pelvic adequacy at the plane of the inlet. For women who have previously given birth, notable descent may not occur until labor is advanced.

The fetal descent associated with lightening can result in women having more room in the upper abdomen, allowing for better lung expansion and increased stomach capacity. However, lightening often causes new discomforts because of the pressure imposed by the presenting part on other structures in the area of the true pelvis. Urinary frequency can be caused by compression of the bladder between the fetal presenting part and the maternal pelvis. An increase in generalized pelvic pressure contributes to the straddling walk of late pregnancy, and women may relate a constant feeling of pelvic pressure. Increased venous stasis and pelvic congestion can cause more dependent edema, development of hemorrhoids, and vulvar or lower extremity varicosities. Spending some time throughout the day in the knee–chest or left side-lying position may temporarily relieve the discomforts related to generalized pressure and venous stasis.

Finally, sciatic nerve pain, characterized by unilateral shooting pain radiating from the buttocks down the back of the leg, can be aggravated or initiated by the fetal descent. This sciatic pain is self-limited to pregnancy and may be relieved by massage, application of heat/cold, or gentle stretching exercises. Sciatic nerve pain that is debilitating or persists into the postpartum period warrants a referral of the woman for evaluation, as these symptoms may be indicative of vertebral disc herniation.

Cervical Changes

The process of cervical change preparatory to labor is referred to as "ripening." The cervix, which is typically long, closed, and semi-firm throughout pregnancy, becomes soft and malleable during this process. Effacement, dilation, and anterior rotation of the cervix may be noted. While ripening is a reassuring change suggestive of progress toward true labor, it is not a reliable predictor of actual labor onset. Evaluation of ripeness is relative to the individual woman and her parity. For example, during the final weeks of pregnancy, a multiparous woman's cervix may be soft and surprisingly dilated; in contrast, a nulliparous woman's cervix may remain firm and closed until near the onset of labor.

Cervical ripening occurs secondary to the influence of prostaglandin, a hormone that acts locally in a paracrine manner to create changes in collagen matrix and increased extracellular water content. Cervical ripening may occur with or without uterine contractions. Unless such an evaluation is being used to inform clinical decision making, routine assessment of cervical ripeness via digital examination in late pregnancy is unnecessary because it is not predictive of labor onset and may be uncomfortable for the woman.

Prelabor or False Labor

"False labor" is the term historically used to describe the experience of uterine contractions of varying intensity that are not associated with progressive cervical change over time. These contractions are actually an intensification of the usually painless Braxton Hicks contractions, which may first become noticeable in the third trimester; thus, the term "false labor" is not accurate. These prelabor contractions do not intensify over time and may be relieved by walking or position changes, whereas true labor contractions will intensify over time, becoming longer, stronger, and closer together. True labor contractions sometimes intensify with walking and are not relieved by position changes. Most importantly, true labor is associated with progressive cervical change. Use of the term "prelabor contractions" in lieu of "false labor" may help women better understand their discomfort and is a more body-affirming term.

Prelabor contractions may occur for days or intermittently for weeks before the onset of true labor. A woman experiencing persistent or recurrent prelabor contractions may fatigue over time and have difficulty coping, as these contractions can be painful and distressing. Provider assurance that the woman will be able to identify a change in the labor pattern indicating true labor and reinforcement of education regarding true labor characteristics and other signs of impending labor can help the woman cope with prelabor contractions. Comfort measures for prelabor contractions are the same as those used to support women in latent-phase labor.

Bloody Show

A mucus plug, created by cervical secretions from proliferation of the glands of the cervical mucosa early in pregnancy, seals the cervical canal throughout pregnancy, serving as a protective barrier. As the cervix ripens, small capillaries may break, mixing blood with the mucus. Bloody show is the expulsion of this blood-tinged mucus.

The mucus associated with bloody show is thick and tenacious. Both history and examination can help differentiate benign bloody show from frank bleeding. Occasionally the entire mucus plug is expelled en masse. More commonly, the mucus plug is expelled over the course of several days, and noticed by the woman as mild irregular spotting when wiping after urination or defecation.

As a predictive sign of labor, bloody show usually signals the onset of labor within the next few days. However, it is of no value as a sign of labor if a vaginal examination or sexual intercourse has recently occurred, because blood-tinged mucus discharge during this time may be the effect of minor trauma to the ripening cervix or disruption of the mucus plug.

Energy Spurt

Some women perceive an energy spurt in the days preceding labor onset, the cause of which is unknown. Women may benefit by anticipatory guidance that includes a caution against "overdoing it."

Gastrointestinal Distress

In the absence of any other causative factors, a brief occurrence of diarrhea, indigestion, nausea, and vomiting is thought to be indicative of impending labor. These gastrointestinal distress symptoms are likely associated with the increased production of prostaglandins and estrogen and the decrease in progesterone levels that occur with the approach of labor.

Prelabor Rupture of Membranes

Rupture of the fetal membranes with associated loss of amniotic fluid prior to the onset of labor is called prelabor rupture of membranes (PROM). PROM occurs in approximately 8% to 10% of women with term pregnancies, 95% of whom will begin labor spontaneously within 33 to 107 hours after rupture, if given this time.[2-4] Because the duration of ruptured membranes before onset of labor can be a short or long period of time, women who experience PROM at term may either wait (expectant management) for the onset of labor or consider immediate induction of labor. Recommended management varies according to several factors described in more detail in the *Complications During Labor and Birth* chapter.

The ACNM, in a position statement on PROM at term,[3] affirmed that women with PROM should receive counseling and engage in shared decision making based on full knowledge of the risks and benefits of the various management options. For women at term, expectant management for a period of time is a safe alternative to induction of labor under the following

conditions: uncomplicated pregnancy, singleton fetus in vertex presentation with clear amniotic fluid; absence of identified infection, including group B *Streptococcus* (GBS) colonization, hepatitis B, hepatitis C, or human immunodeficiency virus (HIV) infection; absence of fever; no variant fetal heart rate patterns that suggest an increased risk for fetal acidemia; and no other indications for induction of labor. Expectant management requires avoiding all digital cervical examinations, including avoidance of a baseline cervical examination.[3] Leopold's maneuvers or ultrasound may be used to ascertain the fetal presentation in lieu of a digital examination in these cases.

A key consideration in the woman experiencing PROM is whether her vagina is colonized with GBS. Vaginal colonization with GBS is a nonpathologic normal condition for many women, but this bacterium can be transmitted to the fetus during passage through the vagina at birth and infect the newborn, causing sepsis. Thus, a woman's status as a GBS carrier may affect decisions related to expectant management, antibiotic prophylaxis, and recommendations for induction. The Centers for Disease Control and Prevention (CDC) has guidelines for GBS screening and management, including recommendations for antibiotic prophylaxis in the presence of PROM when the woman's GBS status is positive or unknown.[5] The CDC management algorithms are endorsed by all professional associations and used in almost all institutions in the United States. The American College of Obstetricians and Gynecologists recommends that women with term PROM who are GBS positive receive antibiotics for GBS prophylaxis immediately, even if expectant management is the chosen plan for care.[2] Institutional guidelines and recommendations should be supported by written instructions and included in the anticipatory guidance offered to all women approaching term.

The steps for diagnosing PROM are listed in **Appendix 25A**. Accurate diagnosis of rupture of membranes can sometimes be difficult. The woman's perceptions of the event, careful physical examination, and laboratory testing can all contribute to confirming the diagnosis. Laboratory tests that may be used to establish the status of the fetal membranes include the arborization test (fern test), pH test (nitrazine test), ultrasound quantification of amniotic fluid volume, and test for the presence of placental alpha microglobulin-1 (PAMG-1)[6] or fetal fibronectin in vaginal secretions. Differential diagnoses that need to be excluded include urinary incontinence, vaginal or cervical discharge, semen, and (rarely) rupture of the chorion alone.

The Normal First Stage of Labor

The rate of cervical dilation in the first stage of labor, expressed in centimeters per hour (cm/hr), is the backbone of decision making for clinicians providing care to laboring women. Abnormalities in expected durations of the latent, active, and second stage of labor are associated with perinatal morbidities such as intra-amniotic infection, cephalopelvic disproportion, cesarean section, and postpartum hemorrhage. Accuracy in determining cervical dilation depends on the skill of the examiner. Even among experienced professionals, however, the assessment may vary to some degree. There is no objective method to validate the measurements, and cervical dilation can change rapidly. Nevertheless, because cervical dilation rates are highly related to labor duration, measures of labor duration also inform the "normal" boundaries of first-stage labor progression.

Latent Phase

The latent phase encompasses the period of time from the beginning of regular uterine contractions to the point when cervical dilation begins to progress rapidly. Application of this definition is difficult at both ends of the spectrum. First, the onset of the latent phase is difficult to determine objectively, as women typically do not seek labor care until after the onset of labor. Thus, identification of latent-phase onset often depends on maternal memory and discernment of prelabor versus true labor contractions. Second, the end of the latent phase is difficult to determine due to the wide variability in the onset of rapid and progressive cervical dilation. In multiparous women, the rate of cervical dilation commonly accelerates after 6 cm dilation; however, the average labor curve for nulliparous women does not always have a clear inflection point of dilation acceleration that marks the end of the latent phase.[7]

Uterine contractions become established during the latent phase as they increase in frequency, duration, and intensity. It is common for contractions during latent labor to initially be of mild intensity, occurring every 10 to 20 minutes and lasting 15 to 20 seconds. As latent labor advances, contractions typically increase to moderate intensity, occurring approximately every 5 to 7 minutes and lasting 30 to 40 seconds. These parameters alone do not define latent labor, however, as the experience of contractions may vary greatly among women at similar points of the labor process. Only demonstrable effacement and dilation of the cervix truly define labor. Little to no descent of the presenting part occurs during the latent phase.

A woman in latent labor typically experiences a mixture of emotions: She may be excited, happy, and relieved that the end of pregnancy has come and the long period of waiting has ended, but simultaneously feel a sense of anticipation and apprehension about what is yet to come. Many women cope well with this situation. For some women, however, the latent phase of labor may be a time of fear and increased sensitivity to pain and external stimuli. This is the ideal time for the midwife to assess coping skills, establish rapport, and develop an initial management plan.

Active Phase of Labor

The *active phase of labor* encompasses the period of time that starts with an increase in the rate of cervical dilation (the end of the latent phase of labor) and ends with complete cervical dilation (the beginning of the second stage of labor). Progressive descent of the fetal presenting part also typically occurs during the latter part of the active phase and in the second stage of labor. Accurately diagnosing active labor is of utmost importance because a woman's rate of cervical dilation in this phase serves as the basis against which her labor progress is assessed, admission decisions are made, and the need for intervention is determined. It is critical that expectations of cervical dilation during active labor be appropriately defined based on the most current research.

Unfortunately, true active labor can never be diagnosed prospectively, which is limiting to clinicians; rather, it can be determined only retrospectively based on an assessment of adequate cervical dilation over time. Both the time intervals for cervical dilation rates and cervical dilation at the onset of the active phase—factors used for the last several decades by clinicians in practice to guide management—have been recently reevaluated for their validity in assessing progression of labor.

Friedman Studies

Clinical expectations of cervical dilation and fetal descent during labor continue to be influenced by the research of Emanuel Friedman, a physician whose work began in the 1950s.[8-13] Friedman observed women during labor, recorded progress, and plotted these recordings to depict the progress of labor as a sigmoid (S-shaped) curve, varying in duration and slope between women who were nulliparous versus multiparous. Active labor, most often beginning between 2 and 3 cm, was divided into three sequential subphases: an *acceleration phase*, a *phase of maximum slope*, and a *deceleration phase*. Friedman reported that the active phase averaged between 4.4 and 4.9 hours for nulliparous women[8,9,12,13] and had an upper "normal" limit of 11.7 hours (mean + 2 standard deviations [SD]).[9,12,13] For multiparous women, the active phase averaged between 2.2 and 2.4 hours,[10-13] with a statistical upper normal limit of 5.2 hours.[10,13] Regardless of parity, approximately half of the total active phase time for the aggregate groups was spent in the acceleration phase, when little progress in dilation is made. Cervical dilation rates in Friedman's phase of maximum slope for nulliparous and multiparous women at the mean were 3.0 cm/hour and 5.7 cm/hour, respectively; the slowest acceptable rates (i.e., mean – 2 SD) were reported to be 1.2 cm/hour and 1.5 cm/hour, for nulliparous and multiparous women, respectively.[9,10,12,13]

Using a subset of women who had a fetus in vertex presentation, spontaneous labor, and no use of medications, Friedman constructed an idealized labor curve. This idealized labor curve has been used extensively to monitor labor progress and diagnose labor progress abnormalities. Unfortunately, these aggregate active-phase dilation rate estimates are of limited prospective use for individual women, because the cervical dilation at which active labor begins varies widely among women and cervical dilation is affected by multiple intrinsic and extrinsic factors in different populations of women. Differences based on these factors have recently been identified.

There are many differences in practice patterns between the 1950s and labor management

practices today. Today women frequently use epidural analgesia to manage labor pain, whereas in the 1950s women received sedatives and morphine to manage this pain. In Friedman's era, if a woman had not given birth spontaneously after 2 hours in the second stage of labor, this stage was terminated at 2 hours via performance of an episiotomy and forceps delivery. Thus, it is worthwhile to review labor duration studies that have included contemporary labor practices and current populations of women who reside in the United States.

Contemporary Studies of Labor Progress

Many midwives use criteria historically associated with Friedman's work to determine the diagnosis of active labor, which is suggested to begin with cervical dilatation between 3 cm and 5 cm, in the presence of regular uterine contractions.[14] However, true active labor onset for many women with spontaneous onset of labor may not be present at 3 to 5 cm of cervical dilation. For example, Peisner and Rosen found that 75%, 50%, and 24% of low-risk women with regular contractions admitted for spontaneous labor (n = 1699) at 3, 4, and 5 cm, respectively, did not experience cervical dilation at rates indicative of active labor, as traditionally defined by Friedman.[15] Such findings highlight two important realities of contemporary clinical practice: (1) Many women are presumed to be in active-phase labor and managed as such, before they are actually in active labor, and (2) guidelines on expected rates of cervical dilation during traditionally defined active-phase labor progress times (1 cm/hr) are overly stringent. In addition, in situations where multiple professionals perform cervical examinations, variations in inter-rater reliability may raise doubt in accuracy of cervical assessments.

In 1989, Kilpatrick and Laros reported that nulliparous (n = 2302) and multiparous women (n = 3767) who gave birth spontaneously without the use of oxytocin or anesthesia required a mean of 8.1 ± 4.3 hours and 5.7 ± 3.4 hours, respectively, to progress from the onset of regular, painful contractions occurring every 3 to 5 minutes and leading to cervical change, to 10 cm or complete dilation.[16] When these authors compared first- and second-stage labor times for women with and without epidural analgesia, they found that the first stage of labor is longer by approximately 2 hours in women who have epidural analgesia.[16] The clinical implications of these findings with regard to second-stage labor duration are reviewed in the *Second Stage of Labor and Birth* chapter.

Zhang et al., using modern statistical interval measurement techniques (as opposed to the simple mathematical means modeling used by Friedman decades ago) analyzed data from the National Collaboration Perinatal Project (NCPP), a large, multicenter study conducted from 1959 to 1966 including 54,390 births experienced by 48,197 women.[17,18] The NCPP data set detailed the labors of women giving birth during the time when Friedman's labor curves were introduced. The different mathematical model used by Zhang et al. found important differences from Friedman's work, including that the active phase of labor may not start, on average, until cervical dilation reaches 5 cm in multiparous women or even later in nulliparous women.[17] Moreover, the labor curve was hyperbolic in shape, with dilation becoming more rapid as labor advanced and without the deceleration phase reported by Friedman. The median time to

dilate from 4 to 10 cm was 3.7 hours (16.7 hours at the 95th percentile) and 2.2 hours (14.2 hours at the 95th percentile) for nulliparous and multiparous women, respectively.[17]

Collectively, the studies reported by Zhang et al. provide compelling evidence about the duration of first-stage labor and the pattern of labor progression among women with spontaneous labor onset.[7,18,19] In these authors' initial 2002 study that included nulliparous women (*n* = 1162), median dilation rates for each centimeter of progression between 3 and 10 cm were 0.4, 0.6, 1.2, 1.7, 2.2, 2.4, and 2.4 cm/hour, respectively.[19] At the 5th percentile, these dilation rates were 0.1, 0.2, 0.3, 0.5, 0.7, 0.8, and 0.7 cm/hour, respectively, but never exceeded 1 cm/hour. Accordingly, the time needed to dilate from one centimeter to the next was commonly shorter with each passing centimeter after the spontaneous onset of labor for both nulliparous and multiparous women. Moreover, as rates of cervical dilation accelerated with advancing labor, the time necessary to dilate from one centimeter to the next was typically less variable.[19]

In perhaps their most influential studies, this research team used data from the Consortium on Safe Labor (CSL), a multicenter, retrospective, observational study that contains the labor and delivery records of 228,668 women who gave birth in different areas of the United States; 87% of these births occurred in 2005–2007.[7] Women included in this data set may have received care including interventions such as amniotomy, oxytocin augmentation, and epidural analgesia. Most importantly, the researchers measured the time interval between one cervical dilation and the next (i.e., how long it took to progress from 4 cm to 5 cm, and then the time interval between 5 cm and 6 cm). This approach contrasts with that used in previous studies, which usually calculated the mean time interval for a particular phase of labor (i.e., the active phase). Durations of the first stage of labor for women of different parity are shown in **Table 25-2**.

Table 25-2 **Duration of First-Stage Labor with Spontaneous Onset in Hours, by Parity, Beginning with Cervical Dilations Commonly Associated with Active Labor Onset**

Initial to Complete Dilatation	Parity 0 (n = 43,576)[a] Median (95%)	Parity 1[b] (n = 27,471)[a] Median (95%)	Parity 2+[b] (n = 27,312)[a] Median (95%)
4 cm to complete dilatation, hours	6.5 (24.0)	—	—
5 cm to complete dilatation, hours	3.6 (15.1)	3.0 (15.0)	2.8 (15.5)
6 cm to complete dilatation, hours	2.2 (10.0)	1.6 (8.9)	1.3 (8.9)

[a] Data from the Consortium on Safe Labor.

[b] Parous women tended to be admitted at more advanced dilations than nulliparous women; thus, measures of labor duration started at 5 cm for these women.

Data from Laughon SK, Branch DW, Beaver J, Zhang J. Changes in labor patterns over 50 years. *Am J Obstet Gynecol.* 2012;206:419.e1-419.e9.[18]

Critical findings from the studies by the Zhang group include the following: (1) The average labor curve for nulliparous women did not show a clear inflection point of dilation acceleration; (2) labor appeared to accelerate after 6 cm in multiparous women; and (3) no deceleration phase was detected.[7,17–19] The slope of cervical dilation was not linear; instead, cervical dilation rates progressively accelerated with each passing centimeter, thereby forming a hyperbolic curve for the aggregate, as shown in **Table 25-3** and **Figure 25-2**.[7,18,19]

Table 25-3 Duration of Labor from One Centimeter Dilation to the Next Centimeter Dilation, by Parity, in Women with Spontaneous Onset of Labor

Cervical Dilation (cm)	Parity 0 (n = 25,624)[a] (hr) Median (95%)	Parity 1 (n = 16,755)[a] (hr) Median (95%)	Parity 2 (n = 16,219)[a] (hr) Median (95%)
3–4	1.8 (8.1)	—	—
4–5	1.3 (6.4)	1.4 (7.3)	1.4 (7.0)
5–6	0.8 (3.2)	0.8 (3.4)	0.8 (3.4)
6–7	0.6 (2.2)	0.5 (1.9)	0.5 (1.8)
7–8	0.5 (1.6)	0.4 (1.3)	0.4 (1.2)
8–9	0.5 (1.4)	0.3 (1.0)	0.3 (0.9)
9–10	0.5 (1.8)	0.3 (0.9)	0.3 (0.8)

When the Zhang et al. group compared labor progress times found in the NCPP (1959–1966) data to labor progress times recorded in the CSL (2002–2008) database (using the same statistical analysis), which contains records of contemporary women giving birth, it became evident that the first stage of labor in the CSL cohort was longer by a median of 2.6 hours in nulliparous women and 2.0 hours in multiparous women, after adjusting for differences in maternal and pregnancy characteristics (e.g., older age, higher body mass index [BMI], and higher birth weight in the CSL when compared to the NCPP cohort).[18] Differences in labor duration may be partially attributed to significant changes in practice patterns over time, increasing prevalence of obesity, and average older age of laboring women. In addition, Friedman's statistical analysis was simpler than the advanced analytic technique applied by Zhang et al.

Spontaneous Active-Phase Labor

Labor and birth is a normal physiologic process. Thus, the sparse number of studies reporting on the duration and progress of women in *spontaneous* active-phase labor who do not experience interventions that could affect labor progress indicates the existence of an important knowledge gap—one that is difficult to study especially today due to the frequency of various interventions in contemporary practice. Albers[20,21] and Jones and Larson[22] specifically aimed to identify the duration of spontaneous active labor (i.e., no oxytocin, no epidurals, and no operative deliveries) among low-risk women who gave birth vaginally. In their studies, active labor was defined as the time necessary for the cervix to dilate from 4 to 10 cm (**Table 25-4**).

Viewed linearly, active labor dilation rates in these studies averaged 0.8 to 1.0 cm/hour for nulliparous women and 1.1 to 1.4 cm/hour for multiparous women; at the mean – 2 SD, rates were 0.3 to 0.5 cm/hour and 0.4 to 0.5 cm/hour, respectively.

Table 25-4 Duration and Cervical Dilation in Women During Spontaneous Active-Phase Labor

Trial	*n*	Dilation Used as Evidence of Active-Phase Onset (cm)[a]	Active-Phase Duration (hr)		Rate of Dilation (cm/hr)[b]	
			Mean (SD)	Mean + 2 SD	*Mean*	*Limit*
Nulliparous Women

[a] Absolute value taken as evidence of active-phase onset (cm).

[b] Calculated based on the assumption that the cervical dilation phase ends at 10 cm, which approximates complete cervical dilation.

Based on Albers LL, Schiff M, Gorwoda JG. The length of active labor in normal pregnancies. *Obstet Gynecol*. 1996;87(3):355-359[20]; Albers LL. The duration of labor in healthy women. *J Perinatol*. 1999;19(2):114-119[21]; Jones M, Larson E. Length of normal labor in women of Hispanic origin. *J Midwifery Womens Health*. 2003;48(1):2-9.[22]

In their systematic review, which was limited to nulliparous women (*n* = 7009), Neal et al. concluded that the weighted mean rate of cervical dilation, based on linear calculations, was 1.2 cm/hour, when beginning with criteria commonly associated with the onset of active labor (i.e., dilation of 3 to 5 cm and regular contractions).[23] The weighted cervical dilation rate at the mean – 2 SD was 0.6 cm/hour. Studies included in this review reflected the diverse care patterns in contemporary practice—for example, frequent use of epidural analgesia, amniotomy, and oxytocin augmentation. These findings confirmed those of Perl and Hunter, who suggested that nulliparous labors progressing at 0.5 cm/hour or faster, in the absence of other problems or symptoms, are within normal limits.[24] In their study, 89.7% of term, nulliparous women with a spontaneous labor onset (*n* = 453 of 505) progressed at a rate of 0.5 cm/hour or faster. Only 8.6% of this cohort required a cesarean section (*n* = 37 of 453) and 0.8% required oxytocin augmentation of labor progress (*n* = 4 of 453).

Current research is exploring normal labor progress in subpopulations who may have intrinsic differences in their duration of labor. Factors such as race, ethnicity, obesity, age, induction of labor, and previous history such as cesarean have been assessed in a few studies to date.[25-30] Women who have a high BMI also progress in labor differently than do women with lower BMIs,[28,30] and induced labor progresses more slowly than spontaneous labor.[29] For midwives, it is critical that dilation rate expectations be based on the best contemporary research evidence and evolve when new evidence comes to light. Only by understanding typical labor progression can clinicians decide if and when interventions aimed at speeding

labor progress should be presented as appropriate options to laboring women.[31]

Partograph Studies

Partographs are tools that allow labor progress to be graphically recorded and visually assessed. They aid in the early detection of abnormal labor progress and are credited by some for decreasing rates of prolonged labor, oxytocin use, cesarean sections, and intrapartum morbidity/mortality as compared to usual care, although authors of a 2013 Cochrane systematic review did not find that use of a partograph was associated with improved outcomes.[32] Common partograph designs display time (in hours) on the *x*-axis and cervical dilation (in centimeters) on the *y*-axis. Correct use of the partograph is initiated during active labor.

Many partographs incorporate a graphically straight "alert" line, first introduced by Philpott and Castle,[33,34] that represents a dilation rate of 1 cm/hour based on findings from Friedman in the mid-1950s (**Figure 25-3**). Alert line incorporation was meant to represent the cervical dilation rate of the slowest 10% of nulliparous women in active labor, so that timely transfer from lower- to higher-resource settings could be accomplished.[33] An "action" line is conventionally placed a number of hours to the right of the "alert" line, most commonly 4 hours. A 4-hour action line is crossed only when cervical dilation averages less than 0.64 cm/hour for partographs initiated at 3 cm, less than 0.60 cm/hour for partographs initiated at 4 cm, and less than 0.56 cm/hour for partographs initiated at 5 cm. Only when the "action" line is reached are more aggressive management interventions, such as oxytocin augmentation, typically initiated in an attempt to accelerate labor progress.

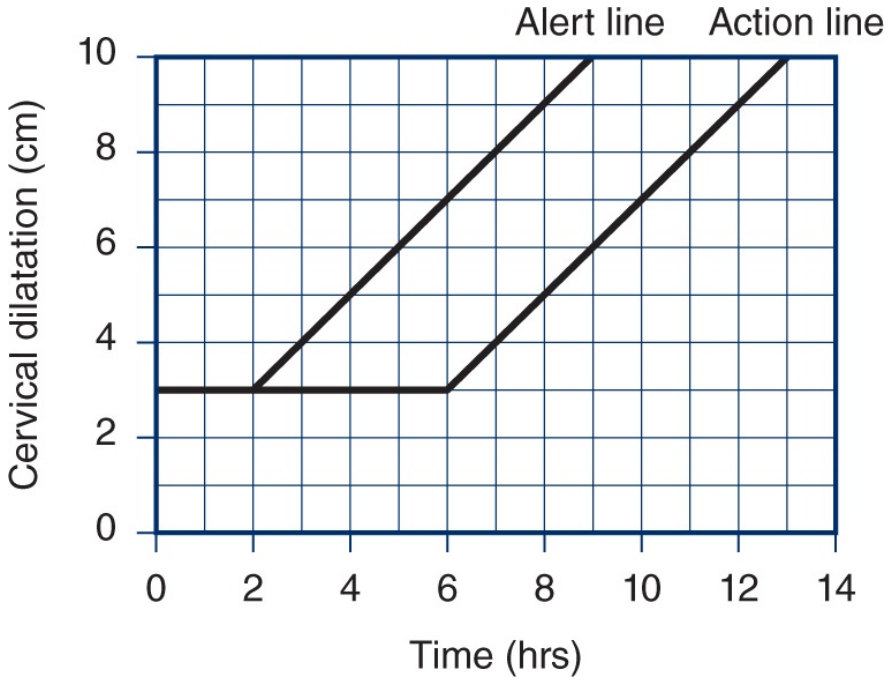

Figure 25-3 Central component of common partographs.

Although the “alert” line is purported to identify only the slowest 10% of nulliparous labors,[33] studies spanning the past four decades have consistently reported that approximately 18% to 56% of nulliparous women cross the “alert” line following partograph initiation.[33-43] Among exclusively multiparous or mixed-parity cohorts, 10% to 42% of women cross the “alert” line.[35,36,42-44] With these findings, it became evident that a linear active labor cervical dilation rate expectation of 1 cm/hour is overly stringent for a large percentage of women diagnosed as being in active labor. Indeed, *it is the “action” line rather than the “alert” line that better segregates the slowest 10% of women*, although even the 4-hour “action” line is crossed by 10% to 45% of women.[36-38,40-43]

Contemporary findings regarding the hyperbolic progression of labor indicate that most existing partographs are not physiologically based for contemporary parturients. Even so, the potential for physiologically based partographs to provide an evidence-based framework for homogeneous labor assessment is great.[45,46] Large-scale, hypothesis-testing studies of physiologic partograph implementation are warranted because such instruments may go a long way toward improving birth outcomes in both low- and high-resource settings.

Current Controversies

Despite a wealth of research, definitive time frames for normal labor progress have not been fully established. The use of different statistical analyses and different populations has resulted in some controversy, primarily with regard to the cervical dilation at which most women are in active versus latent labor.[47,48] Findings from contemporary studies indicate that a cervical dilation rate approximating 0.5 cm/hour is achievable for approximately 90% of nulliparous laboring women with spontaneous labor onset. However, this *linear* rate must be evaluated judiciously in light of the physiologic acceleration of dilation that occurs during typical labor. Assessments of active labor progression are best based on appropriate hyperbolic labor curves; linear conceptualizations of cervical dilation, although common in contemporary practice, are fundamentally flawed and should be abandoned. The inter-individual variability in rate of progression during normal first-stage labor is sufficiently broad that management must be individualized to provide every woman with complete and accurate information so she can make informed health decisions.

Clinical Correlates of Duration of Labor Studies

Labor Dystocia

The expectation of cervical dilation during active labor is intimately linked to diagnosis of labor *dystocia*, which is broadly characterized as slow, abnormal progression of active labor. Furthermore, dystocia is the most common indication for primary cesarean birth in the United States.[49,50] To lower the rate of cesarean births, the diagnosis of dystocia and the management of women with this diagnosis need to be reevaluated.

In practice, diagnoses of dystocia are most often based on ambiguously defined delays in cervical dilation, beyond which labor augmentation is deemed justified. Criteria used to diagnose dystocia vary widely among clinicians, and commonly used definitions of dystocia neither differentiate normal from abnormal labor progress nor discriminate labors more prone to adverse outcomes. When clinicians have expectations for cervical dilation rates that are faster than physiologic reality, women with normal labor progression are at risk of being misdiagnosed with dystocia and receiving subsequent interventions aimed at expediting birth. The clinical tendency to over-diagnose dystocia explains, in part, why half of nulliparous women with spontaneous labor onset receive oxytocin augmentation.[7,19,51,52] This practice jeopardizes birth safety—oxytocin is the intervention most commonly associated with preventable adverse perinatal outcomes.[53-55]

Of even greater concern, dystocia is the indication for half of all cesarean births in nulliparous women.[49,56,57] At present, cesarean deliveries account for approximately one-third of all births in the United States.[58] The World Health Organization maintains that a cesarean rate higher than 10% is not associated with better health outcomes,[59,60] and higher rates may contribute to excess morbidity and mortality without benefit to mothers or babies.[61-64] Safely decreasing the cesarean rate is an ongoing national priority in the United States, and specific definitions for dystocia based on contemporary population-based criteria are needed to achieve this goal.

Pre-Active Labor Admission

The timing of when a woman is admitted for labor care significantly influences the labor process and outcomes; indeed, the timing of admission is one of the most important decisions that is made. Many women are inadvertently admitted prior to being in active labor, yet they are held to dilation expectations of active labor once admitted to a hospital setting. Women who are admitted early (e.g., less than 4 cm dilation) are approximately twice as likely to be augmented with oxytocin when compared to women admitted in active labor.[65-68] Indeed, the rate of oxytocin use is inversely related to cervical dilation at admission ($r = –0.79$, $P < 0.05$).[69] Moreover, the cesarean rate following early labor admission is reported to be more than twice as high as the reference group rate in most studies.[65-67,70-72] Cesarean births for dystocia are significantly more frequent in early-admission groups in studies reporting specific surgical indications.[65-68,71] Half of all cesarean births in nulliparous women for dystocia have historically occurred at 5 cm or less dilation.[73] This finding raises concern that many cesareans

may be performed prior to active-phase labor onset.

Zhang et al.'s findings can be used to illustrate the shortcomings of viewing cervical dilation linearly and to explain how this practice pertains to dystocia.[7] From 3 cm forward, calculations based on these authors' data demonstrated that dilation rates conceptualized as linear are faster than actual rates until some point after 5 cm dilation, when the linear rates become slower than actual rates, as described previously (**Figure 25-4**).[74] As a consequence, diagnoses of dystocia and interventions aimed at correcting "slow" labor are much more likely in earlier active labor—a point at which linear dilation expectations are less likely to be met. For this reason, it is important that clinicians base cervical dilation expectations on an evidence-based, hyperbolic labor curve.

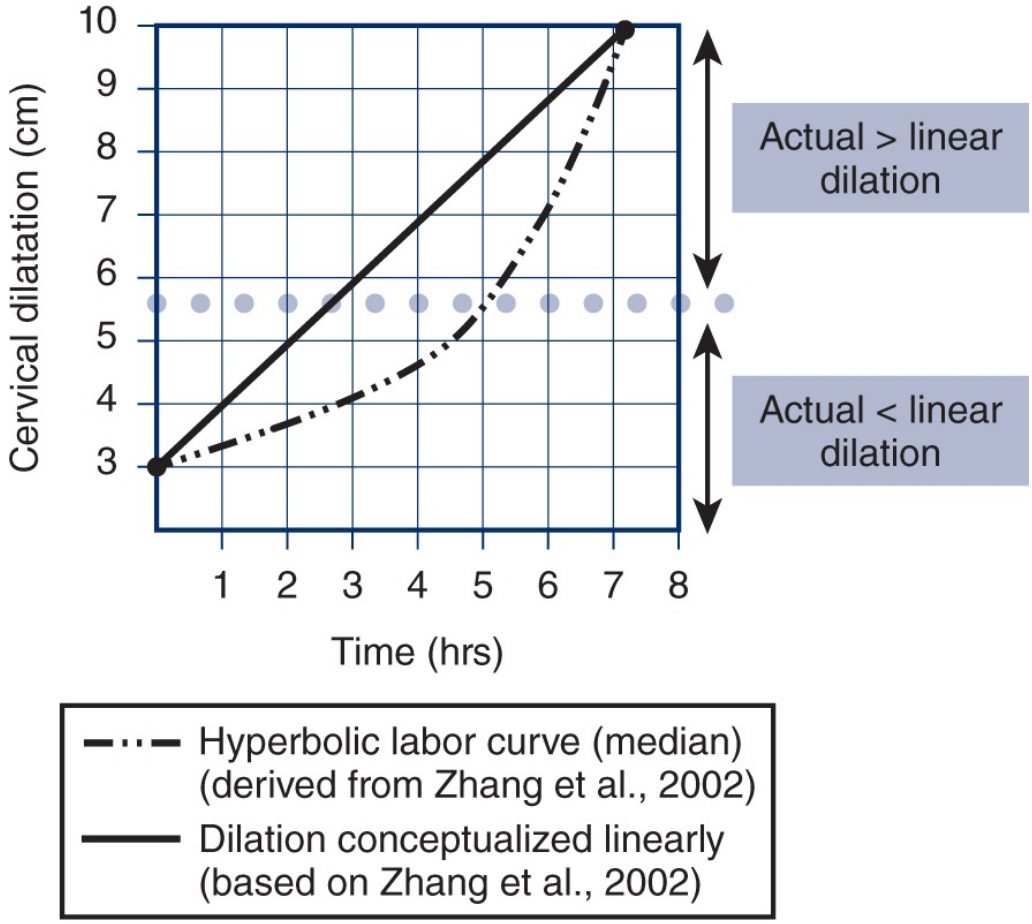

Figure 25-4 Hyperbolic, median nulliparous labor curve with linear conceptualization.

Data from Zhang J, Troendle JF, Yancey MK. Reassessing the labor curve in nulliparous women. *Am J Obstet Gynecol*. 2002;187(4):824-828.[19]

Reproduced with permission from Neal JL, Lowe NK, Patrick TE, Cabbage LA, Corwin EJ. What is the slowest-yet-normal cervical dilation rate among nulliparous women with spontaneous labor onset? *J Obstet Gynecol Neonatal Nurs*. 2010;39(4):361-369.[74]

Augmentation of Labor

Once a woman in spontaneous labor is in the active phase, attempts to accelerate labor may be justified if the dilation rate becomes slower than the expected minimum rate for the population.

Accelerative interventions are primarily used to decrease the number of dystocia-related cesarean births that are performed. However, the main interventions used by clinicians in an attempt to accelerate labor—that is, amniotomy and oxytocin augmentation—are used at surprisingly high rates in contemporary practice. For example, when Zhang et al. limited their analyses of the CSL database to only women with spontaneous labor onset, vertex presentation, vaginal delivery, and normal neonatal outcome (n = 62,415), approximately 45% were found to have received oxytocin augmentation during labor.[7] Oxytocin is a "high-alert medication" per the Institute for Safe Medication Practices,[54,75] Misuse of this drug is cited in half of all paid obstetric litigation claims.[55]

While studies comparing oxytocin use to no treatment are sparse, authors of a recent Cochrane Collaboration review found that early versus delayed oxytocin use results in a higher risk of uterine tachysystole associated with fetal heart rate changes requiring intervention (relative risk [RR] = 2.51; 95% confidence interval [CI] = 1.04–6.05).[76] Early oxytocin use reduces the mean duration of labor by approximately 2 hours. However, oxytocin was not effective in reducing the cesarean birth rate in this systematic review (RR = 0.88; 95% CI = 0.66–1.19).[76] This finding needs to be viewed with some caution. Oxytocin will induce uterine contractions and can be an important intervention for some women, but the decision to perform a cesarean section is affected by multiple factors and the finding that oxytocin does not decrease the cesarean rate is not conclusively related to an effect of the drug itself. With regard to amniotomy, there are no statistically significant differences in outcomes for women who undergo amniotomy and control groups in terms of first-stage labor duration or cesarean birth rates.[77]

Clinicians should bear in mind that the extent to which the relationship between prolonged labor and labor morbidity is causal is by no means certain; that is, it remains unclear whether the risks associated with longer labors are more strongly related to time in labor or to the interventions commonly used to shorten labor. Thus, prior to implementing interventions aimed at accelerating labor, any potential benefits must be weighed against the potential disadvantages, risks, iatrogenic consequences, and their attendant costs.

Midwifery Management During the First Stage of Labor

The dynamic nature of maternal and fetal responses to labor make the cyclic characteristics of the midwifery management process especially valuable as a structure for planning labor care. Continual reassessment with ongoing evaluation and modification of the management plan throughout the labor is expected as part of midwifery care.

Initial Evaluation of the Woman and Fetus

Initial evaluation of a woman presenting with signs and symptoms of labor includes review of history, physical assessment, and, often, laboratory investigations. The initial assessment of a woman who presents in labor not only seeks to ascertain the current physical well-being of the woman and fetus, but also assesses the encounter within the context of the woman's medical and obstetric history, social situation, and expectations. A comprehensive approach is necessary to identify actual and potential problems and to create a mutually agreeable and appropriate plan of care.

History

If the woman's prenatal record is available, it can be used as the source of information for much of the history. Specifically, personal information, past obstetric history, past medical and primary healthcare history, and family history should be reviewed. Present pregnancy history should be reviewed to confirm gestational age and estimated date of delivery, significant prenatal events, and presence of a personalized plan for birth. This spares the woman from having to reiterate history she has given before and from being disturbed at a time when she may be coping with the demands and stresses of labor. Critical items of the history should be double-checked with the woman to verify the existence of drug allergies, blood transfusions and reactions, and major obstetric or medical complications during her pregnancy. Documentation that the prenatal record was reviewed should be included in her intrapartum medical record. An interim history that includes any change in health status from the time of the last documented visit to the present encounter, chief complaint, and history of present illness, coupled with a brief review of pertinent systems, will complete the history database and give direction to the physical examination.

A woman presenting for labor evaluation without an available prenatal record presents a special challenge for caregivers. The woman may have been receiving regular prenatal care but simply not have records available for a variety of reasons, such as miscommunication about expected birth location or travel. However, women who have not received adequate prenatal care are at increased risk of unexpected adverse obstetric complications including preterm birth and stillbirth, giving birth to infants who are large or small for gestational age, and early neonatal death.[78] In the absence of a prenatal record, the midwife must elicit essential information, beginning with those data most relevant to the acuity of the clinical scenario. **Table 25-5** outlines the essential components of the health history when evaluating a woman presenting for labor evaluation and identifies their significance.

Table 25-5	Essential Components of Health History When Evaluating a Woman Presenting with Signs and Symptoms of Labor
History Element	**Significance**
Age	Birth at the extremes of the reproductive lifespan is associated with an increased risk for adverse perinatal outcomes
Parity	Influences labor progress and labor duration (e.g., progress is typically slower in nulliparous women compared to multiparous women)
Estimated date of delivery and estimated weeks of gestational age	Identifies the potential for newborn complications related to prematurity or postmaturity; establishes a baseline for evaluating fetal size as related to gestational age
Complications of current pregnancy, including group B *Streptococcus* status	Identifies existing or potential problems that may influence management of the current labor and birth
Major complications of previous pregnancies, including prenatal, intrapartum, and postpartum periods	Identifies potential recurring problems that may affect the current labor and birth
Previous labor experience, including duration	Previous labor experience influences expectations for labor progress and makes known previously used labor coping strategies
Mode of previous births/deliveries	Identifies previous operative vaginal deliveries or cesarean sections, which may influence management of the current labor and birth
Size of previous babies	Suggests an estimate of pelvic adequacy
Fetal movement pattern	Reflects fetal well-being
Vaginal bleeding	Differentiated from bloody show, frank vaginal bleeding is abnormal and typically contraindicates performance of a digital cervical examination; it indicates necessity for further evaluation including physician consultation, collaboration, or referral
Status of membranes	Duration of ruptured membranes and characteristics of amniotic fluid will influence management decisions
Time of onset of contractions, and character of contractions from onset to the present, including frequency, duration, intensity, and aggravating and relieving factors	Establishes the probable start of labor and helps discriminate prelabor contractions from true labor
Last oral intake	Provides a baseline from which to assess energy reserves and fluid status; also useful in anesthesia management in the event of surgery

Physical Examination

Essential components of the physical and pelvic examination performed at the initial labor evaluation are presented in **Table 25-6**. A physical examination that was performed prenatally can be reviewed as a baseline for the current physical examination when a prenatal record is available. An abbreviated examination can then be performed that focuses on any problem areas identified and areas where new information is needed to make management decisions. Documentation that the previous examination was reviewed should be included in the woman's healthcare record. A comprehensive physical examination is indicated when a woman has no prenatal records available or has received inadequate prenatal care.

Table 25-6 **Essential Components of the Physical Examination When Evaluating a Woman Presenting with Labor Signs and Symptoms**

Components of Examination	Significance
Physical Examination	
Vital signs: blood pressure, temperature, pulse, respirations	Elevated blood pressure may indicate a hypertensive disorder, while lowered blood pressure may indicate shock. In the presence of a normal diastolic measurement, elevation in systolic blood pressure usually indicates anxiety or pain. Elevated temperature indicates an infectious process or dehydration. Elevated pulse and/or respirations may indicate infection, shock, dehydration, or anxiety.
Auscultation of heart and lungs	Screens for and identifies acute or previously unrecognized conditions that could potentially adversely affect the current labor and birth.
Abdominal palpation to determine contraction pattern and fetal lie, presentation, position, and engagement	The contraction pattern helps determine labor status. Fetal lie, presentation, and position influence the course of labor and guide care decisions regarding mode of delivery and necessity for consultation, collaboration, or referral. Engagement of the fetal presenting part is reassuring for pelvic adequacy.
Abdominal palpation to determine estimated fetal weight and fundal height	In relation to gestational age, identifies the possibility of inaccurate dating, smaller or larger than expected fetus or multifetal gestation, oligohydramnios or polyhydramnios, or other abnormalities and their associated complicating factors.
Visual inspection for abdominal scars	Confirms surgical history or identifies previously unidentified surgical procedures, including previous cesarean sections.
Assessment for presence of peripheral or facial edema	Facial edema alone or in association with peripheral edema is a classic sign of preeclampsia.
Pelvic and Cervical Examination	
Cervical effacement and dilatation	Progressive cervical effacement and dilatation is the mark of true labor.
Position of the cervix	Location of the cervix in an anterior or middle position is associated with greater readiness for labor compared to a cervix that is posterior.
Station of fetal presenting part	Progressive fetal descent is indicative of progressive labor and pelvic adequacy.
Presence of molding or caput succedaneum	The presence or absence of molding and/or caput indicates fetal adaptation to the maternal pelvis and indirectly reflects the degree of pelvic adequacy.
Fetal lie, presentation, and position	Digital examination findings confirm and enhance abdominal examination findings relative to fetal lie, presentation, and position.
Tone and elasticity of vagina and length of perineum	The potential for perineal lacerations may be suggested by assessment of the tone and elasticity of the vagina and length of perineal body.
Confirmation of membrane status	Palpation of intact fetal membranes or amniotic fluid expulsion upon cervical examination is suggestive of membrane status.
Visual inspection of perineum	Identification of lesions, vulvar varicosities, and/or vaginal discharge including frank bleeding will impact the management plan.
Assessment of fetal heart rate	Indicates absence or presence of risk factors for fetal acidemia based on fetal heart rate characteristics and response to uterine contractions.
Optional or Supplemental Examinations	

Measurement of maternal weight	Relevant when compared to prepregnancy weight to ascertain total weight gain during pregnancy, or when compared to previous prenatal visit measurements to assess interval weight gain. Very rapid weight gain is an indirect measure of edema and possibly preeclampsia.
Clinical pelvimetry	Supports clinical judgment when estimating pelvic adequacy.
Evaluation of reflexes and determination of the presence of clonus	Hyperreflexia and clonus are signs of severe preeclampsia/eclampsia.
Speculum examination	Provides visualization of the cervix and vaginal vault to confirm rupture of membranes, collect laboratory specimens, and estimate cervical dilation and effacement.

Physical examination findings or vital signs indicative of a potential or actual complication require further evaluation. For example, an elevated blood pressure is an indication for eliciting and evaluating reflexes and for assessing for the presence of clonus.

Controversy exists about the role of digital cervical examinations in the initial and ongoing evaluation of a woman with labor signs and symptoms. The unique clinical situation of the laboring woman and her desires, along with the clinical judgment and expertise of the midwife, are taken into consideration when considering the necessity of performing a digital cervical examination.

In institutions that have continuous electronic fetal monitoring capability, it is common practice to obtain a baseline fetal heart rate (FHR) recording (e.g., 20 minutes) as the means of initial evaluation of fetal well-being for most, if not all, women presenting for evaluation of labor. This practice, when applied to women who do not have an obstetric or medical risk for fetal acidemia, does not improve maternal or neonatal outcomes and, when compared to initial assessment by intermittent monitoring, may be associated with an increase in intrapartum interventions including continuous electronic fetal monitoring (RR = 1.30; 95% CI = 1.14–1.48) and cesarean delivery (RR = 1.20; 95% CI = 1.00–1.44).[79] National guidelines are silent on the preferred method of evaluating fetal heart rate for women presenting for evaluation with labor signs and symptoms, but are clear regarding the appropriateness of intermittent auscultation for ongoing evaluation of low-risk women in labor.[2,80,81]

Laboratory Investigation

Available prenatal records can be reviewed to identify the woman's blood type and Rh status, anemias, glucose tolerance testing, and specific perinatal infections including GBS carrier status, hepatitis B infection or carrier status, and HIV status. In the case of a woman presenting with no prenatal record, all routine prenatal laboratory tests will be obtained to provide a baseline for development of a management plan.

Clinical judgment and institutional policy will influence the decision to order further laboratory studies. If the woman will be having an intravenous infusion, blood specimens can be obtained concurrently with intravenous line placement. **Table 25-7** identifies laboratory studies commonly performed for evaluation of a woman with labor signs and symptoms.

Table 25-7	**Commonly Performed Laboratory Investigations for a Woman Presenting with Labor Signs and Symptoms**

Laboratory Test	Significance
Complete blood count (CBC)	Provides baseline measures of hemoglobin and hematocrit, thereby evaluating for anemia (a risk factor for postpartum hemorrhage)
	Provides a baseline for the white blood cell count, which can indicate infection—although transiently high values are common with labor
	Provides a baseline platelet count, which may be used by anesthesia personnel when determining anesthesia eligibility
Blood type, Rh status, and antibody screen[a]	Confirms prenatal blood group and Rh status
	Provides a comparative value to prenatal results, allowing for assessment of maternal antibodies development
	Provides basic information for a blood bank in the event that blood transfusion is needed
Urinalysis	Identifies the presence of protein, a marker for preeclampsia
	Identifies the presence of glucose, a marker for poorly controlled diabetes
	Identifies the presence of ketones, a reflection of fat metabolism and current nutrition status
	Indicates hydration status (i.e., specific gravity measurement)
	Identifies abnormal components in the urine that may direct differential diagnosis toward urinary tract infection

Confirmation of Labor Status

A diagnosis of labor warrants the woman's admission to the birth center/hospital or continuous midwife attendance when a home birth is planned. Because cervical dilation rates indicative of active labor do not begin for many women until cervical dilatation reaches 6 cm or more,[7] labor status determinations must be based on at least two adequately spaced cervical examinations—for example, 2 to 4 hours apart. In the presence of regular, painful contractions and complete or near-complete effacement, it is reasonable to consider a woman to be in active labor at 4 cm or 5 cm dilation *if that state of dilatation is immediately preceded by cervical change over time* (i.e., 1 cm or more in a 2-hour or shorter window), or at 6 cm or more regardless of the rate of previous cervical change. Unless labor is clearly advanced, a single-point cervical dilation measurement does not reliably differentiate labor phases. When a diagnosis of labor cannot be made with relative certainty, observation before admission to the birthing unit is prudent, assuming the woman is planning to give birth in the hospital.

It may take several hours of ongoing assessment to differentiate between prelabor, latent labor, and active labor. Between assessments and after fetal well-being is confirmed, the woman may be encouraged to walk, rock, sit on a birthing ball, or simply rest. In hospital and birth center settings, when no change in dilation is noted at the next examination before active labor, the woman may safely go home if she has no transportation problems and wants to go home.

In making a diagnosis of labor, clinicians must carefully differentiate not only between true labor and prelabor, but also between labor and any obstetric or non-obstetric discomforts or complications that can masquerade or be misinterpreted as labor, such as urinary tract infections or placental abruption.

Components of Midwifery Care for Laboring Women

Labor Support and Pain Management

Labor support and pain management are intertwined. Labor support consists of techniques and interventions that support the physical and emotional experiences of the woman in labor and includes recognizing the therapeutic value of human presence—a hallmark of the art and science of midwifery. Reviewed in detail in the *Support for Women During Labor* chapter, the inclusion of labor support and pain management as a basic component of midwifery care reflects the importance of intentionally and continually evaluating and modifying the midwifery care provided throughout labor. Women who receive continuous labor support are more likely to have a spontaneous vaginal birth, use less pain medication, have slightly shorter labors, and be more satisfied with their birth experiences than women who do not receive such support.[82]

Although some practice environments essentially preclude the midwife from personally acting as the exclusive continuous labor support provider, midwives remain in the unique position of advocating for this essential care. Midwives can engage with and support local doulas and/or other labor support caregivers so that they are engaged in the labor support process.

Maternal Position and Level of Activity

The level of physical activity and positions used during labor are ideally those chosen by the laboring woman. It is rare that a woman would have a contraindication to assuming any position that she prefers. When given a choice, many women prefer an upright position or ambulation throughout much of their labor. However, the birth environment may affect the level of empowerment a woman has to assert her desires, and many hospital labor settings have a culture of lying in bed during the first stage of labor. While laboring in bed is considered to be convenient to some providers, it may not be optimal for the progress of physiologic labor or for the comfort of the laboring woman.

Women assuming upright positions have shorter labor durations by approximately 1 hour and are less likely to have an epidural or cesarean birth, as compared to women who maintain recumbent positions.[83] Creative use can be made of furniture, pillows, birthing balls, or an adjustable bed to support a laboring woman in a variety of upright positions, including hands and knees, sitting, standing, and squatting. The midwife can support unlimited activity and freedom of choice of positions for low-risk women in labor by routine use of intermittent fetal auscultation and becoming comfortable with and skilled at the process of assessing fetal heart rate and contractions with women in a variety of positions.

When resting in bed is necessary or desired, lateral recumbent positions are preferred to supine positions because they reduce the potential for aortic/venae cavae compression with resulting maternal hypotension and potential fetal compromise. Lateral positions also facilitate kidney function and do not interfere with coordination and efficiency of uterine contractions.

Rupture of the fetal membranes is not usually a contraindication to ambulation and upright positions. Once fetal well-being is assured, if the fetus is in a cephalic presentation and the fetal presenting part is engaged in the pelvis or well applied to the cervix, there is no reason to

restrict ambulation or upright positions. These activities may be desirable to the woman, as the intensity of the contractions often increases after rupture of membranes and upright positions tend to facilitate maternal comfort. Ambulation or upright positions may be contraindicated upon rupture of membranes if the fetal head is unengaged or in the case of a malpresentation because of the heightened risk of umbilical cord prolapse.

Women with medical or obstetric conditions such as severe preeclampsia, placental abruption, or acute infections will necessarily have their activity restricted due to their physiologic instability, the effect of medications, or increased fetal risk requiring continuous electronic fetal monitoring. Women who have physical mobility disabilities may require additional modifications to facilitate comfort and labor progression. Finally, women who have a history of sexual or physical abuse may find any position such as lithotomy, or having providers stand over her, a trigger of previous trauma. For these women, if a plan has not been established prenatally for labor management, discussion early in labor to identify positions of comfort will be of value.

Hydration and Nutrition

Hydration and nutrition are potentially important variables for optimal uterine perfusion and myometrial function and, therefore, may be related to uterine efficiency during labor. Contemporary management of labor in the United States typically involves limited oral nutritive intake and noncaloric intravenous fluid administration. The primary rationale cited for withholding food and fluid during labor is the decreased risk of gastric content aspiration during general anesthetic induction—an extremely rare but serious syndrome first described by Mendelson in 1946.[84] Of course, obstetric anesthesia has changed considerably since the 1940s, with greater use of regional anesthesia and better general anesthetic technique. Moreover, fasting does not guarantee an empty stomach or less acidity. Overall, modern evidence shows no benefits or harms associated with oral intake during labor, so there is no justification for the restriction of fluids and food in labor for women at low risk for complications. Adequate hydration during labor would seemingly assist in the delivery of oxygen and nutrients as well as facilitate the elimination of waste from the contracting uterus, akin to how proper hydration benefits the skeletal muscle of athletes.

Four randomized studies have been conducted to investigate maternal hydration as a potential variable in labor progress, all focusing on nulliparous women.[85-88] In the earlier studies, Garite et al.[85] and Eslamian et al.[86] randomized low-risk, nulliparous women in spontaneous labor to receive 125 or 250 mL/hour of intravenous isotonic fluids while receiving little or nothing by mouth. In the 250 mL per hour groups, Eslamian et al. reported a shorter first stage of labor duration (3.9 ± 1.4 versus 6.1 ± 1.8 hours, respectively; $P < 0.0001$),[86] while Garite et al. demonstrated a strong nonsignificant trend toward a shorter first-stage labor.[85] Both research teams found fewer prolonged labors in the 250 mL per hour group, and Eslamian et al. reported that oxytocin augmentation was significantly less likely in the women who received more fluids (8.1% versus 20.4%, respectively; $P < 0.001$).[86]

Coco et al.[87] studied whether giving low-risk, nulliparous women more intravenous fluid reduced labor duration when oral intake was unrestricted (e.g., water, juice, or even

carbonated soft drinks). This team found that increased intravenous hydration does not decrease labor duration when women are permitted to drink freely, nor does it decrease rates of oxytocin augmentation or cesarean births. Likewise, Kavitha et al.[88] found no significant differences in labor duration, oxytocin augmentation, or mode of delivery between women receiving oral fluids only or intravenous fluids at a rate of either 125 or 250 mL/hour, although those women who received intravenous hydration were less likely to vomit during labor. A significant shortcoming in all of these randomized hydration studies was that none measured maternal hydration by scientific means (e.g., urine specific gravity). Thus, the women's actual hydration status remained unknown.

Nutritional needs during labor are not well understood, although it has been reported that women in the third trimester of pregnancy exhibit a state of "accelerated starvation," characterized by rapid rises in plasma beta-hydroxybutyric acid (the principal labor ketone) and a concomitant fall in plasma glucose. This process of accelerated lipolysis conserves glucose for the fetus. Ketones are produced in the liver as a by-product of fat catabolism when glycogen stores are unavailable (e.g., in starvation states or during exercise) and are normally oxidized to carbon dioxide, water, and alternative forms of energy that are usable by tissues such as a contracting uterus.[89,90] Production of ketones in quantities above the level of need results in ketosis and may have deleterious effects on uterine function.[89]

Authors of a Cochrane review published in 2013 found no significant differences in duration of labor, augmentation of labor, cesarean births, or Apgar scores between women with and without oral fluid and food restriction during labor.[91] Given the current state of evidence, women should be free to drink and eat in labor as they wish and encouraged to maintain their fluid intake.

Intravenous Access

Routine prophylactic insertion of intravenous access is a practice that is unnecessary in the provision of normal labor and birth care for women who have no significant obstetric or medical risks. Instead, the decision to initiate and maintain intravenous access during labor should be based on actual or potential risk factors for each woman. Women who cannot tolerate oral fluid intake may require intravenous fluids. Intravenous access is also necessary for administration of some medications, such as antibiotic prophylaxis for women who are carriers of GBS, pain medications, or oxytocin augmentation. Prior to initiation of epidural anesthesia, establishing intravenous access allows for administration of isotonic fluid blood volume expanders to mitigate epidural-related hypotension; continuing access after epidural placement allows for ongoing fluid administration and medication administration should complications develop. Institutional policies that require intravenous access exist in many hospital birth settings, and eliminating these policies is one example of changes needed so that policies are in line with existing evidence to support normal physiologic labor and birth.

Membrane Management

Historically, being born "in the caul" or with intact membranes was considered a sign of good

fortune and occasionally magic gifts. Yet artificial rupture of membranes (AROM) during labor has commonly been believed to accelerate the progress of labor and is used frequently in contemporary practice. AROM can be employed to induce labor either alone or with other agents, used routinely during labor in an effort to speed progress, or used selectively as a treatment for dystocia. Because AROM is associated with adverse outcomes, however, the effectiveness of AROM for each of these situations must be examined. Risks associated with AROM include umbilical cord compression with resultant fetal heart rate decelerations, umbilical cord prolapse, maternal discomfort from the procedure, increased risk of infection, and, rarely, rupture of fetal vessels (vasa previa).[77]

Two trials have evaluated the effectiveness of early amniotomy (during latent labor) as an adjunct during induction. Macones et al. evaluated outcomes for nulliparous women who were induced at term and who had an amniotomy before 4 cm dilation compared to outcomes for women who had an amniotomy after they were at 4 cm dilation.[92] More women in the early amniotomy group gave birth within 24 hours (68% versus 56%, $P = 0.002$) and there was a mean 2-hour shorter labor in the early amniotomy group.

The use of AROM to treat dystocia has also been investigated. Rouse et al. randomized women with active-phase arrest to amniotomy with oxytocin or oxytocin alone ($n = 108$).[93] No significant differences in mode of birth or duration of labor were observed between the two groups. The women in the amniotomy group had a nonsignificant trend toward more chorioamnionitis and endometritis. Because they had internal uterine pressure catheters and fetal scalp electrodes placed at the time of amniotomy, it is not clear if AROM or the other interventions increased this risk for infection; however, there is known relationship between use of intrauterine pressure catheters and increased risk for infection.

Wei et al. evaluated early versus late use of amniotomy and oxytocin augmentation for both prevention and treatment of dystocia in a Cochrane meta-analysis ($n = 8033$).[94] In the prevention of dystocia trials, women in the early amniotomy/oxytocin groups had a modest reduction in cesarean birth rates (RR = 0.87; 95% CI = 0.77–0.99) and shorter labor (mean difference: –1.57 hours). In the treatment of dystocia trials, there was no reduction in cesarean birth rates (RR = 1.47; 95% CI = 0.73–2.96), nor was there a reduction in the duration of labor between women who had early versus late amniotomy and oxytocin augmentation. There were no differences in the rate of infection or adverse neonatal outcomes.

Current evidence suggests that when amniotomy is used in conjunction with oxytocin for induction or as a method of preventing dystocia in women who have mild labor delays, the decrease in labor duration associated with amniotomy may be statistically significant but not clinically relevant. The reduced risk of cesarean birth is significant but modest. In contrast, amniotomy alone does not appear to be a beneficial treatment for women with active-phase arrest.

The use of AROM as a routine measure to speed the progress of labor in women without dystocia has been evaluated in several randomized trials and a Cochrane meta-analysis. Unlike in the dystocia trials, AROM in women who do not have dystocia was associated with a trend toward an increased risk for cesarean birth (RR = 1.27; 95% CI = 0.99–1.63; $n = 5583$; 15 trials) without a concomitant shortening of the first stage of labor.[73] There was a similar trend toward more fetal heart rate abnormalities (RR = 1.09; 95% CI = 0.97–1.23) but no

differences in serious neonatal morbidity. The American College of Obstetricians and Gynecologists recently recommended that amniotomy should not be performed in women with normally progressing labor unless required to facilitate monitoring—a position that supports a long-standing midwifery practice.[2]

If there is a clinical rationale to perform an amniotomy, a cephalic presentation and engagement in the pelvis should be confirmed. Before performing AROM, the midwife carefully reassesses the fetal station and ensures the fetal head is well applied to the cervix. Keeping the fingers in the cervix, the membranes can be gently disrupted with the Amniohook. Care should be taken to avoid scratching the fetal head and the clinician's fingers should be left in place during the initial gush of fluid to ensure a prolapsed cord does not occur. The fetal heart rate should be assessed during the procedure and monitored frequently for a short time afterward.

In summary, routine amniotomy for women in spontaneous term labor may do more harm than good. This procedure should be reserved for treatment of dystocia, as an adjunct intervention for women who have a clear indication for induction of labor, and when internal monitoring is required. The woman should be reassured that aside from the potential discomfort associated with any vaginal examination, there is no pain associated with AROM for her or her fetus. Finally, the woman should give consent for this procedure and a formal shared decision-making process that reviews the benefits, risks, and alternatives should be conducted.

Fetal Heart Rate Monitoring

Fetal monitoring does not necessarily imply "continuous electronic fetal monitoring," but rather reflects an attitude of heightened sensitivity on the part of the midwife to fetal well-being, via ongoing evaluation of the fetal heart rate via the method most appropriate to the individual woman and fetus. The *Fetal Assessment During Labor* chapter details the methods and indications for intermittent auscultation of the fetal heart rate as well as continuous external and continuous internal fetal heart rate assessment.

Uterine Contraction Monitoring

Uterine activity can be evaluated by correlating the woman's perceptions of contractions with observation and abdominal palpation and/or one of two electronic monitoring methods: an external tocodynamometer or an intrauterine pressure catheter.

Labor progress is the best indicator of adequate contractions. Nevertheless, it is generally accepted that three contractions within 10 minutes is the minimum frequency necessary to achieve progressive cervical change in active labor. "Adequate" labor contractions typically do not allow indentation of the uterine fundus when palpated abdominally at their acme. The maternal response to contractions provides insights into the frequency, duration, and intensity of contractions, but it is important to keep in mind that women's responses to labor vary widely. The intensity of a woman's external response to a contraction is influenced by environment, culture, and individual coping abilities.

When considering application of an electronic uterine monitor, the need for uterine activity data must be weighed against the need of the woman for mobility and freedom of movement. The rise of the uterus within the abdomen during a contraction can be easily visualized on a woman of average or low BMI. This change in abdominal shape is the mechanism by which an external electronic tocodynamometer functions; that is, this device captures the graphic image of a contraction as the abdomen lifts against the pressure transducer, which is held in place by the resistance of an abdominal band. External tocodynamometry can present graphically the frequency and duration of uterine contractions, but it relies on correct placement and calibration and may not work well for women who are overweight or obese. In addition, the tocodynamometer is unable to provide accurate information regarding the intensity of contractions. It is highly sensitive to maternal movement, predisposing the graphic data to artifacts and errors.

To counter limitations of the traditional tocodynamometer, researchers are investigating the use of electrical uterine myography. This emerging method of electronic uterine monitoring uses noninvasive electrodes placed on the maternal abdomen to report electrical activity of the uterine muscle, similar to how an electrocardiogram records the electrical conduction of the heart. This promising technology is able to graphically present the same information as that provided by a tocodynamometer, while having the advantage of being less sensitive to maternal body type and movement.

Women generally sense contractions when the contractions exert approximately 15 mm Hg of intrauterine pressure; this is also the minimum strength of contraction that can be detected by an observer's hand. In contrast, internal uterine monitoring detects the increase in tonus slightly sooner than the woman or her attendants[95] (**Figure 25-5**). Internal uterine monitoring is the most accurate but most invasive method of evaluating uterine activity (**Figure 25-6**). The intrauterine pressure catheter requires membranes to be ruptured and has a low—albeit real—risk of uterine or placental perforation and infection. When placed correctly (i.e., within the amniotic fluid compartment), the intrauterine pressure catheter provides information regarding frequency, duration, and intensity of contractions. The intrauterine pressure catheter has the added feature of enabling the instillation of fluid into the uterus (amnioinfusion) to treat recurrent variable fetal heart rate decelerations associated with fetal umbilical cord compression.

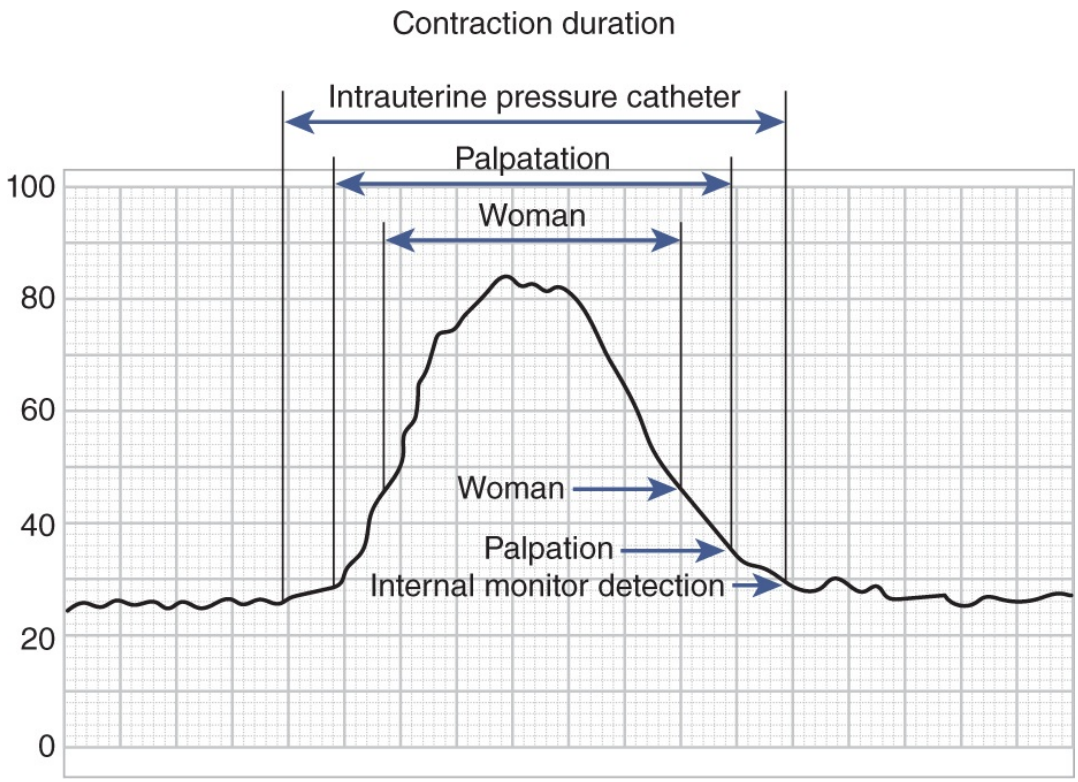

Figure 25-5 Relative sensitivity of various methods available for detection of uterine contractions.

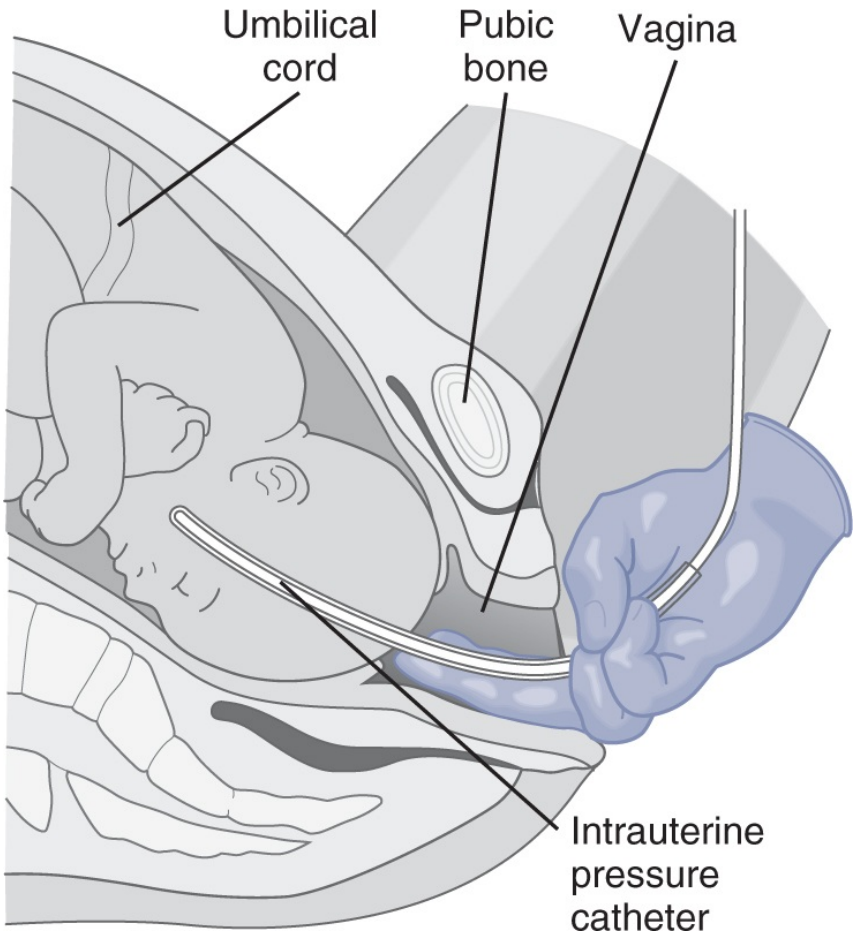

Figure 25-6 Insertion of an intrauterine pressure catheter.

Montevideo units (MVUs) are used to assess the effectiveness of uterine contractions measured via an intrauterine pressure catheter. MVU levels are determined by subtracting the numeric amplitude of each contraction that occurs in a 10-minute window from the baseline uterine tonus amplitude (in millimeters of mercury [mm Hg]) and then summing the total calculated rise in amplitude over the 10-minute time period. Historically, 200 to 250 MVUs has been used to define “adequate” contractions based on Calderyo-Barcia’s studies from the 1960s, which determined the minimum MVU values that reliably predict vaginal birth.[96]

Introduction of an intrauterine pressure catheter may be indicated during labor augmentation when labor dystocia is suspected. However, this device has no place in the management plan for labor in the absence of fetal or obstetric complications.

Continuing Evaluation During Labor

Continuing evaluation during labor has three primary focuses: (1) maternal well-being, (2) fetal well-being, and (3) labor progress. Assessing maternal status includes monitoring maternal vital signs, urinary output, coping status, and general well-being. Continuing evaluation of the fetus includes the monitoring of fetal heart rate. In addition to monitoring cervical dilation over time, evaluation of fetal presentation and position and fetal adaptation to the maternal pelvis is an essential component of evaluating labor progress.

Maternal Well-Being

Maternal Vital Signs

The frequency with which vital signs are assessed in the absence of complications may vary among settings, but is typically detailed in an institutional policy to ensure adherence to a minimum standard. Unfortunately, the standards for the frequency of vital signs for low-risk women in labor may be based in nursing and institutional tradition rather than on evidence of clinical relevance in laboring women. The following schedule for checking vital signs is frequently encountered as policy for a woman (without epidural anesthesia) during the first stage of labor who does not have a specific condition that would require more frequent monitoring:

- Blood pressure, pulse, and respirations: every hour
- Temperature: every 2 to 4 hours when the temperature is normal and the membranes are intact, and every 1 to 2 hours if the temperature is abnormal and/or after the membranes have ruptured

As a woman's status may change over the course of her labor, the frequency of assessing vital signs should be adjusted to match her unique situation.

Urinary Output

The bladder is a pelvic organ. A distended bladder can impede the progress of labor by preventing fetal descent as well as increasing the discomfort and pain in the lower abdomen that women frequently experience during labor. A woman in labor should be encouraged to empty her bladder at least every 2 hours during the active phase of the first stage of labor. This provides an opportunity for the clinician to evaluate maternal hydration status. Presence of ketones or protein in the urine may be helpful in developing the management plan and can be assessed as indicated.

With deepening descent of the fetal presenting part into the true pelvis during labor, the bladder may be compressed to the point at which even small urine volumes cause distension. In the third stage of labor, a distended bladder can inhibit the ability of the uterus to contract effectively, increasing the risk of postpartum hemorrhage secondary to uterine atony. Bladder hypotonicity, urine stasis, and infection during the postpartum period can result from traumatic

pressure exerted on a distended bladder during labor.

A distended bladder may appear as a bulge above the symphysis pubis and, in severe cases, may extend as high as the umbilicus. When the fetus is in a posterior position, the contour of the woman's abdomen may look as though she has a full bladder; bladder distension must then be ruled out.

In the event of bladder distension, the first step is to facilitate spontaneous voiding. The best method is for the woman to walk to the toilet if there are no contraindications to ambulation. If she is unable to be out of bed and if the common methods (having her listen to the sound of running water; running warm water over her perineum; applying light suprapubic pressure; and having her practice perineal relaxation) do not initiate urination, then catheterization may be considered.

Bladder distension can occur in any laboring woman, but is especially likely in women with epidural anesthesia who receive a bolus of fluid prior to initiating the epidural. Once the epidural is active, the woman cannot feel the urge to urinate and may not have the muscle control needed to void. Intermittent or indwelling insertion of a urinary catheter to drain the bladder should be considered to minimize the risk of urinary retention or infection for these women, especially if they are remote from delivery.

General Maternal Condition

Continuing evaluation of maternal status includes evaluation of several areas that interrelate and overlap: the woman's level of fatigue and physical depletion, her behavior and responses to labor, her perception of pain, and her ability to cope with labor.

A woman's level of fatigue and physical depletion is affected by her state at the start of labor, maintenance of hydration during labor, length of labor, and her ability to cope with the demands placed upon her by labor. This can be a vicious cycle: A woman's lack of ability to cope may increase fatigue, and fatigue can decrease her ability to cope. Occasionally a woman enters labor truly exhausted and dehydrated from days of the general aches and symptoms characteristic of the end of pregnancy or from a prolonged latent phase. A mutually agreed-upon hospital-based management plan for such a woman might include considering an early epidural and intravenous fluids.

A woman's behavior changes throughout labor, and these changes can be used in evaluating her response to labor. Her expressions and behaviors are also affected by her degree of self-efficacy, anxiety or fear, expectations, and the amount of pain she is experiencing. In another cycle of interplay, these factors affect her coping ability, and her ability to cope in turn affects her self-efficacy, anxieties, and fears. Evaluation of the woman's behavior during labor will help determine the support and comfort measures needed, including consideration for medication. That said, interpretation of another persons expressions or behavior is heavily influenced by cultural expectations and can be easily misjudged. Therefore, the midwife must evaluate a laboring woman in the context of her world view, and be careful to avoid making judgements based on the midwife's cultural dictates.

Fetal Well-Being

Ongoing and standardized fetal heart rate assessment is essential to evaluating fetal well-being throughout labor regardless of the method chosen. The *Fetal Assessment During Labor* chapter provides details on fetal assessment in labor.

Labor Progress

Digital Cervical Examinations

Internal cervical examinations are intrusive and often uncomfortable for women; however, appropriately timed digital cervical dilation examinations inform labor management. Use of contemporary guidelines that account for normal duration of labor and rate of cervical dilation is important. While it is appropriate to wait several hours prior to doing a cervical examination as the cervix changes in early active labor (e.g., from 4 cm to 5 cm), it may be inappropriate to wait for such a long period of time later in labor (e.g., between 8 cm and 9 cm).

Supplemental indicators of labor progress in addition to cervical dilation can and should be obtained from each digital cervical examination that is performed during labor, including (1) cervical effacement, (2) position (posterior, mid-position, anterior), (3) consistency (firm or soft), and (4) fetal station and position. The frequency with which cervical examinations are performed depends both on the woman's condition and on the midwife's ability to use other parameters for evaluating progress in labor. It is not always necessary to perform an internal examination to gain insights into the progress of labor. The traditional practice of conducting cervical examinations every 1 to 2 hours simply subjects the woman to unnecessary discomfort, intrusion, and increased risk of infection. Astute observation of the woman—including her behavior, contraction pattern, signs and symptoms of transition into second-stage labor, change of location of back pain, change in location of maximum intensity of fetal heart tones, and change in position of fetal heart tones—can give valuable insights into labor progression. This information does not, however, negate performance of a cervical examination if a question arises regarding labor progress.

During normal first-stage labor, a cervical examination may be indicated in the following situations:

- To establish an informational baseline that can be used for appropriately timing further examinations to establish labor status prior to admission or labor interventions (prelabor, latent, or active labor)
- As an appropriately timed second examination to determine the woman's labor state prior to labor admission (prelabor, latent, or active labor)
- To inform management decisions related to management of labor pain
- To verify complete dilation
- To check for a prolapsed cord after spontaneous rupture of membranes if a prolapsed cord is a suspected risk (e.g., ballottable presenting part or fetal heart rate decelerations that do not resolve with usual maneuvers)

Unfortunately, digital cervical examinations rely on the clinical experience and

proprioceptive skill of the examiner. Labor care providers accurately determine actual cervical dilation in only half of all cases,[97-100] but are accurate to within 1 cm (plus or minus 1 centimeter) of actual cervical dilatation in approximately 90% of cases.[97,99,100] This imprecision is a significant shortcoming for accurately evaluating labor progress, considering that a laboring woman who is truly dilated to 4 cm may be determined to be 3 cm to 5 cm by a labor care clinician, and so on, for subsequent examinations. Thus, true cervical change over time is only *estimated* by cervical examinations. Because of this shortcoming in labor progress evaluation, it is recommended that cervical examinations be performed by the same professional whenever possible, and be interpreted conservatively so that unnecessary interventions aimed at accelerating labor are not imposed on women who are adequately progressing in labor.

Fetal Presentation, Position, and Station

Assessment of descent and internal rotation of the fetal presenting part is as important as assesment of progressive cervical dilation when monitoring labor progress. The studies that have determined normal time frames for labor progress are largely based cohorts of women whose fetus is in a vertex presentation. Most commonly the fetus enters the pelvis in an occiput transverse position and then internally rotates to occiput anterior at the level of the pelvic ischial spines. Thus, it is common to find no cervical dilation between one digital examination and the next, yet to identify progressive changes in fetal descent or internal rotation over the same interval. In contrast to slow dilation as the fetus in an occiput position descends and rotates, arrest of descent is an important finding that may indicate true cephalopelvic disproportion.

Because cephalic presentations are by far the most common, it is vital that a midwife be proficient in identifying the essential landmarks of the fetal skull (as described in the *Anatomy and Physiology During Labor and Birth* chapter). Cervical examination provides information regarding (1) fetal presentation; (2) fetal position; (3) fetal station; (4) the adaptation of the fetus to the pelvis—specifically, synclitism or asynclitism of the fetal head; (5) the presence or absence of molding; and (6) the presence or absence of caput succedaneum. Each of these elements should be determined at every cervical examination conducted during active labor.

The formation of a few millimeters of caput succedaneum is not unusual or abnormal. A small caput succedaneum may be indicative of a somewhat prolonged labor resulting from uterine inertia with weak contractions. Formation of extensive caput succedaneum, which makes the identification of fetal sutures and fontanels difficult, combined with severe amounts of molding, is usually seen only when intrauterine pressure has been great and labor prolonged. Cephalopelvic disproportion must be suspected when significant molding or overriding sutures are noted. A sizable caput may also be seen from positional pressure when the fetal position is occipitoposterior.

Recently, point-of-care ultrasound has been explored as a mechanism for diagnosing malpositions and asynclitism. Ultrasound appears promising for this use; however, treatments for specific fetal malpositions have not been the subject of sufficient research to establish effectiveness.[101] Use of differing maternal positions and movements for treatment of fetal

malpositions is reviewed in the *Complications During Labor and Birth* chapter. Care of women who have a fetus in a persistent occiput posterior position is reviewed in the *Second Stage of Labor and Birth* chapter, as interventions are rarely needed for this fetal position prior to the second stage.

Conclusion

Normal physiologic labor is an intricate interplay of physiologic and psychological forces within the woman. Caring for women during labor involves attention to three different but equally important variables: the well-being of the woman, the well-being of the fetus, and labor progress. Historical measures for evaluating labor progress have been found to be unreliable, but new indices are not yet available for all populations. Given the differences in labor patterns noted in Friedman's traditional findings and contemporary research, it is inappropriate to base clinical expectations of cervical dilation during labor on Friedman's work. That is, contemporary patterns of labor should be used, as this body of research continues to grow and evolve.

Evaluation and Diagnosis of Ruptured Membranes

JEREMY L. NEAL, NANCY K. LOWE, SHARON L. RYAN, LINDA A. HUNTER, AND AMY MAROWITZ

© hakkiarslan/iStock/Getty Images Plus/Getty

When evaluating a woman whose history suggests rupture of membranes, the differential diagnoses include urinary incontinence, vaginal or cervical discharge, semen, and (rarely) rupture of the chorion alone.

Several laboratory tests can confirm or support a diagnosis of rupture of membranes (ROM), including the arborization test (fern test), pH testing (nitrazine test), ultrasound assessment of amniotic fluid volume, and testing for the presence of placental alpha microglobulin-1 (PAMG-1) or fetal fibronectin in vaginal secretions. Several of these tests can be directly performed on samples of fluid obtained during the physical examination.

Tests for and Classic Signs of Rupture of Membranes

1. Observation of fluid coming from the cervical os is diagnostic for ROM.
2. The *fern test* is a classic method of assessing for ROM and is considered diagnostic in many settings when the classic pattern of ferning is clearly seen (**Figure 25A-1**). During a sterile speculum examination, a sterile cotton swab is used to obtain a specimen of the fluid from the posterior vaginal fornix. Care must be taken not to touch the cervical os to avoid collecting cervical mucus. The specimen is spread thinly onto a microscope slide and allowed to dry thoroughly. The slide is then inspected without using a cover slip using a microscope at 10× power for a fern-like pattern (arborization) caused by crystallization due to the high sodium chloride and protein concentrations in amniotic fluid.

   The sensitivity and specificity of the fern test among nonlaboring women are 51.4% and 70.8%, respectively; for women in labor, these results improve to 98% and 88.2%, respectively.[1] Cervical mucus and semen can also show fern-like patterns, which may

cause a false-positive result. The results of a fern test must be viewed within the context of the history and physical examination and may best be viewed as a supportive test rather than a conclusive one if active leaking from the cervical os is not visible.

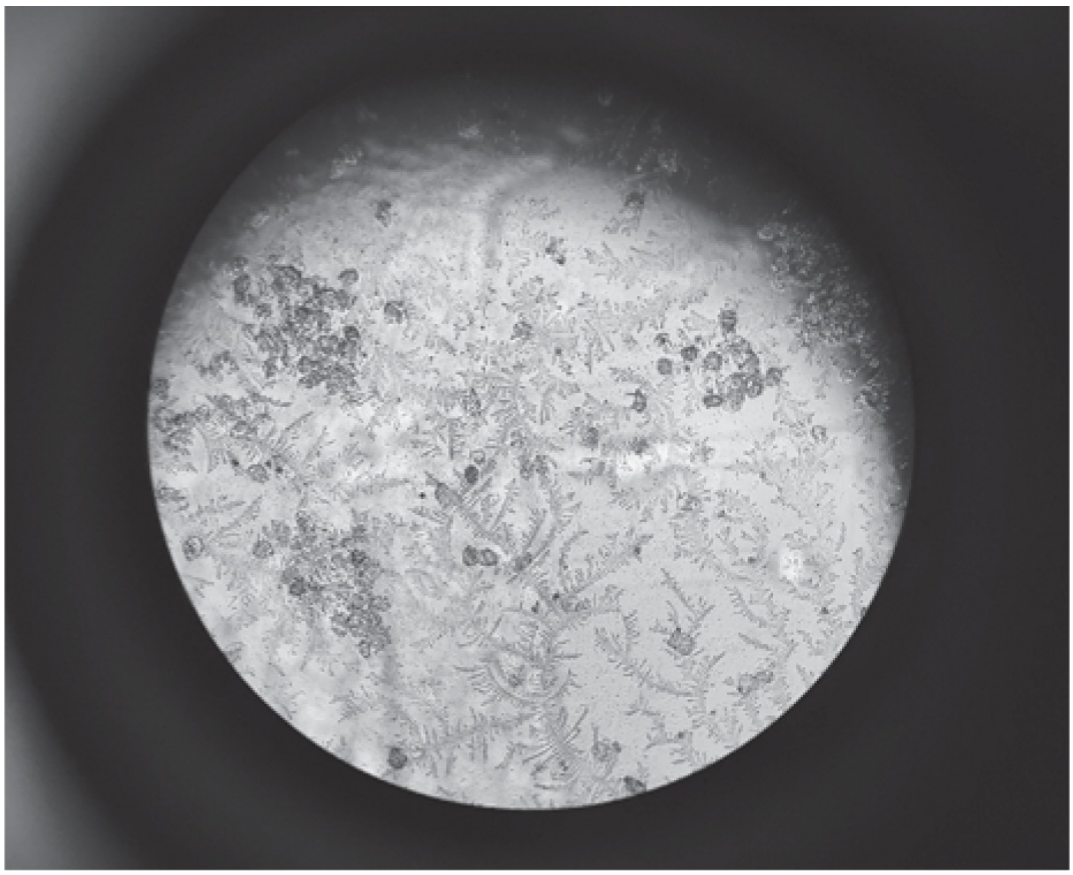

Figure 25A-1 Fern pattern of amniotic fluid.

Courtesy of Philapeter. Creative Commons license available at https://creativecommons.org/licenses/by-sa/4.0/deed.en.

3. The *nitrazine test* uses limited-range pH paper or a commercially prepared swab to detect the rise in pH in vaginal discharge associated with the presence of amniotic fluid. The normal pH of the vagina of most women is acidic (approximately 4.5), whereas amniotic fluid is neutral to slightly alkaline (7.0–7.5). The mustard-gold nitrazine will turn dark blue in the presence of alkaline material. When using nitrazine paper, the procedure is to collect a sample of fluid from the posterior fornix with a sterile cotton swab and then touch the nitrazine paper with the saturated swab. A well-saturated cotton swab can be used to prepare a slide for the fern test, then touched to the nitrazine paper. Alternatively, the paper can be touched in the fluid collected at the tip of the sterile speculum when it is withdrawn from the vagina. Commercially prepared nitrazine swabs are available and are accompanied by manufacturer instructions that must be carefully followed.

   The sensitivity and specificity of the nitrazine method in confirming ROM are approximately 87% and 81%, respectively.[2] False-positive results can occur in the

presence of vaginal infections, blood, semen, or other alkaline substances, while false-negative results can be caused by a "high" or minimal leak of amniotic fluid.

4. Pooling of fluid in the posterior fornix of the vagina is a helpful sign, but it is not diagnostic for ROM without confirmation via ferning or nitrazine testing.
5. Ultrasound quantification may also be used, although a woman can have ruptured membranes and still have a normal amount of amniotic fluid, especially if the membranes are only leaking. Ultrasound documentation of oligohydramnios does not confirm ROM but may be helpful in making a management plan.

Diagnosis of Rupture of Membranes

The diagnosis of ruptured membranes is typically made via the constellation of history, physical examination, and positive testing. When two or more tests are positive, the accuracy of the diagnosis is approximately 93%.[3] This method is generally considered acceptable for women at term. For women who are preterm, accurate diagnosis is more critical. Physician consultation is needed if the diagnosis is inconclusive for a woman who is at a preterm gestation.

Evaluation for Ruptured Membranes

History

1. Inquire about the time, amount, color, consistency, odor, and pattern of leaking (e.g., large gush, continued trickling).
   a. These data are especially important for development of a management plan because the length of time from rupture of membranes to delivery is directly correlated with risk of maternal–fetal infection. The characteristic of the fluid can reveal clues to fetal well-being.
   b. ROM typically will cause a large gush of fluid, followed by a continuous watery discharge necessitating use of sanitary pads or even washcloths or towels.
   c. In some instances of ruptured membranes, the only symptom the woman may notice is a feeling of moistness on her undergarments from a small, continuous discharge. Assessing the woman's ability to control the leakage with contraction of the pelvic floor muscles (Kegel) helps to differentiate PROM from urinary incontinence.
2. Inquire about any recent fever, abdominal pain, vaginal bleeding, abnormal discharge, urine symptoms, and last intercourse.
   a. Semen expelled from the vagina can sometimes be mistaken for amniotic fluid.
3. Inquire about signs of labor: contractions, bloody show, fetal movement, recent cervical assessments, or intercourse.
4. Confirm pregnancy dating (this is especially important if less than 37 weeks' gestation).
5. Review the prenatal record for past obstetric history, prenatal issues, or current medical

problems.

Physical Examination

The earlier an examination is performed after the rupture of membranes occurs, the easier it is to diagnose ruptured membranes. When more than 6 to 12 hours passes, many of the diagnostic observations become unreliable because of lack of fluid.

1. Measure temperature, pulse, respirations, and blood pressure.
2. Perform heart and lung auscultation.
3. Palpate the abdomen for tenderness.
4. Perform Leopold's maneuvers to assess fetal position, estimated fetal weight, and presenting part.
    a. Ultrasound confirmation of the presenting part may be required.
5. Perform fetal assessment with Doppler or electronic fetal heart rate monitoring per institutional or practice guidelines. Continuous electronic fetal heart rate monitoring is required for women who are between 24 to 37 weeks' gestation.
6. Perform a sterile speculum examination.
    a. Note the color, consistency, and amount of any fluid leaking from the vaginal introitus.
    b. As the speculum is carefully inserted, be alert for any evidence of prolapsed cord, bulging forebag, or protruding fetal parts.
    c. Visualize the cervical os and note any pooling of fluid in the vaginal vault or fluid leaking directly from the os.
        i. Normal amniotic fluid can be clear, straw colored, or cloudy. Flecks of white or creamy vernix may be noted in the amniotic fluid of preterm or near-term infants. Dark yellow or green fluid indicates the presence of meconium in the amniotic fluid. Meconium-stained fluid increases the risk for chorioamnionitis and can be an indication of fetal compromise.
        ii. Amniotic fluid has a distinct musty odor, which differentiates it from urine, while foul-smelling fluid can be an indicator of infection.
        iii. If there is no visible fluid leaking from the os:
            1. Have the woman perform a Valsalva maneuver or cough.
            2. Alternatively, consider having an assistant apply gentle fundal pressure or gently elevate the presenting part abdominally to allow fluid to pass by the presenting part and flow through the cervical os.
            3. Another option is to have the woman remain semi-reclining for 30 to 60 minutes and then repeat the sterile speculum examination.
    d. Obtain sterile swab specimens of any fluid or discharge seen, avoiding the cervical mucus.
        i. Using a sterile swab, collect a sample of fluid for 10–15 seconds from the vaginal pool at the posterior fornix or along the vaginal wall. Avoid the cervix.
        ii. If a nitrazine swab is being used, the color change can be read directly from the

swab.

iii. If nitrazine paper is being used, apply the swab to pH paper before proceeding. A pH of 6.5 or higher is suggestive of amniotic fluid rupture.

iv. Immediately roll the swab across a dry, clean slide to create a thin film. Thick specimens may obscure ferning. Set aside for 10 minutes.

1. Ferning is based on crystallization of the sodium chloride in amniotic fluid. This occurs as the liquid evaporates, so false-negative results are possible if the slide is examined before it is completely dry.

v. Obtain a wet mount of any discharge.

e. Obtain a specimen for gonorrhea and chlamydia culture per protocols as required.

f. Obtain GBS culture if the woman's status is unknown or if it has been more than 5 weeks since the last GBS result.

g. Visualize the cervix for dilation and length/effacement.

h. *Do not* perform a digital vaginal/cervical examination unless signs of active labor are present.

Microscopy Evaluation

1. Examine the dry slide under low power (10×) for the presence of ferning (see **Figure 26A-1**).
2. Examine the wet mount slide for the presence of yeast, bacterial vaginosis, or trichomoniasis.

CHAPTER

26

Fetal Assessment During Labor

TEKOA L. KING

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

The fetal assessment techniques used during labor are intended to identify the fetus experiencing acute impairment of gas exchange. None of the current methods that monitor the fetal heart directly measures fetal oxygenation or acid–base balance in fetal tissue. Therefore, it is important to know the value of the fetal assessment technologies that are in use and the extent of their capabilities. This chapter reviews fetal acid–base physiology, continuous electronic fetal heart rate monitoring (EFM), intermittent auscultation techniques, umbilical cord gas assessments that reflect fetal acid–base balance immediately prior to birth, and midwifery management of fetal heart rate (FHR) patterns.

To date, no single indicator has been identified that has a high positive predictive value for detecting clinically significant fetal acidemia. It may be that the threshold for permanent damage differs among individual fetuses; perhaps today's instruments are not individually or collectively sensitive enough; or perhaps both of these considerations play a role.[1,2]

History of Fetal Heart Rate Monitoring

The electronic fetal monitor was introduced as an instrument for monitoring women with high-risk pregnancies in the 1960s. Clinicians originally anticipated that EFM would be a screening test that would identify fetal asphyxia early enough to allow interventions before fetal damage occurred. Unfortunately, continuous EFM was rapidly adopted in clinical practice before adequate research assessing the relationship between FHR characteristics and newborn outcomes had been conducted.

The first observational studies of FHR monitoring were historical in nature. These studies compared newborn outcomes in settings before the introduction of FHR monitoring to those after widespread adoption of FHR monitoring. Those studies documented a significant decrease in the incidence of intrapartum stillbirth in women who were continuously monitored during labor—an outcome that remains one of the key benefits of EFM.[3]

No randomized controlled trials (RCTs) have compared continuous EFM to no monitoring. RCTs conducted in many developed nations, comparing continuous EFM to intermittent auscultation of the fetal heart with a Pinard stethoscope or a handheld Doppler device were performed in the 1990s. Most of these trials included one-to-one nursing, and several included women at high risk for adverse outcomes. Neither the RCTs nor the subsequent meta-analyses found that EFM improved outcomes when compared to intermittent auscultation (IA) with regard to Apgar scores, cerebral palsy, or perinatal mortality.[4,5] However, continuous EFM was associated with an approximately 50% increase in rates of cesarean section (relative risk [RR], 1.63; 95% confidence interval [CI], 1.29–2.07) and a slight increase in operative vaginal birth (RR, 1.15; 95% CI, 1.01–1.33).[6]

The largest RCT, which was performed in Dublin, Ireland, found EFM resulted in a 50% decrease in early neonatal seizures (1.8% in the EFM group versus 4.1% in the IA group). Newborn seizures were used as an indicator of long-term neurologic dysfunction and perinatal mortality. When the cohort of newborns in this trial who had seizures and survived were reexamined at age 4 years, those in the EFM group and those in the IA group had equal proportions of cerebral palsy—a finding that suggests EFM was not effective in decreasing the rate of cerebral palsy.[7,8] However, it is not possible to draw clinically relevant conclusions about the effect of EFM from these data and the small number of affected children. Nonetheless, EFM may have a protective effect in decreasing the incidence of early newborn seizures, although the long-term implications are unclear.

The negative findings of the meta-analysis of the RCTs evaluating EFM resulted in many clinicians concluding that EFM has no clinical value. However, the RCTs' failure to detect a benefit of EFM occurred secondary to several methodologic problems; thus, the results are not considered conclusive or reliable for practice today.[9] For example, when these studies were conducted, cerebral palsy was believed to result from intrapartum asphyxia. Subsequent studies have shown that most children with cerebral palsy acquire a brain injury in the prenatal or neonatal period, so intrapartum interventions such as EFM are not likely to prevent this disorder. The marked increase in cesarean sections noted in the EFM-recipient groups may be at least partially attributed to the criteria used to define fetal distress in the RCTs. Although it was known at the time that transient decreases in oxygenation cause late decelerations, the

importance of FHR variability as the best indicator of cerebral oxygenation was not recognized. Some of the FHR patterns (e.g., late decelerations with moderate FHR variability) that signaled fetal distress and resulted in cesarean section in the trials are known today to be poorly predictive of fetal acidemia. Finally, perinatal mortality is a rare enough event that more than 37,000 participants in an RCT would be needed to detect a change in perinatal mortality rates.

In short, the RCTs did not answer the question of whether EFM improves neonatal outcomes because they had the wrong outcome measures, they did not monitor for FHR patterns that are known today to indicate fetal compromise, and the studies were not large enough to detect meaningful changes in perinatal mortality. Thus, it is as inappropriate to claim EFM has no value as it is to advocate for universal EFM.

One of the difficulties encountered by researchers investigating EFM, especially in the older studies, was lack of a standardized lexicon. Moreover, clinicians often had difficulty communicating with one another without a common language. In 1997, the National Institute of Child Health and Human Development (NICHD) convened an expert panel charged with developing a standard terminology for interpreting FHR patterns. This panel created mutually exclusive definitions for each FHR characteristic that is used in clinical practice today; the same definitions have been used in FHR research over the last decade (**Table 26-1**).[10]

Table 26-1 Terminology for Fetal Heart Rate Characteristics

Term	Definition
Baseline rate	Mean FHR rounded to increments of 5 bpm during a 10-minute segment excluding periodic or episodic changes, periods of marked variability, and segments of baseline that differ by > 25 bpm. Duration must be ≥ 2 minutes.
Bradycardia	Baseline rate < 110 bpm.
Tachycardia	Baseline rate > 160 bpm.
Variability	Fluctuations in the baseline FHR ≥ 2 cycles/min.
Absent variability	Amplitude from peak to trough undetectable.
Minimal variability	Amplitude from peak to trough > undetectable and ≤ 5 bpm.
Moderate variability	Amplitude from peak to trough 6–25 bpm.
Marked variability	Amplitude from peak to trough > 25 bpm.
Acceleration	Visually apparent abrupt increase (onset to peak < 30 seconds) of FHR above baseline. Peak ≥ 15 bpm. Duration ≥ 15 bpm and < 2 minutes. In gestations < 32 weeks, peak ≥ 10 bpm above baseline and duration ≥ 10 seconds is an acceleration.
Prolonged acceleration	Acceleration ≥ 2 minutes and < 10 minutes' duration. An acceleration ≥ 10 minutes is a baseline change.
Early deceleration	Visually apparent *gradual* decrease (onset of deceleration to nadir ≥ 30 seconds) of FHR below baseline. Return to baseline associated with a uterine contraction. The nadir of the deceleration occurs at the same time as the peak of the contraction. Generally, the onset, nadir, and recovery of the deceleration occur at the same time as the onset, peak, and recovery of the contraction, respectively.

Late deceleration	Visually apparent *gradual* decrease (onset of deceleration to nadir ≥ 30 seconds) of FHR below baseline. Return to baseline associated with a uterine contraction. The nadir of the deceleration occurs *after* the peak of the contraction. Generally, the onset, nadir, and recovery of the deceleration occur after the onset, peak, and recovery of the contraction, respectively.
Variable deceleration	Visually apparent *abrupt* decrease (onset of deceleration to nadir < 30 seconds) in FHR below baseline. Decrease ≥ 15 bpm below baseline. Duration ≥ 15 seconds and < 2 minutes from onset to return to baseline.
Prolonged deceleration	Visually apparent decrease in FHR below baseline. Decrease ≥ 15 bpm below baseline. Duration ≥ 2 minutes but < 10 minutes from onset to return to baseline.

Abbreviations: bpm, beats per minute; FHR, fetal heart rate.

Based on National Institute of Child Health and Human Development Research Planning Workshop. Electronic fetal heart rate monitoring: research guidelines for interpretation. *Am J Obstet Gynecol.* 1997;17:1385-1390; *JOGNN.* 1997;26:635-640.[10]

In 2008, an NICHD expert panel met again to reevaluate the prior decade of research. The 1997 terminology was reaffirmed and new definitions for uterine tachysystole were devised. In addition, the panel recommended a 3-tier system for interpreting FHR patterns as normal (Category I), indeterminate (Category II), or abnormal (Category III); they remain the three categories used in clinical practice today (**Table 26-2**).[11]

Table 26-2 Fetal Heart Rate Interpretive Categories

Category	FHR Patterns Assigned to This Category
Category I (Normal)	
Baseline rate 110–160 bpm, moderate variability, and absence of late or variable decelerations must *all* be present.	Baseline rate: 110–160 bpm Baseline FHR variability: moderate Late or variable decelerations: absent Early decelerations: present or absent Accelerations: present or absent
Category II (Indeterminate)	
All FHR tracings not categorized as Category I or Category III. Includes *any* of these patterns.	Baseline rate: Bradycardia not accompanied by absent baseline variability Tachycardia Baseline FHR variability: Minimal baseline variability Absent baseline variability Marked baseline variability Accelerations: Absence of induced accelerations after fetal stimulations Periodic or episodic decelerations: Recurrent variable decelerations accompanied by minimal or moderate baseline variability Prolonged deceleration > 2 minutes but < 10 minutes Recurrent late decelerations with moderate baseline variability

	Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” or “shoulders”
Category III (Abnormal)	
Includes *either* pattern.	Absent baseline FHR variability and any of the following: Recurrent late decelerations Recurrent variable decelerations Bradycardia Sinusoidal pattern

Abbreviations: bpm, beats per minute; FHR, fetal heart rate.

Based on Macones GA, Hankins GD, Spong CY, Hauth J, Moore T. The 2008 National Institute of Child Health and Human Development Research Workshop report on electronic fetal heart rate monitoring. *Obstet Gynecol.* 2008;112:661-666; *JOGNN.* 2008;37:510-515.[11]

Despite the controversy about the value of continuous EFM, this form of fetal surveillance is used in almost all hospital birthing units. Many possible reasons exist for this enigma. It has been suggested that continuous EFM reassures women and caregivers alike, whereas the risks associated with cesarean section births are not considered as significant in comparison. In addition, FHR monitoring allows for remote surveillance without the need for a continuous bedside provider. Thus, it is important that midwives are familiar with the current evidence regarding the relationship between FHR patterns and fetal acidemia, was well as the benefits and limitations of this technology. First, a brief review of fetal oxygenation and acid–base physiology is in order.

Fetal Physiology

The aspects of fetal physiology that affect transport of oxygen and nutrients between the mother and the fetus include uteroplacental circulation, gas exchange across the placenta, factors that affect the FHR, and the fetal response to hypoxia, which is markedly different than the adult response.

Uteroplacental Circulation and Gas Exchange

Optimal transfer of oxygen, carbon dioxide, and nutrients from the maternal circulation to the fetal circulation can occur only when the following five components function well: (1) adequate maternal blood flow into the intervillous space, (2) a large enough placental area to facilitate gas and nutrient exchange, (3) efficient diffusion of gases and nutrients across the three membranes that separate the maternal and fetal circulations, (4) unimpaired umbilical vein circulation into the fetus, and (5) adequate oxygen transport capacity in the fetus.

In women without preexisting medical disorders, placental growth is usually adequate, and gas and nutrient exchange across the placental membranes is efficient. Furthermore, the fetus has enhanced oxygen-carrying capacity relative to an adult because of several physiologic mechanisms:

- Fetal hemoglobin binds to oxygen more easily than does adult hemoglobin, which favors transfer of oxygen from the maternal circulation to the fetal circulation.
- The fetus has more hemoglobin in circulation than do adults (the average fetal hematocrit ranges from 43% to 63%).
- The fetus has a higher cardiac output and heart rate for an overall faster circulation.
- Organs that need oxygen such as the heart and brain are over-perfused in the fetus.

These physiologic differences allow the fetus to survive well at a PO_2 of approximately 35 mm Hg, which is approximately the same as the maternal venous system. The same mechanisms also provide a buffer during the intermittent decreases in maternal blood flow into the intervillous space that occur during uterine contractions. Therefore, the components of uteroplacental function most likely to adversely affect fetal gas exchange are decreased perfusion to the placenta (e.g., uterine tachysystole, maternal supine positioning) and decreased umbilical vessel perfusion (e.g., cord compression).

Approximately 500 to 900 mL of maternal blood flows to the uterus each minute at term.[12,13] The majority of this blood (70–90%) enters the maternal spiral arteries, which run perpendicular through the uterine endometrium. During active labor, uterine contractions constrict these arteries, which temporarily interrupts blood flow in and out of the intervillous space.

As reviewed in the *Anatomy and Physiology of Pregnancy* chapter, the uterine spiral arteries become deinnervated during pregnancy as their endothelial linings are replaced with trophoblastic tissue. As a consequence, the arteries become maximally dilated so as to facilitate blood flow into the intervillous space.[14] In addition, the arteries lose their ability to

constrict if pressure in the vessel drops.

The clinical significance of this placental structure is that maternal hypotension, hypertension, and uterine contractions can all decrease blood flow into the intervillous space. Very little can be done physiologically to increase uterine blood flow if it is needed (**Figure 26-1**). Maximal arterial flow to the spiral arteries can be supported via use of side-lying positions to prevent compression of the inferior vena cava and administration of tocolytics that stop uterine contractions for a short time.

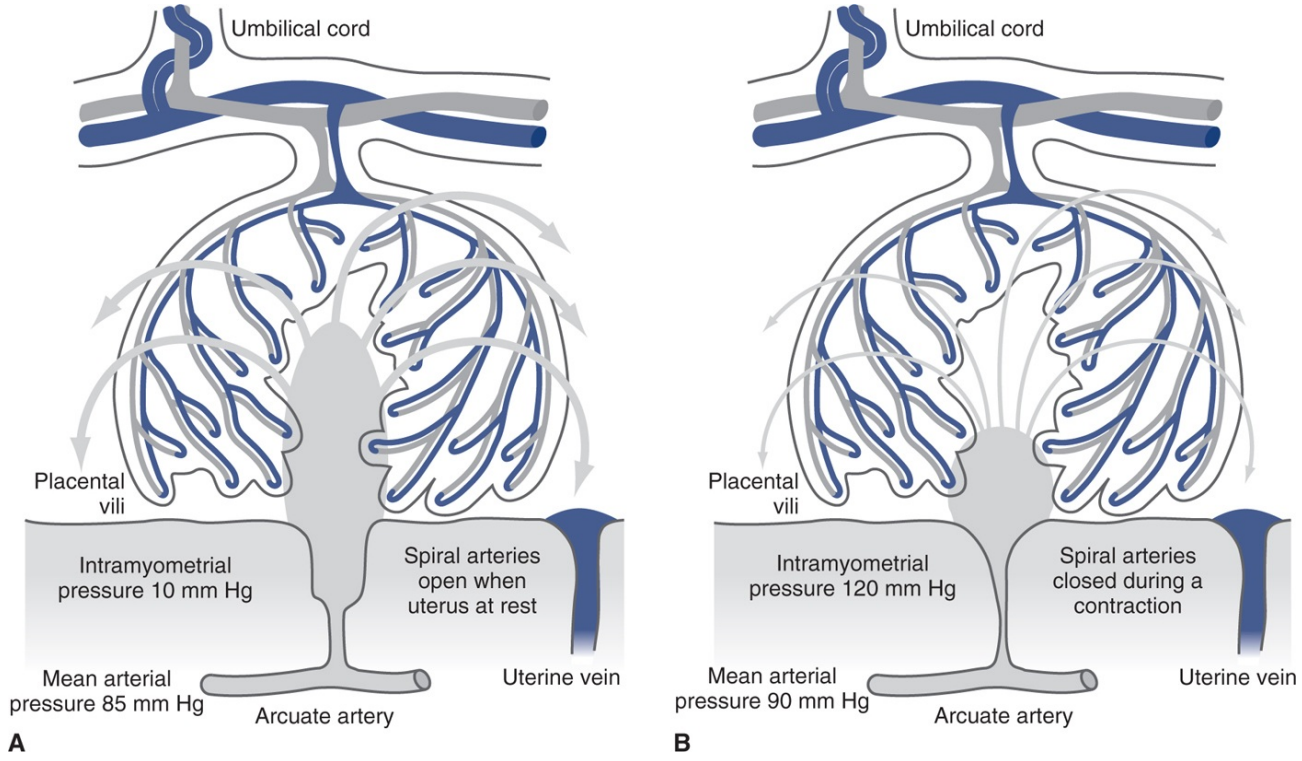

Figure 26-1 Effect of uterine contraction on blood flow into the intervillous space in the placenta. **A.** Blood flow into the intervillous space between uterine contractions. **B.** Blood flow into the intervillous space stops or is reduced during myometrial contraction.

Factors That Control the Fetal Heart Rate

The fetal heart rate is controlled by sympathetic, parasympathetic, chemoreceptor, baroreceptor, and central nervous system (CNS) inputs.

Sympathetic and Parasympathetic Input

The average baseline heart rate in the normal term fetus before labor is 140 bpm (range: 120–160 bpm). Early in pregnancy, the FHR is even higher, albeit not significantly higher. The FHR of a preterm fetus is likely to be on the higher end of this range.

The sympathetic fibers that innervate the myocardium respond to catecholamine stimulation by increasing the FHR. As the parasympathetic nervous system matures during the second trimester, parasympathetic input—which is mediated via the vagus nerve—becomes dominant over sympathetic stimulation; in turn, the baseline heart rate gradually slows.

The fetal heart is similar to the adult heart in that it has intrinsic pacemaker activity. The sinoatrial node, in the right atrium, has the highest intrinsic rate; thus, the sinoatrial node sets the pace for the fetal heart beats.[15(p33)] The vagus nerve originates in the medulla oblongata and terminates in the sinoatrial node of the fetal heart, where vagal stimulation changes the FHR by causing the interval between successive beats to vary.[16]

Chemoreceptors and Baroreceptors

Chemoreceptors found in the aortic arch and central nervous system are sensitive to changes in oxygen and carbon dioxide content within the blood. Increased carbon dioxide causes the chemoreceptors to signal the medulla oblongata, which stimulates the vagus nerve and slows the FHR. In the adult, central chemoreceptor detection of hypercarbia produces tachycardia, whereas peripheral chemoreceptor detection of hypercarbia produces bradycardia. The responses to chemoreceptor stimulation in the fetus are not totally understood, but the result of transient hypercarbia is clearly a slowing of the FHR. Baroreceptors in the aortic and carotic arches rapidly detect changes in blood pressure. When blood pressure rises, a quick reflex occurs (via the vagal nerve) to slow the fetal heart rate (**Figure 26-2**).

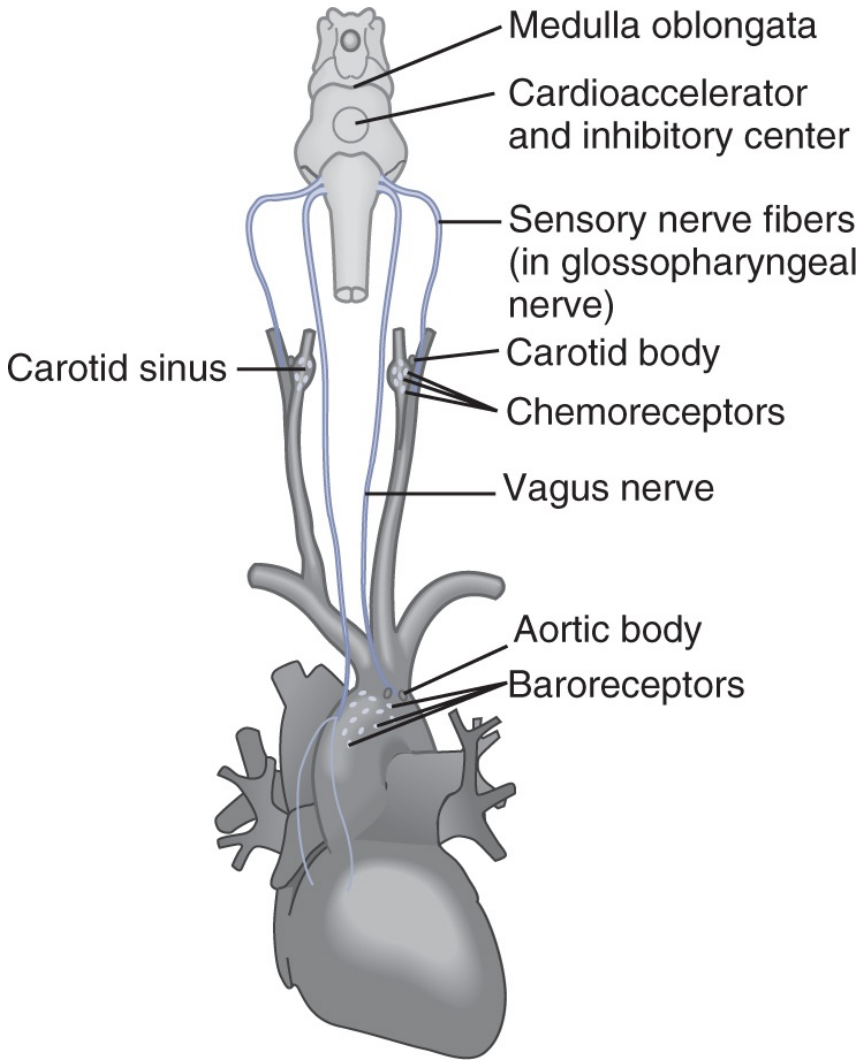

Figure 26-2 Chemoreceptors and baroreceptors.

Fetal Response to Hypoxia

Hypoxia is a reduced or insufficient level of oxygen in body tissues; definitions related to hypoxia are listed in **Table 26-3**.[15,17] The fetus responds to hypoxia in three ways: (1) a transient bradycardia that decreases oxygen consumption by as much as 60%, (2) redistribution of blood to vital organs, and (3) use of anaerobic metabolism.[15(p58)]

Table 26-3 Definitions of Terms Related to Hypoxia

Term	Definition
Acidemia	Increased concentration of hydrogen ions in the blood.
Acidosis	Increased concentration of hydrogen ions in the tissues of the body.
Aerobic metabolism	Metabolism of glucose using oxygen.
Anaerobic metabolism	Metabolism of glucose without the use of oxygen.
Asphyxia	Comes from the Greek word for "pulseless." A decrease in O_2 and increase in CO_2 secondary to an interference with gas exchange. Asphyxia is a continuum described by degrees of acidosis; this term is used clinically when tissue damage or death occurs.
Base	A substance that is capable of accepting hydrogen ions, thereby decreasing acidity.
Base excess (BE)	The amount of base or HCO_3^- that is available for buffering hydrogen ions. As metabolic acidosis increases, the base excess decreases.
Bicarbonate (bicarb)	HCO_3^- is the base or hydrogen acceptor that is part of the primary buffering system within the blood.
Buffer	A chemical substance that is both a weak acid and a salt. Buffers can absorb or give up hydrogen ions, thereby maintaining a constant pH value. The primary buffer involved in fetal oxygenation is HCO_3^-.
Hypercarbia	Excessive carbon dioxide in blood.
Hypoxemia	Decreased oxygen in blood.
Hypoxia	Decreased oxygen in tissue.
Metabolic acidemia	Low bicarbonate (negative base excess).
pH	The concentration of hydrogen ions in blood. The term pH refers to *puissance hydrogen*, which is French for "strength (or power) of hydrogen." A pH of 7.0 is the same as 0.0000001 (10^{-7}) mole per liter of hydrogen ions.
Respiratory acidemia	High PCO_2.

Reproduced with permission from Parer JT, King TL, Ikeda T. *Electronic Fetal Heart Rate Monitoring: The 5-Tier System*. 3rd ed. Burlington, MA: Jones & Bartlett Learning; 2018.[15]

During normal *aerobic metabolism*, the fetus produces carbonic acid (H_2CO_3), which dissociates into water and carbon dioxide (CO_2). Both CO_2 and water diffuse across the placenta very quickly. When oxygen is not available for aerobic metabolism, anaerobic

metabolism occurs. *Anaerobic metabolism* utilizes glucose and glycogen to produce energy, with the final dissociation product being lactic acid ($C_3H_6O_3$). Unlike water and CO_2, lactic acid does not cross the placenta quickly. When anaerobic metabolism persists, the accumulating lactic acid will overwhelm the buffering capacity within the fetal circulation and lower the pH, resulting in a state of metabolic acidosis.

Mechanism of Asphyxia

Asphyxia is a state of extreme deficiency of oxygen and carbon dioxide excess. Severe asphyxia results in metabolic acidosis and ultimately organ failure. Because asphyxia is a continuum that cannot be directly measured, and because the individual response to asphyxia varies, there is no clear threshold at which one can say metabolic acidosis will have long-term adverse effects in the fetus/newborn. Thus, the term "asphyxia" is not used clinically or in written documentation when describing the newborn's status.

Respiratory acidosis in a fetus refers to a condition of elevated carbon dioxide. *Metabolic acidosis* refers to a loss of physiologic buffering capability and low pH in tissue, most often secondary to a buildup of lactic acid. When metabolic and respiratory acidosis become severe, normal metabolic processes begin to fail. Neurons have a high metabolic rate and the brain does not store glucose, so the fetal brain is particularly vulnerable to asphyxial damage. In addition, oxygen deficiency in brain tissue results in both acidemia and ischemia because the cardiovascular adaptive mechanisms that preserve cerebral perfusion become overwhelmed when the arterial O_2 falls below a critical threshold. Autoregulation of cerebral blood flow fails, such that cerebral perfusion becomes pressure dependent and then, in the presence of hypotension, the brain becomes ischemic.[18-24] Cellular metabolism is quickly compromised (**Figure 26-3**). Thus, the final pathway to brain injury is termed "hypoxic–ischemic."

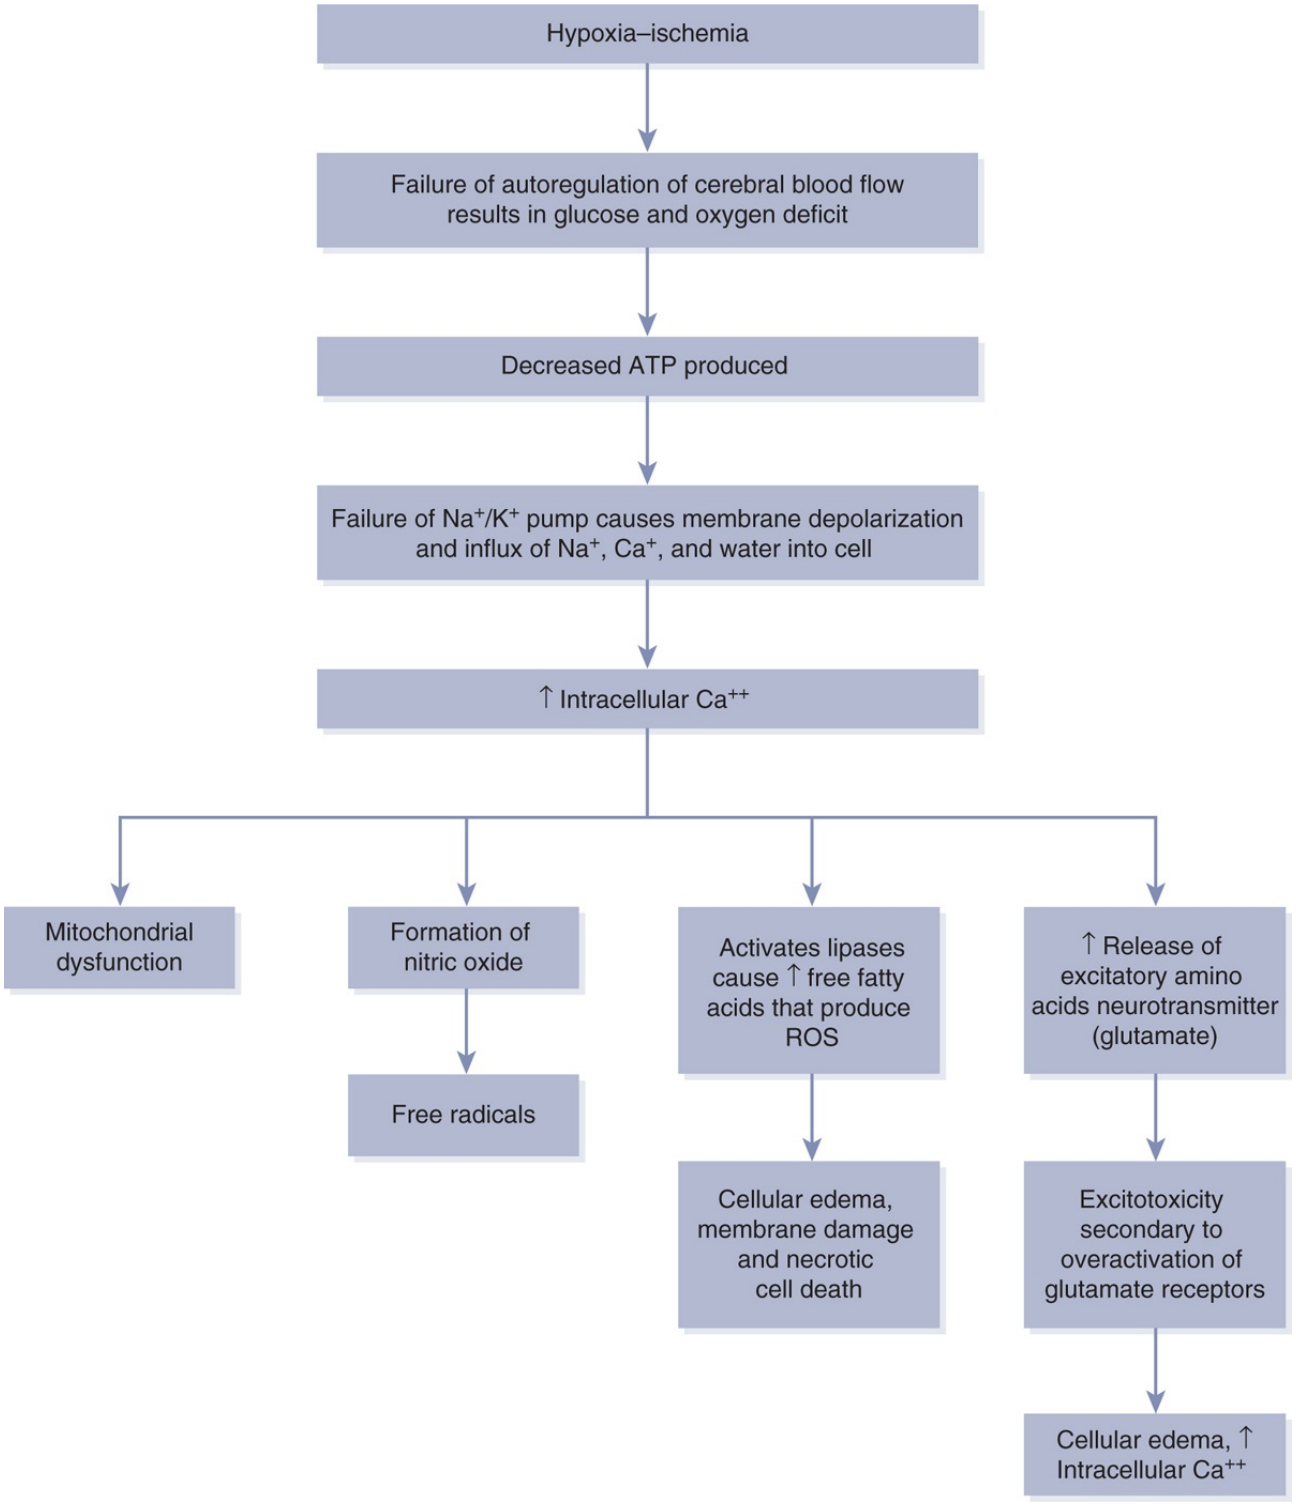

Figure 26-3 Primary energy failure: mechanism of hypoxic–ischemic injury.

Abbreviations: ATP, adenosine triphosphate; ROS, reactive oxygen species.

Hypoxic–Ischemic Encephalopathy and Neonatal Encephalopathy

Hypoxic–ischemic encephalopathy (HIE) is a descriptive term that describes the type of

lesion seen in the brains of newborns who survive a severe asphyxial insult. HIE occurs in approximately 1.5 per 1000 term births.[24] Approximately 66% of newborns with severe HIE will die or experience long-term sequelae. Conversely, the majority of infants with mild HIE have no adverse effects.[25]

Neonatal encephalopathy is a clinically defined syndrome of impaired central nervous system function in a newborn that includes disturbed neurologic function in an infant born at or after 35 weeks' gestation and with a subnormal level of consciousness or seizures.[26] Neonatal encephalopathy occurs in approximately 2 per 1000 live births. The criteria necessary to assign the etiology of neonatal encephalopathy to intrapartum asphyxia are listed in **Table 26-4**.[26,27]

Table 26-4 **Acute Peripartum or Intrapartum Events Sufficient to Cause Neonatal Encephalopathy**

Neonatal Characteristic	Description
Apgar score	< 5 at 5 and 10 minutes after birth.
Umbilical artery acidemia	pH < 7.0 and/or base deficit ≥ 12 mmol/L.
Magnetic resonance imaging	MRI abnormalities that appear after 24 hours of life. MRI obtained between 24 and 96 hours after birth is the most sensitive for determining the timing of cerebral injury. Conventional qualitative MRI findings of diffusion abnormalities, deep nuclear gray matter, or watershed cortical injury are most likely to indicate hypoxic–ischemic injury.
Multisystem organ failure	Can include renal injury, hepatic injury, hematologic abnormalities, gastrointestinal injury, cardiac dysfunction, metabolic derangements, or a combination of these abnormalities.
Sentinel hypoxic or ischemic event	A hypoxic or ischemic event that occurred immediately before or during labor and delivery (e.g., ruptured uterus, placental abruption, vasa previa, and amniotic fluid embolism).
Fetal heart rate patterns	Category II tracing identified on presentation or for longer than 60 minutes that includes minimal/absent variability and no accelerations; suggests a previously compromised fetus.
	Category I FHR pattern that develops into a Category III pattern over the course of labor.
	Additional FHR patterns consistent with hypoxic ischemic events: tachycardia with recurrent decelerations and persistent minimal variability with recurrent decelerations.
Other proximal or distal factors	No evidence of other proximal or distal factors that could contribute to neonatal encephalopathy.

Abbreviations: FHR, fetal heart rate; MRI, magnetic resonance imaging.

Based on American College of Obstetricians and Gynecologists Task Force on Neonatal Encephalopathy. *Neonatal Encephalopathy and Neurologic Outcome*. 2nd ed. Washington, DC: American College of Obstetricians and Gynecologists; 2014.[26]

Hypoxic–ischemic brain injury is a subset of neonatal encephalopathy, in that it is one of many etiologies that cause neonatal encephalopathy. Because neither hypoxia nor ischemia can be assumed to have been the unique initiating causal mechanism for a specific newborn with neurologic impairment, the term "hypoxic–ischemic encephalopathy" is not used clinically and has been replaced by "neonatal encephalopathy."[26]

The region of the brain that is damaged depends on the gestational age of the fetus, as

hypoxic–ischemic injury typically occurs in border zones between the ends of major cerebral vessels. Spastic quadriplegia cerebral palsy may result from hypoxic–ischemic injury in term infants because the regions of the brain that are most likely to suffer insult at that point of gestation are those involved in motor cordination.[26]

The relationship between hypoxic–ischemic injury secondary to oxygen deprivation during labor and subsequent development of cerebral palsy is complex. Cerebral palsy has multiple etiologies. Many of the symptoms of brain injury that are evident in the newborn reflect a common pathway that several different pathologic events exhibit. For example, placental lesions, intrauterine infection, and intrauterine stroke are all potential inciting events that may result in fetal brain damage and subsequent cerebral palsy.

Methods of Fetal Assessment During Labor

Fetal well-being can be assessed during labor via intermittent auscultation of the FHR as well as continuous or intermittent EFM. Fetal scalp stimulation may be used as an adjunctive test to determine whether the fetal pH is in the normal range.

Intermittent Auscultation

Auscultation of the fetal heart rate may be performed with a fetoscope, a Doppler device, or even the external ultrasound transducer of the electronic fetal monitor. The DeLee-Hillis fetoscope and the Allen fetoscope use bone conduction in the listener's cranium to amplify the sounds of the FHR. Because fetoscopes that do not use Doppler all require use of bone conduction and close proximity of the examiner's head to the pregnant abdomen, maternal position, habitus, and activity can limit assessment of the FHR with a fetoscope.

Doppler ultrasound technology projects an ultrasound wave into the uterus. This wave is reflected off the moving fetal ventricle, and the waveform changes as it is reflected back to the Doppler transducer. The transducer detects the heart movement of each heartbeat and emits an electronically created sound that can be counted or displayed digitally. Doppler devices can detect the fetal heart movement when the woman is in most positions, and some models can be safely used underwater, allowing for their use during hydrotherapy in labor and birth. Auditory counting of the fetal heart rate by Doppler technology and by fetoscope has been demonstrated to be equivalent in pregnant women who are not in labor.[28,29]

Use of the EFM Doppler transducer for intermittent documentation is somewhat controversial. Advocates find use of the EFM ultrasound transducer to be convenient, and a printout of the tracing can be made. Caution is warranted, however: When an FHR tracing is obtained, data including the FHR variability and possible accelerations or decelerations are evident and must be interpreted according to continuous EFM guidelines. No standard exists in this regard; each institution and individual clinician must consider the pros and cons of relying on these data. The technique for performing intermittent auscultation is presented in **Appendix 26A.**

Electronic Fetal Heart Rate Monitoring

The electronic fetal monitor displays the fetal heart rate pattern and the uterine contraction pattern. It can be used with devices that are placed externally on the maternal abdomen or internally into the uterus through the vagina. The fetal monitor record has both upper and lower display areas. The upper portion displays the fetal heart rate pattern, with increments of 10 bpm graphed on the vertical axis. The lower portion displays the uterine contractions, with gradations for 0 to 100 Montevideo units on the vertical axis. The horizontal axis is divided into 10-second and 1-minute segments. Therefore, the FHR pattern, the contraction pattern, and the timing and relationship between the two are displayed on the device.

External Monitoring

For external fetal heart rate monitoring, a Doppler device that has a transducer and a receiver is secured onto the maternal abdomen, over the area of the fetal heart. The Doppler transducer transmits a high-frequency ultrasound pulse of approximately 2.5 MHz, then records a number of points on the changed wavelength that is reflected off the moving fetal heart during each beat. A replica from these points is constructed using a technique called autocorrelation.

In brief, the monitor counts the interval between fetal heartbeats and calculates a beat-per-minute (bpm) rate. It then plots this rate on the graph paper, which scrolls continuously so that the individual plot points merge into a jagged line. This *fetal heart rate variability* line is jagged because the time interval between each heart beat typically varies. Because the vagus nerve is responsive to input from the central nervous system, and because frequent changes in timing between beats occur secondary to vagus input, the variability seen on EFM primarily reflects central nervous system function and well-being.

Fetal heart rate monitoring technology has improved over the last decade such that the FHR recorded using an external Doppler transducer now closely approximates the exact FHR recorded on an electrocardiogram (ECG).[30] Early fetal monitors did not have an autocorrelation function, which meant that they often displayed too much interference to allow accurate interpretation of baseline variability. Today's external fetal monitoring offers the same reliability as internal monitoring for assessment of all FHR characteristics.

External fetal monitoring is appropriate for the majority of women for whom continuous EFM during labor is indicated. In most situations, with careful placement of the abdominal transducer and tocodynamometer, the FHR and contractions will be visually displayed adequately for interpretation. The equipment and its electrical cords limit the distance a woman can move about unless a telemetry unit is available. Telemetry units currently in use allow women to walk long distances, shower, or be in a tub. However, maternal movement can cause interference in the signal, occasionally obscuring or making the data being collected unreadable.

Internal Fetal Heart Rate Monitoring

Internal monitoring is used when the fetal heart rate or the contractions need to be monitored continuously and an adequate tracing is not available via external monitoring, such as when a woman with a high body mass index (BMI) is in labor. Internal monitoring requires ruptured membranes. A fetal scalp electrode (FSE) is placed a few millimeters into the fetal scalp. The wires extending from the electrode are entrapped in an electronic transmission device that is secured to the woman's thigh with an elastic or Velcro belt. The fetal scalp electrode transmits the fetal electrocardiogram to the monitor, which displays a digital signal of the FHR as well as a continuous graph of the heart rate. The procedure for placing an FSE is described in **Appendix 26B.**

Uterine Activity Monitoring

Uterine contractions can be monitored via maternal perception, manual palpation, external tocodynamometer attached to an electronic fetal monitor, or internal placement of an

intrauterine pressure catheter (IUPC).

Although there is significant variability between individuals, maternal perception of a painful contraction usually occurs when the intrauterine pressure reaches a minimum of 15 mm Hg.[31] This pressure is the amount required to distend the lower uterine segment and create pressure on the cervix. A uterine contraction is first detectable via manual palpation when the intrauterine pressure exceeds 10 mm Hg.[31]

A uterine pressure tocodynamometer (toco) is placed on the maternal fundus and secured with a belt that goes around the woman's abdomen. The toco records changes in pressure that occur when the fundus tightens during a contraction. Although this device records contraction duration and frequency, it does not record intensity accurately. Moreover, tightening the monitor straps or changing the position of the toco can cause the device to show a very different apparent intensity of contractions.

Internal uterine monitoring is accomplished by placing an intrauterine pressure catheter through the cervix and into the uterine cavity. The IUPC has the advantage of providing specific information about the resting tone of the uterus, the actual pressure generated by the contractions, and accurate timing of the onset, peak, and completion of a contraction. If amnioinfusion is needed, it can be done through the same catheter used to perform internal uterine monitoring. Disadvantages of this technology include an increased risk of infection if the IUPC is left in place for an extended period of time and the requirement that the woman remain tethered to a bed.

If the progress of labor is slower than expected, an IUPC may be used to provide a quantitative measurement of uterine contraction intensity in Montevideo units—a concept first introduced by Caldeyro-Barcia in 1957.[32] The Montevideo unit is calculated by adding together the peak pressures of all contractions that occur in a 10-minute window. Montevideo units of approximately 200 when subtracting the baseline tone, or 240 when the baseline tone is included, are considered adequate for labor that progresses normally.

Fetal Heart Rate Patterns

The characteristics of the fetal heart rate are classified as baseline, periodic, or episodic.[10] The baseline features, which include the heart rate, variability, and accelerations, are assessed between uterine contractions. Periodic changes occur in association with uterine contractions. Episodic changes are not clearly associated with uterine contractions.

Baseline Fetal Heart Rate

The baseline fetal heart rate at term ranges from 110 to 160 bpm. Bradycardia is defined as an FHR of less than 110 bpm; tachycardia is defined as a baseline rate of more than 160 bpm. Fetal tachycardia alone is not usually associated with poor outcomes in the term fetus. Mild tachycardia is common in the fetus of less than 28 weeks' gestation because parasympathetic (vagal) tone does not predominate until the third trimester. Thus, heart rates of 140 to 160 bpm are normal baseline rates in a preterm fetus.

Sustained tachycardia in a term fetus may be caused by developing acidemia,[33,34] maternal or fetal infection,[35] or cardiac arrhythmia,[36] or it may be idiopathic. Other causes include administration of beta-mimetic drugs or ephedrine given to correct maternal hypotension. More rarely, fetal tachycardia occurs secondary to fetal anemia (Rh isoimmunization), acute fetal blood loss (placental abruption), an abnormal fetal conduction system (fetal arrhythmia), or poorly controlled maternal hyperthyroidism.

Short periods of tachycardia are a normal compensatory response to transient hypoxemia. Sustained tachycardia, especially if accompanied by minimal variability and recurrent decelerations, may indicate that the fetus's ability to compensate for repeated hypoxia is limited.[33,37] This pattern can appear after recurrent decelerations are present for some period of time but before a terminal bradycardia becomes evident, and is characteristic of FHR pattern evolution when acidemia is increasing.

Both asphyxial and non-asphyxial causes of fetal bradycardia are possible. Non-asphyxial causes include fetal heart block and maternal hypothermia. A mild bradycardia in the 100–120 bpm range can be idiopathic and is often seen in the postmature fetus, as the heart rate progressively slows over the course of gestation and early childhood. Bradycardia can also develop during rapid descent of the fetal presenting part or at the end of the second stage of labor when fetal head compression causes increased intracranial pressure, which then initiates a vagal response and bradycardia. In such a case, the fetus will maintain cerebral oxygenation at an FHR higher than 80 bpm and variability will be retained. Fetal bradycardia also can occur after administration of intrathecal opioids or local anesthetics for epidural analgesia. This etiology is usually attributed to maternal hypotension, secondary to the sympathetic block, which causes a decrease in uteroplacental blood flow. These transient bradycardias or prolonged decelerations usually retain normal FHR variability and are rarely associated with adverse outcomes. Fetal bradycardia that is accompanied by moderate variability is not associated with fetal acidemia. The presence of moderate variability during a mild bradycardia can reassure the midwife that no intervention is required.[37]

Asphyxial causes of bradycardia include acute emergency events such as prolapsed cord,

placental abruption, uterine rupture, or vasa previa.[38] An FHR of less than 60 bpm is an emergency. At this heart rate, the fetus is unable to increase stroke volume to sustain adequate circulation through the heart and supply the coronary arteries. Thus, when an acute bradycardia occurs, the depth, duration, and the presence or absence of variability are the key factors associated with subsequent neonatal morbidity.

Fetal Heart Rate Variability

The presence of moderate FHR variability signifies that the fetus has an intact cerebral cortex, midbrain, vagus nerve, and cardiac conduction system. Moderate variability is the single best indicator that the fetus does not have cerebral tissue hypoxia or ischemia.[37,39] Approximately 98% of all fetuses with moderate variability will not have clinically significant acidemia at the time the variability is observed, even if recurrent fetal heart rate decelerations are present (**Figure 26-4**).[37]

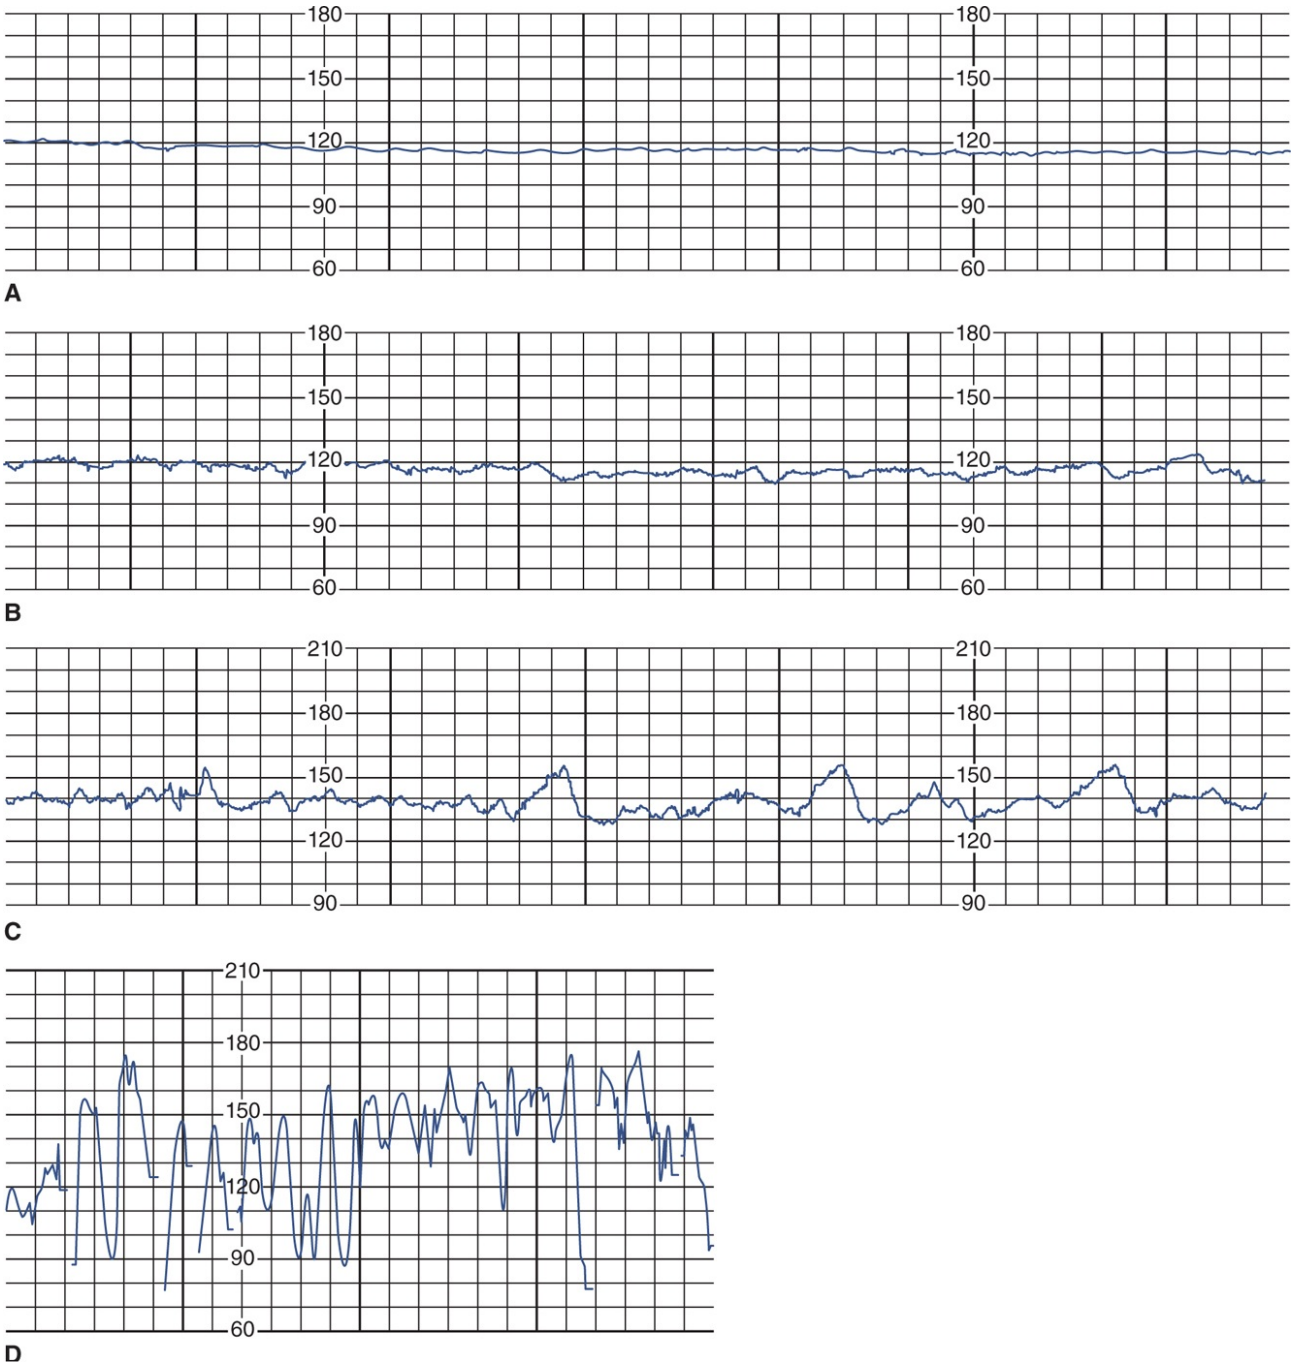

Figure 26-4 Fetal heart rate variability. **A.** Absent variability. **B.** Minimal variability. **C.** Moderate variability. **D.** Marked variability.

Minimal variability is interpreted based on the presence or absence of accelerations or recurrent decelerations. If the variability is minimal and FHR decelerations are not present, this condition has no correlation with fetal acidemia.[37] Fetal rest cycles are associated with uncomplicated minimal variability, with these periods of minimal variability typically lasting 20 to 40 minutes but sometimes persisting for as long as 75 to 80 minutes.[40] Administration of opiates (e.g., morphine, butorphanol, fentanyl), promethazine (Phenergan), or beta-adrenergic agents such as terbutaline (Brethine) to the mother will also decrease the amplitude of FHR variability.

Like minimal variability, absent variability is interpreted based on the presence or absence of decelerations. Absent variability without decelerations can be idiopathic and not consistently associated with fetal acidemia. In contrast, minimal or absent variability in the presence of recurrent late or variable decelerations is one of the FHR patterns most consistently associated with fetal acidemia and requires urgent assessment and intervention.[14,33,37,41-43] The evolution of moderate to minimal to absent variability in the presence of recurrent decelerations that become progressively deeper is the classic pattern evolution that reflects developing fetal acidemia over time.[37,41-43]

Marked variability is relatively rare. It is hypothesized that this FHR characteristic is a response to a short period of hypoxia. Marked variability is not associated with adverse newborn outcomes.

Accelerations

Accelerations are transient increases of the fetal heart rate above the baseline (**Figure 26-5**). They are a reassuring indicator of fetal well-being, in that they are associated with a normal pH at the time the acceleration occurs.[44] Accelerations are often associated with fetal movement. Fetal scalp stimulation and acoustic stimulation can be used to induce an acceleration.

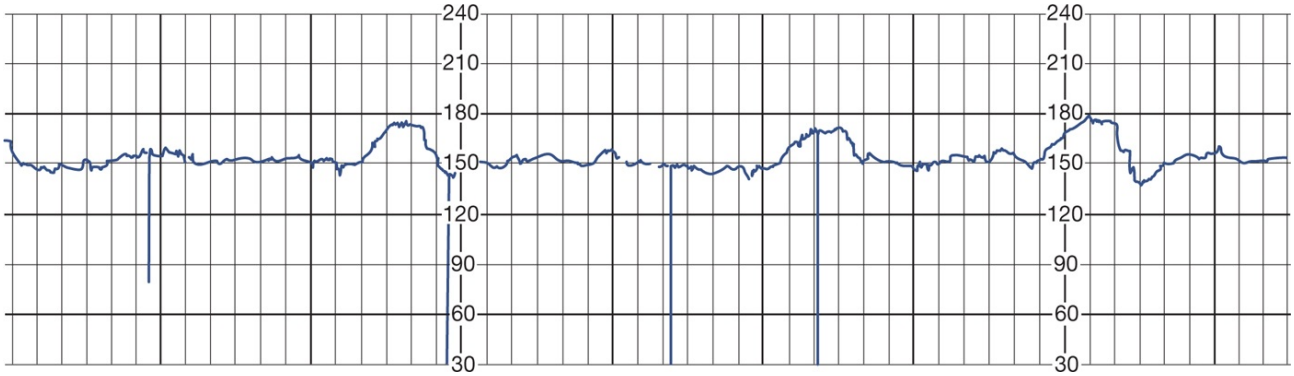

Figure 26-5 Accelerations of the fetal heart rate.

Early Decelerations

The mechanism underlying early decelerations has not been determined. These decelerations appear in active labor and are associated with moderate variability. Although one theory suggests that early decelerations are caused by head compression, head compression results in a vagal response and variable decelerations.[15(p5)] Regardless of the underlying physiologic mechanism, early decelerations are benign and do not require intervention, although it is important to carefully differentiate between early and late decelerations (**Figure 26-6**).

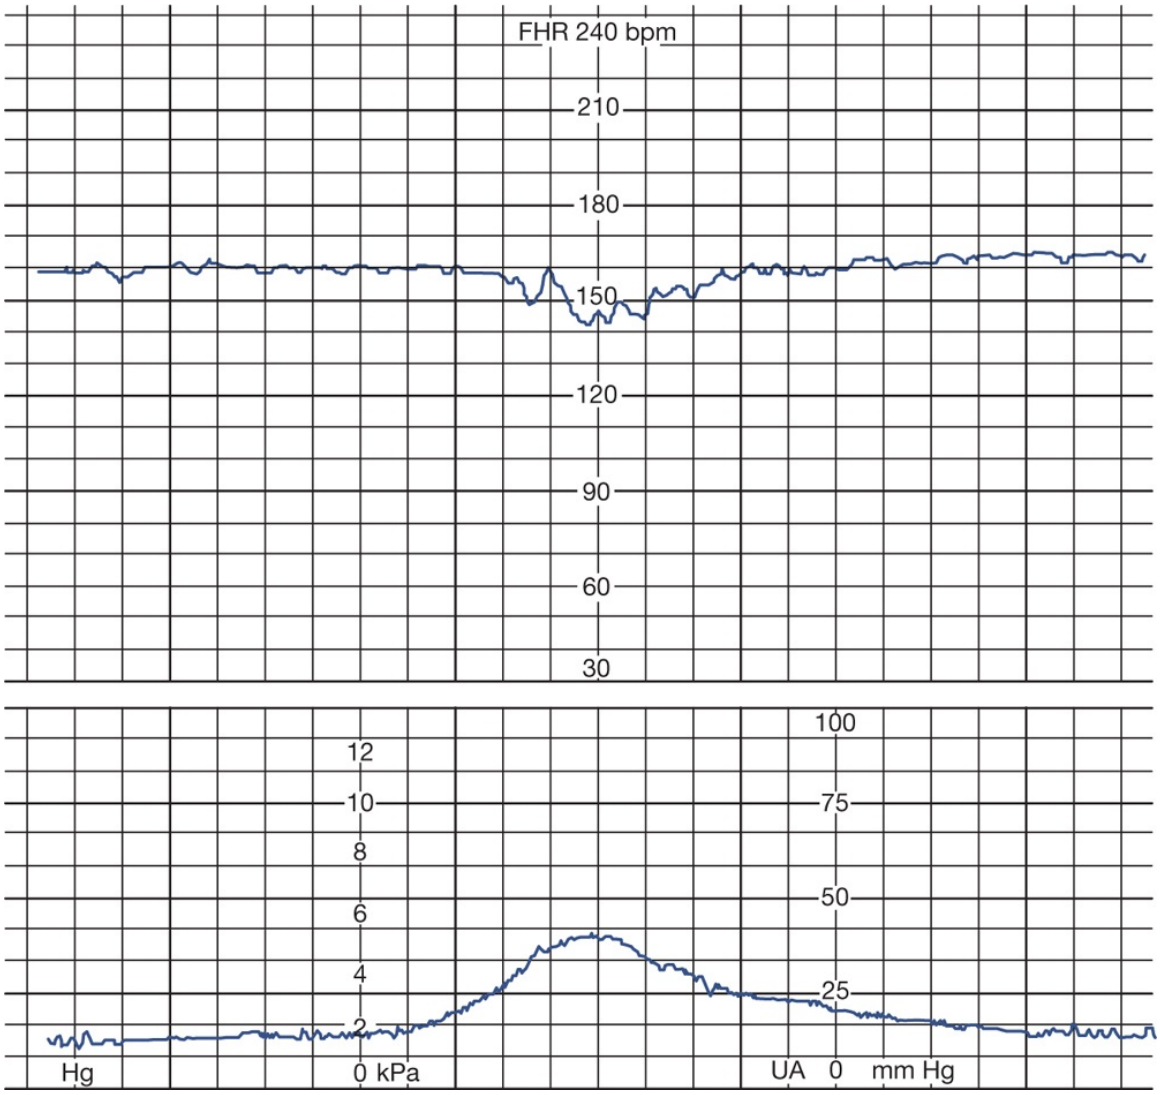

Figure 26-6 Early decelerations.

Abbreviations: bpm, beats per minute; FHR, fetal heart rate; UA, uterine activity.

Late Decelerations

Late decelerations are a response to transient decreases in oxygen tension. This mechanism starts with a uterine contraction that causes a decrease in uteroplacental perfusion, which is followed by lower oxygen levels in the fetal circulation. The hypoxemia is detected by chemoreceptors in the fetal carotid artery, carotid sinus, and aortic arch. Chemoreceptor activation signals a vagally mediated drop in fetal heart rate. The nadir of the fetal bradycardia is "late" relative to the peak of the uterine contraction, because the physiologic pathway that results in chemoreceptor stimulation takes time. The relatively deoxygenated blood must first traverse the umbilical vein before reaching the chemoreceptors (**Figure 26-7**).

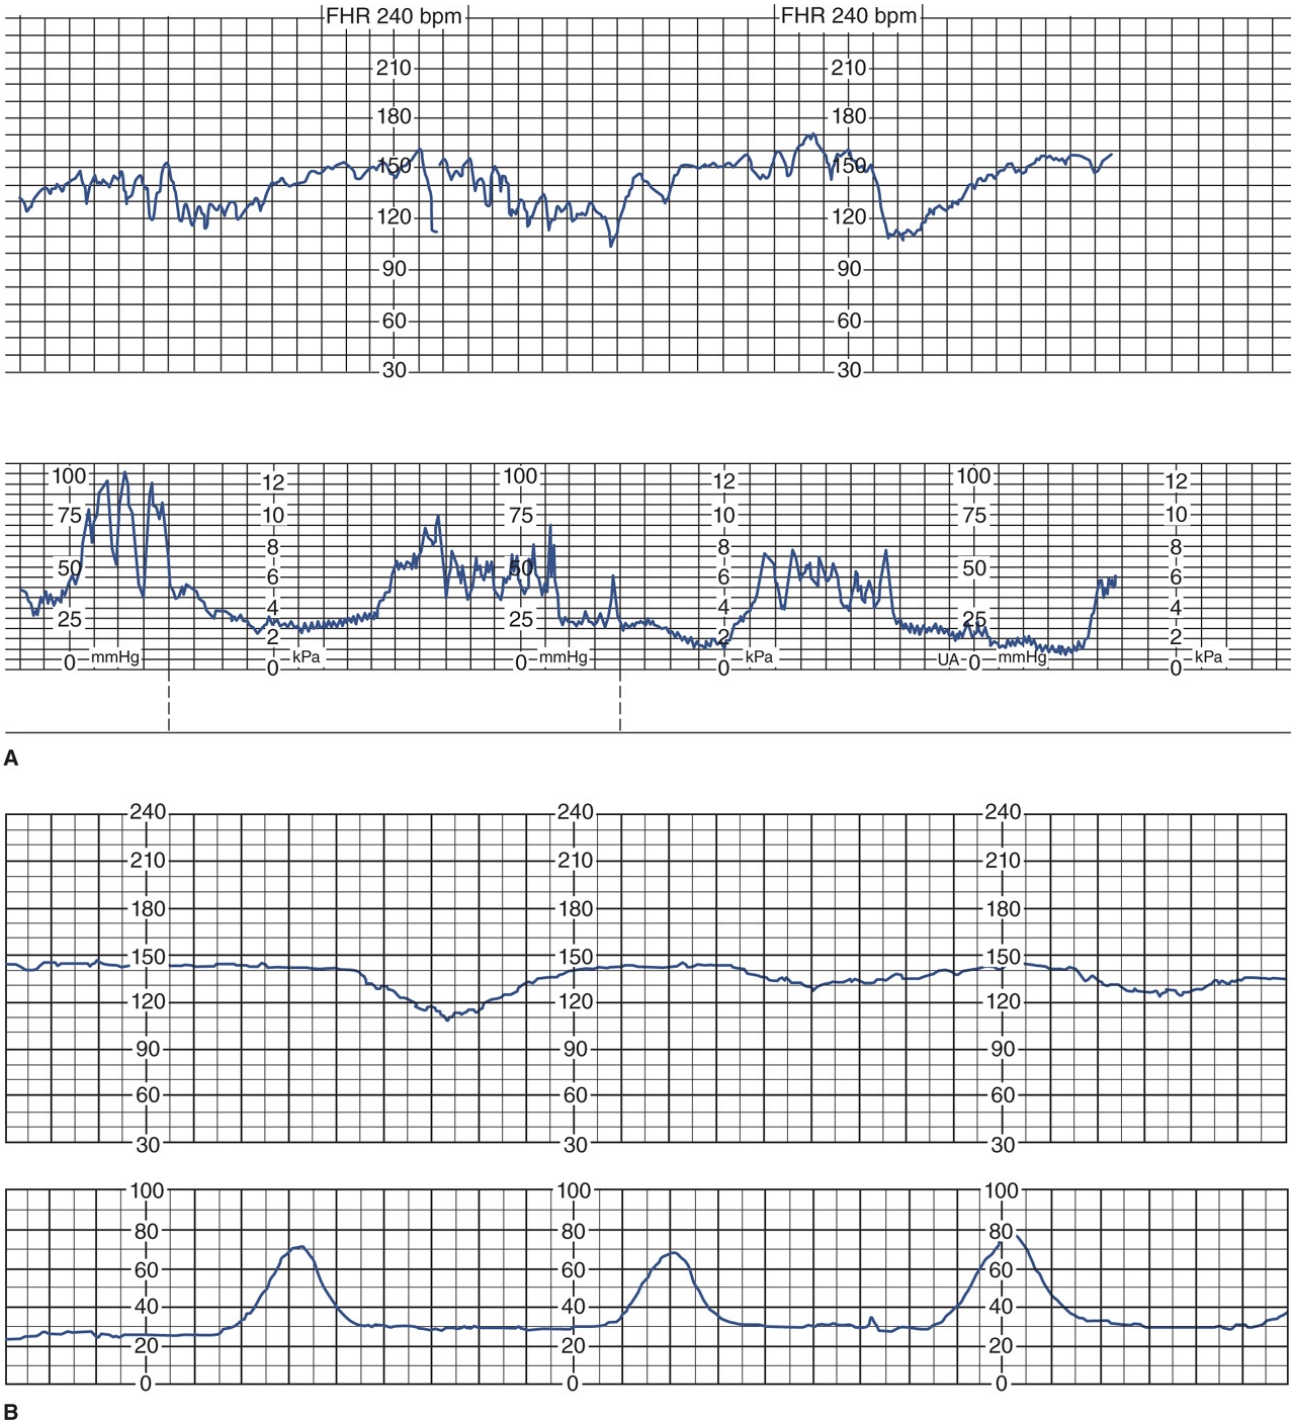

Figure 26-7 Late decelerations. **A.** Late deceleration with moderate variability. **B.** Late deceleration with absent variability.

Abbreviations: bpm, beats per minute; FHR, fetal heart rate.

Recurrent late decelerations are associated with uteroplacental insufficiency. *Uteroplacental insufficiency* refers to any condition in which the placenta is not able to supply sufficient oxygen or nutrients to the fetus. It can be chronic or acute. Causes of chronic uteroplacental insufficiency include maternal hypertensive disorders, diabetes, hyperthyroidism, autoimmune disorders such as lupus, and abnormal placentation. All of these disorders are associated with narrowed spiral arteries, small placentas, and/or placental

infarcts that decrease the placental area available for transfer of oxygen and nutrients. In addition, uteroplacental insufficiency is associated with postmaturity. Acute uteroplacental insufficiency can develop in the setting of uterine tachysystole or maternal hypotension. Finally, fetal anemia secondary to fetal–maternal hemorrhage, Rh sensitization, or nonimmune hydrops will effectively lower the oxygen-carrying capacity of the fetus, so that the transient decreases in oxygen present in the intervillous spaces associated with uterine contractions result in significant declines in fetal oxygen tension.

Late decelerations in the presence of moderate variability represent a physiologic response to transient hypoxemia, rather than an indicator of the presence of acidemia.[37] Conversely, recurrent late decelerations in the presence of minimal or absent variability is one of the FHR patterns most commonly associated with fetal acidemia.[11,37]

Late decelerations can be classified as mild (≤ a 15-bpm drop from baseline to nadir), moderate (> a 15-bpm drop but less than a 45-bpm drop from baseline to nadir), or severe (≥ 45-bpm drop from baseline to nadir). Although these classifications are not part of the NICHD terminology, good evidence supports the observation that late decelerations become progressively deeper as fetal acidemia worsens.[37,45]

Variable Decelerations

Variable decelerations occur secondary to an interruption in umbilical blood flow. Numerous causes of umbilical cord compression have been identified. In vertex presentations, these etiologies include cord occlusion secondary to the cord around the fetus's neck or body, true knots in the cord, frank and occult prolapse of the cord, and compression due to decreased amniotic fluid that cushions the cord. Variable decelerations are also common in the second stage of labor, in which case they are presumed to be secondary to head compression and the direct effect of increased intracranial pressure on the vagus nerve. Variable decelerations can be either episodic (occurring at random times) or periodic (occurring with each uterine contraction).

Variable decelerations are the most common variant FHR pattern, seen in approximately 45% to 75% of all labors.[46,47] The association between variable decelerations and fetal acidemia depends on the frequency, depth, duration and associated baseline FHR variability. Variable decelerations that return to baseline in less than 60 seconds with concomitant normal baseline and moderate variability are not associated with fetal acidemia. Recurrent variable decelerations with minimal or absent variability, similar to recurrent late decelerations with minimal or absent variability, are associated with fetal acidemia and require urgent evaluation and consideration of intervention (**Figure 26-8**).

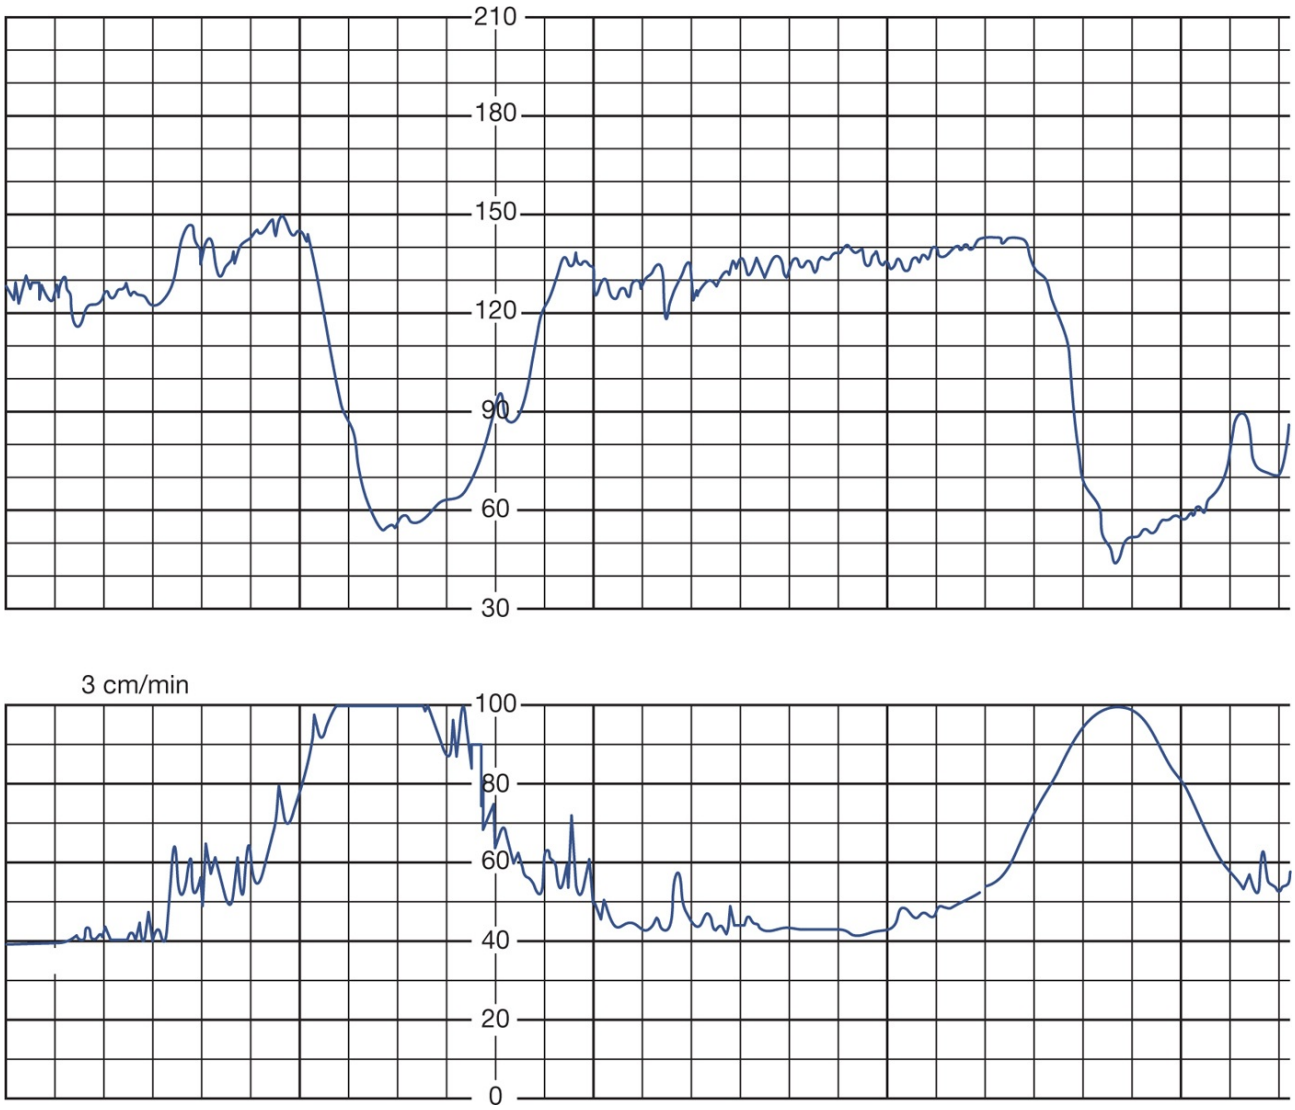

Figure 26-8 Variable decelerations.

Categorization of variable decelerations as mild, moderate, or severe has not proved to be clinically useful. Alternatively, variable decelerations may be categorized as typical or atypical based on their shapes. For example, variable decelerations often have a short increase in FHR above the baseline that precedes or is part of the final variable complex. These short increases are called shoulders and overshoots, respectively. Several studies have attempted to determine which characteristics of variable decelerations are most likely to be associated with acidemia, albeit without success.[47,48] Animal studies of umbilical cord occlusion that resulted in variable decelerations have shown that increasing depth, duration, and frequency are positively correlated with increasing acidemia, but specific deceleration shapes do not appear to be strongly correlated with specific degrees of fetal acidemia.[49]

Prolonged Decelerations

Prolonged decelerations have multiple causes. Known precipitating factors include umbilical cord compression; maternal hypotension related to supine positioning and epidural or spinal

anesthesia; paracervical anesthesia (which can cause decelerations by direct fetal uptake of local anesthetic, maternal hypotension, or uterine hypertonus); uterine tachysystole; maternal hypoxia associated with seizures or acute respiratory depression; and rapid descent of the fetal head (**Figure 26-9**).

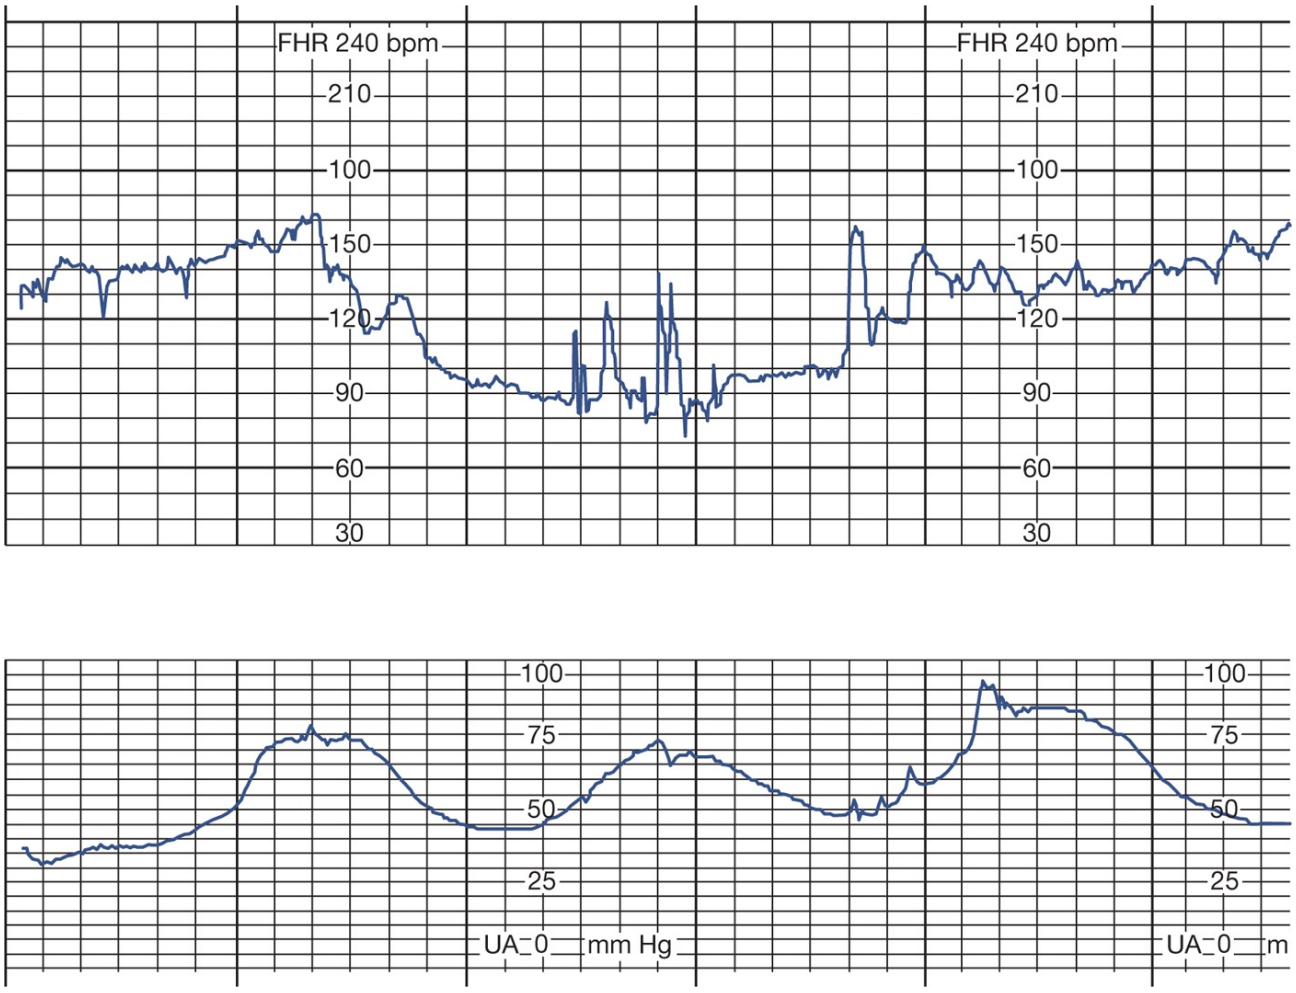

Figure 26-9 Prolonged decelerations.

Abbreviations: bpm, beats per minute; FHR, fetal heart rate; mm Hg, millimeters of mercury; UA, uterine activity.

Management of prolonged decelerations depends on the putative etiology, length of deceleration, baseline at nadir, and baseline variability. Most often, the fetus will recover with a period of tachycardia, decreased variability, or occasional late decelerations for a short time following a prolonged deceleration. If the precipitating cause is alleviated, the FHR generally returns to the previous baseline. Intermittent prolonged decelerations are not associated with an increased risk for fetal acidemia in the presence of moderate variability.

Sinusoidal Pattern

A sinusoidal pattern is characterized by an undulating, recurrent uniform fetal heart rate equally distributed 5 to 15 bpm above and below the baseline (**Figure 26-10**). The undulation occurs at a rate of 2 to 6 cycles per minute and is identified by an absence of short-term variability.

True sinusoidal patterns are extremely rare.

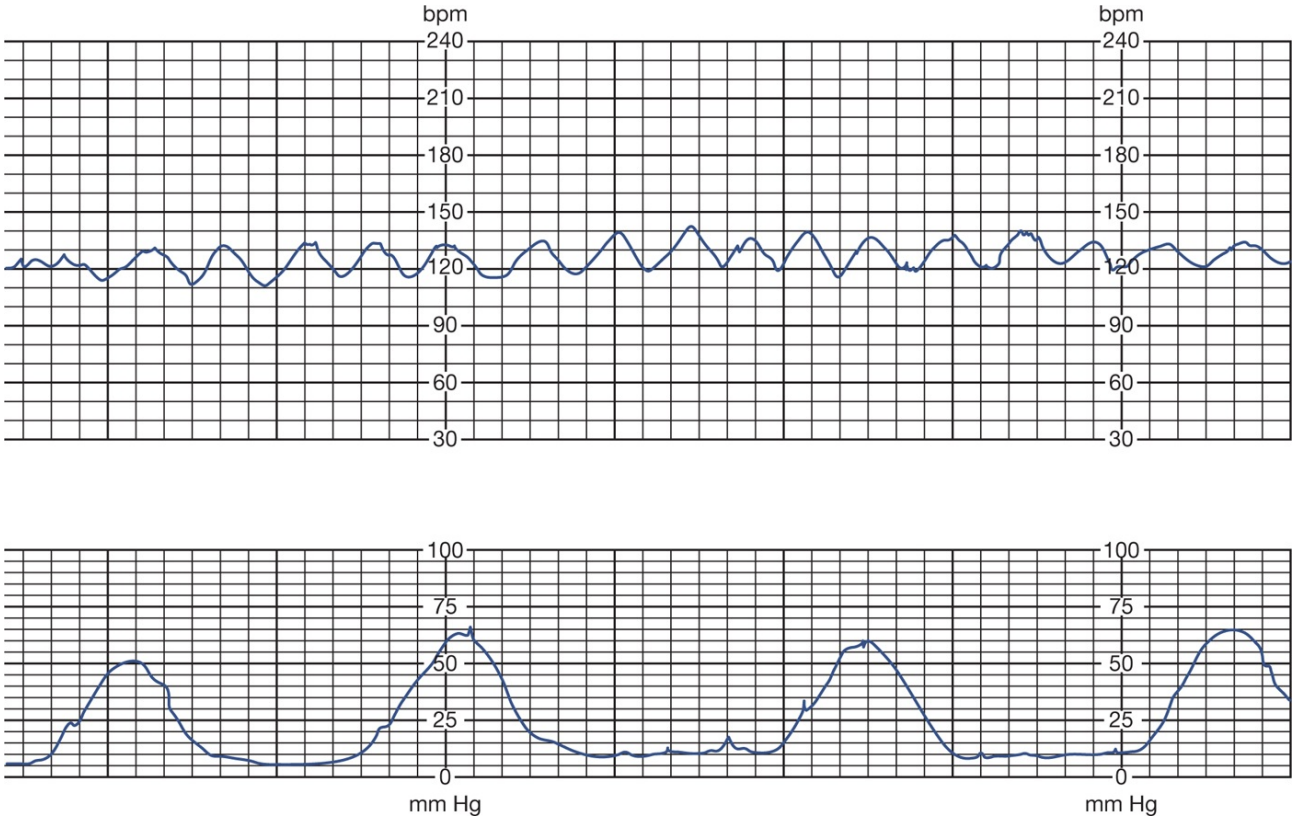

Figure 26-10 Sinusoidal pattern.

Abbreviation: bpm, beats per minute.

The sinusoidal FHR pattern is seen when the fetus is experiencing clinically significant anemia, such as occurs during a maternal-fetal hemorrhage following vasa previa, uterine rupture, or placental abruption. Historically, this pattern was seen in fetuses with anemia secondary to Rh isoimmunization. It may also appear shortly before death in a severely asphyxiated fetus. A sinusoidal heart rate pattern is always an ominous fetal heart rate pattern, and immediate intervention is indicated. The midwife should notify the consulting physician promptly and prepare the woman for emergency cesarean section. The neonatal team should be notified to prepare for a potentially anemic or hypovolemic newborn.

Pseudo-sinusoidal Fetal Heart Rate Pattern

The pseudo-sinusoidal pattern is not an NICHD-recognized FHR pattern because it is commonly the result of opioid administration, rather than being an intrinsic FHR characteristic. This clinically insignificant pattern is intermittent and bracketed by periods of moderate variability. A pseudo-sinusoidal FHR pattern differs from a real sinusoidal pattern in two ways—namely, variability is retained and there are more than 2 to 6 cycles per minute.

Wandering Baseline

Wandering baseline is not part of the official NICHD FHR terminology, but it continues to be

used in clinical practice and, therefore, deserves mention. A wandering baseline is a very late development in the progression of fetal deterioration. It is often within the normal baseline parameters of 120 to 160 bpm and is identifiable by absent variability. This pattern is an ominous indicator of fetal acidemia and requires immediate notification of a consulting physician and preparation for emergency operative birth if vaginal birth is not imminent. Neonatal/pediatric providers should be present at the birth. The key characteristic is the absence of variability, rather than the fact that the baseline changes over the course of several minutes.

Fetal Arrhythmias

Fetal arrhythmias occur among approximately 1% to 3% of fetuses at term.[50,51] Approximately 90% of fetal arrhythmias are transient and benign in nature. A consulting physician should evaluate any fetus with an arrhythmia, and a plan should be made for ongoing collaboration as long as the arrhythmia is present. Arrhythmias can be heard on audible Doppler devices and can be seen on FHR tracings, but cannot be accurately diagnosed via EFM (**Figure 26-11**). Thus, neonatal/pediatric attendance at birth may be recommended depending on the rate and persistence of the arrhythmia.

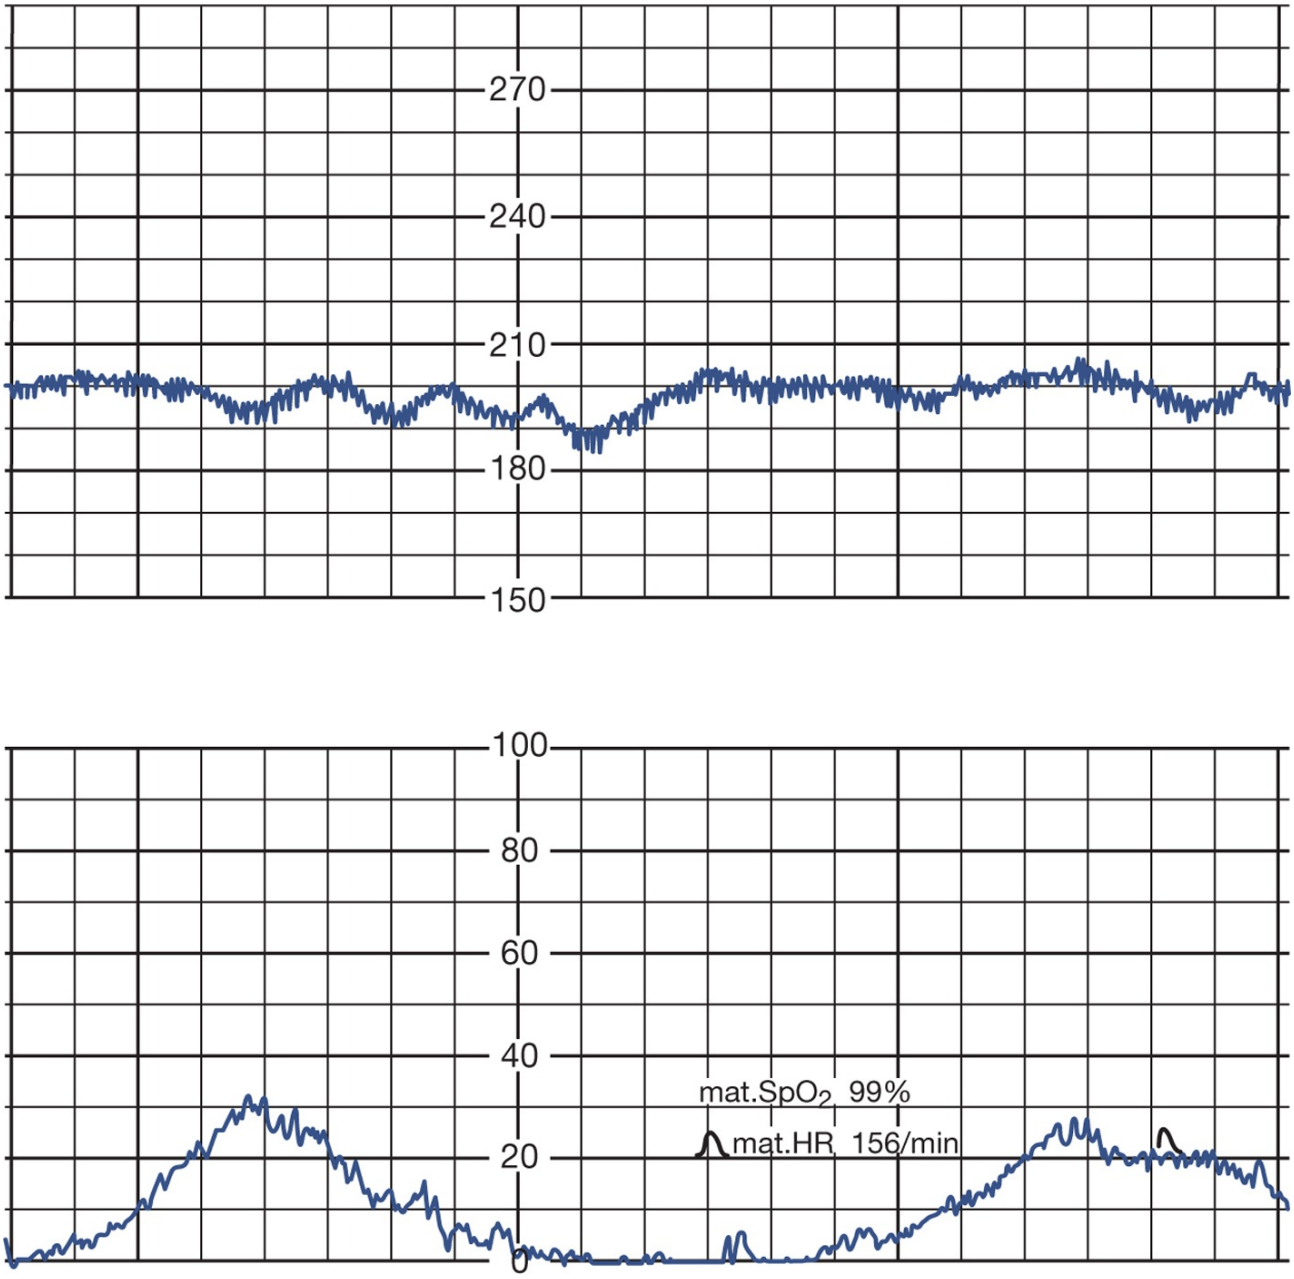

Figure 26-11 Fetal arrhythmia.

Fetal Heart Rate Pattens That Reflect Fetal Acidemia

Parer et al. reviewed the FHR research published between the 1960s and 2005 that evaluated the relationship between FHR patterns and newborn outcomes in term gestations.[15,37] In this review, the following themes were identified that capture the relationship between FHR patterns and clinically significant newborn acidemia:

1. Moderate variability is strongly predictive of neonatal vigor independent of the presence of variant patterns. Moderate FHR variability has a negative predictive value of 98% to 99% in a term fetus.
2. Minimal and absent variability in the presence of late or severe variable decelerations are the FHR patterns most likely to be associated with fetal acidemia, although the positive predictive value is only in the range of 10% to 30%.
3. A positive relationship can be found between the depth and severity of decelerations or bradycardia and the degree of acidemia.
4. Newborn acidemia with decreasing FHR variability in combination with decelerations develops over a period of approximately 1 hour in a previously healthy term fetus.

Clinically, significant metabolic acidosis in the fetus can develop in one of three ways:

- Acidosis may develop as the result of frequent, unremitting hypoxic insults (e.g., uterine contractions) that occur too frequently to allow transfer of respiratory and metabolic components across the placenta.
- Metabolic acidosis may develop rapidly following an acute emergency such as uterine rupture. An acute unremitting bradycardia may be both the cause and result of sudden marked decrease in oxygen delivery to the fetus.
- Prenatally, metabolic acidosis may develop slowly over time during the course of intrauterine growth restriction, fetal infection, or other fetal disorder.

Pattern Evolution During Labor

In a term healthy fetus, it takes approximately 1 hour to develop clinically significant metabolic acidemia once a pattern of recurrent late or variable decelerations and diminishing variability begins during labor.[37] Midwives, nurses, and physicians interpreting EFM results should recognize the typical pattern evolution that occurs as acidemia is developing (**Figure 26-12**) as well as the specific Category III FHR patterns that herald a significant risk for fetal acidemia. In all cases, this pattern starts with recurrent decelerations, and a terminal bradycardia will herald fetal demise if the problem is not remedied before the fetus is born. However, the onset of deeper decelerations, tachycardia, and diminution of variability can appear in any order. For example, tachycardia may develop before or after the variability starts to decrease. Similarly, the decelerations may not become visibly deeper and of longer duration until after the variability begins decreasing.

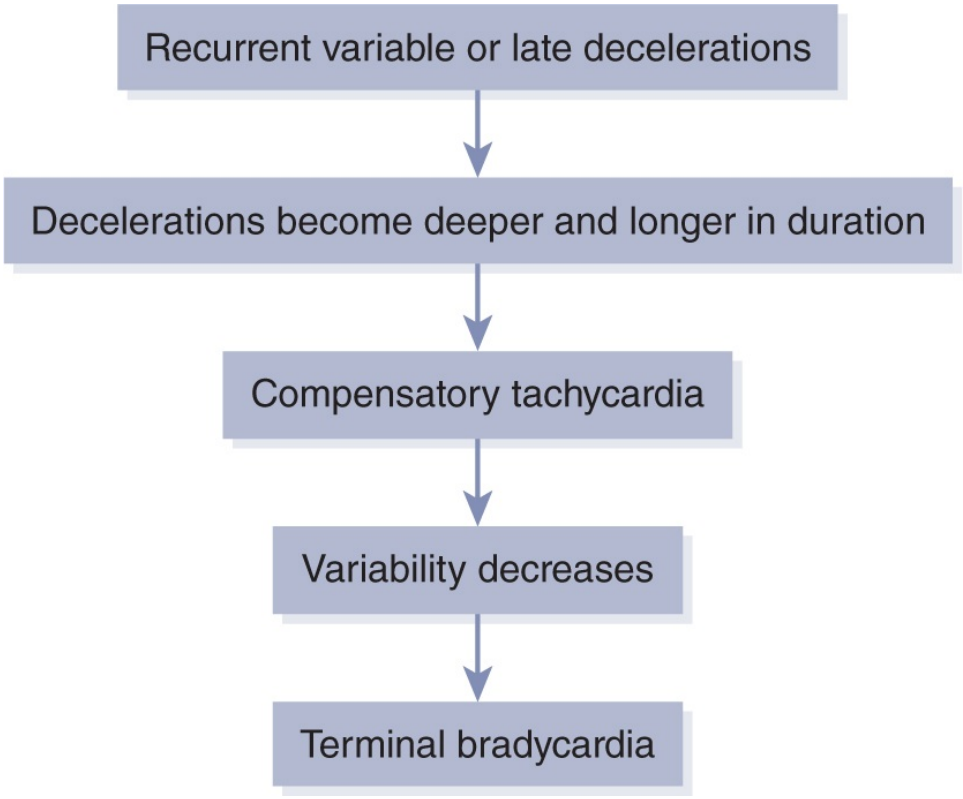

Figure 26-12 Fetal heart rate pattern evolution from normal to fetal acidemia.

Reproduced with permission from Parer JT, King TL, Ikeda T. *Electronic Fetal Heart Rate Monitoring: The 5-Tier System.* 3rd ed. Burlington, MA: Jones & Bartlett Learning; 2018.[15]

Recent work using current technologies to more precisely measure both the depth and the duration of recurrent decelerations as a combined indicator have analyzed the "area under the curve" to calculate the total duration of time that an FHR remains below a specific bpm threshold during a defined period of time before birth.[48,52-54] These studies have correlated the total deceleration time to newborn outcomes. Although the results are preliminary, it appears that the total deceleration area has the best predictive power for identifying newborn acidemia.[48,52-54]

Acute Bradycardia

Sudden bradycardia can occur secondary to uterine rupture, placental abruption, cord prolapse, shoulder dystocia, maternal hypotension, amniotic fluid embolism, vasa previa, and other causes. In a retrospective analysis of cases of uterine rupture, Leung et al. found none of the newborns in the series had significant metabolic acidemia when the bradycardia-to-birth time was less than 18 minutes if a normal FHR without decelerations preceded the bradycardia.[55] By comparison, when the bradycardia was preceded by recurrent decelerations, metabolic acidemia occurred as early as 10 minutes after the bradycardia started. In general, if the FHR remains greater than 80 bpm, both coronary and cerebral oxygenation will be preserved and variability is often retained.[56] In contrast, when the FHR remains less than 80 bpm, the variability will diminish rapidly as a metabolic acidemia develops. In this scenario,

the fetus becomes unable to maintain circulation. If the bradycardia is 60 bpm or less, the fetus cannot maintain stroke volume and will be unable to oxygenate the coronary arteries.

Relationship Between Fetal Heart Rate Patterns and Newborn Outcomes

Several different newborn variables have been used in studies to identify the relationship between fetal heart rate patterns and neonatal outcomes, including Apgar scores, newborn seizures, umbilical cord blood gases, and—more recently—magnetic resonance imaging (MRI) findings in newborns with signs of neonatal encephalopathy.

Apgar Scores

The Apgar score was created to assess the adaptation of the infant to extrauterine life, rather than as a measure of prebirth acidemia. This distinction may appear trivial at first glance but, in fact, is an important one. While a 5-minute Apgar score of 7 or higher almost completely eliminates the possibility of fetal acidemia prior to birth, the converse is not true. Apgar scores can be markedly affected by drugs given prior to birth, infant resuscitation techniques, gestational age, and infection—all of which will result in a lower score.[57] Likewise, Apgar scores do not reliably predict newborn outcomes except in the extreme range of or less than 5 at 5 minutes. Therefore another index is needed that accurately reflects fetal status prior to birth and predicts newborn outcomes. Umbilical cord blood gases meet both of these requirements.

Umbilical Cord Blood Gases

Umbilical artery cord blood gases reveal the presence or absence of respiratory acidosis, metabolic acidosis, or mixed acidosis. pH is an indication of the degree of acidemia. The PCO_2 value is a reflection of the respiratory component, and the PO_2 value indicates the oxygen content. The base deficit (or base excess if negative numbers are used) indicates the severity of metabolic acidosis; it reflects how much buffer capability has been lost as lactic acid accumulates in the fetal circulation and tissue.[58] Umbilical artery cord pH and base deficit are the most useful measurements for determining the presence or absence of fetal acidemia at the time of birth. When they are in the normal range, intrapartum development of acidemia can be ruled out as the etiology of neonatal encephalopathy in a depressed or compromised newborn.[59]

Technique for Obtaining Umbilical Cord Blood Gases

Umbilical cord blood gases are obtained by collecting a sample of umbilical arterial blood and then a sample of umbilical venous blood in a heparinized syringe, from a section of umbilical cord that has been clamped at both ends. The fetal vessels on the surface of the placenta may be used if a length of umbilical cord is not available. The blood gases in the umbilical artery (UA) reflect the status of the fetus, whereas the blood gases in the umbilical vein (UV) reflect the status of the intervillous space. Thus, the values of import are those obtained from the umbilical artery. However, both UA and UV samples are needed so the

results can be correctly interpreted. When only one sample is obtained or when the samples yield the same results, one cannot be certain if the values are from the UA or the UV.

Umbilical cord blood gases should be obtained when a concern arises that the fetus might have experienced clinically significant acidemia. There are no standard guidelines that recommend indications for umbilical cord blood gas analysis. Clinical scenarios that are associated with an increased risk for metabolic acidemia in the newborn are listed in **Table 26-5**.[60]

Table 26-5	Selected Indications for Umbilical Cord Blood Gas Analysis
Cesarean section birth for fetal compromise	
Operative vaginal birth	
Preterm birth	
Fetal growth restriction	
Breech presentation	
Hypertension/preeclampsia	
Low 5-minute Apgar score	
Category III fetal heart rate pattern in last hour prior to birth	
Maternal thyroid disease	
Intrapartum fever	
Multifetal gestations	
Diabetes	
Maternal thyroid disease	
Meconium	
True knot in cord	
Substance use	

Newborns may benefit from delayed cord-clamping, and delayed cord-clamping is currently recommended for all newborns. The effect of delayed cord-clamping on umbilical cord blood gases is a current area of study.[61-63] The umbilical cord blood gas results may identify a higher P_aO_2 when samples are obtained from umbilical cords that are not immediately clamped and cut.[61-63] This phenomenon presumably occurs because there is ongoing circulation through the cord to the fetus at the time the sample is obtained. Other parameters such as pH and base excess do not appear to be affected by the few minutes of delay that allows for placental transfusion.

Interpretation of Umbilical Cord Blood Gases

The risk of neonatal morbidity is inversely related to newborn umbilical cord blood pH, although the precise level of acidemia that is pathologic for an individual newborn remains unknown. The result of fetal acidemia is an interaction between the magnitude of the stress and the responsiveness of the individual, with the latter being subject to a great deal of individual variation. In addition, although one might expect a small amount of asphyxia to cause a small amount of damage and larger amounts of asphyxia to have more adverse consequences, the

concept of a "continuum of causality" may not be correct when it comes to the fetal response to hypoxia. Instead, the fetal response to hypoxia is more likely a threshold effect—that is, damage becomes evident only after a certain threshold has been exceeded.

Despite these caveats, pathologic acidemia is generally defined as a UA pH value of less than 7.0 and a base deficit of greater than 12 mEq/L (**Table 26-6**).[64-68] This pH has consistently been identified as the inflection point at which the risk for neonatal encephalopathy becomes strongly significant statistically (RR, 16.86; 95% CI, 8.45–32.49).[65] The majority of infants with a pH less than 7.0 will be vigorous and have normal Apgar scores,[24] but approximately 20% to 24% will experience neonatal morbidity or mortality.[65] Many infants with a low pH have a respiratory acidosis that is quickly corrected following an initial few breaths. Newborns with a base deficit higher than 12 mEq/L are more likely to have significant neonatal morbidity or mortality.[64-68]

Table 26-6 Guidelines for Interpretation of Umbilical Arterial Cord Gases in Term Newborns

Diagnosis	pH	PCO_2 (mm Hg)	Bicarbonate (HCO_3)	Base Deficit[a] (mEq/L)
Normal,[b] mean (standard deviation)	7.26 (± 0.07)	53 (± 10)	22.0 (± 3.6)	4 (± 3)
Respiratory acidemia	Normal or low	High	Normal	Normal
Metabolic acidemia[c]	Low	Normal	Low	High
Mixed (metabolic–respiratory) acidemia[c]	Low	High	Low	High

[a] May be reported as base excess (negative values) or base deficit (positive value); however, the numeric value is the same.
[b] Data from term infants with an Apgar score ≥ 7 at 5 minutes.
[c] Clinical association exists with adverse neonatal outcomes when pH < 7 and base deficit > 12 mEq/L.
Based on Helwig JT, Parer JT, Kilpatrick SJ, Laros RK Jr. Umbilical cord blood acid–base state: what is normal? *Am J Obstet Gynecol.* 1996;174(6):1807-1814[58]; Gilstrap LC, Cunningham G. Umbilical cord blood acid–base analysis. In: *Supplement #4: Williams' Obstetrics.* 19th ed. Raritan, NJ: Ortho Pharmaceutical; 1994:1-24.[59]

Infants with a UA pH between 7.0 and 7.1 have an increased risk for short-term neonatal problems such as transient tachypnea, need for supplemental oxygen, or hypothermia. In some larger observational studies, although the absolute risk is still less than 2%, the relative risk for neonatal encephalopathy begins to be significant in newborns with a pH of 7.1 (RR, 5.18; 95% CI, 2.18-12.33).[65] Newborns with pH values in this range rarely experience long-term complications. A clinically significant metabolic acidemia is highly unlikely in newborns with a UA pH greater than 7.1.

Umbilical cord blood gases have an important limitation. Measurements of the UA pH and base deficit provide information about the severity of the asphyxial insult but do not provide any information about the duration, whether the insult was continuous or intermittent, or the ability of the individual fetus to compensate for the insult.

Interpretation and Management of Fetal Heart Rate Patterns

The recommended terminology and interpretation guidelines from the two NICHD expert panels apply to intrapartum FHR tracings for term fetuses. Although the same terminology is often used for preterm fetuses, there is a paucity of research on the relationship between fetal heart rate patterns and neonatal outcomes in preterm births.

Labor Admission Test with Fetal Heart Rate Monitoring

An initial EFM assessment of the fetus is commonly used in hospital birth settings to assess fetal status at the time of admission. The underlying concept assumes that if the FHR pattern shows a reactive nonstress test (NST) or a negative oxytocin challenge test (OCT), no decelerations, and moderate variability, this result can be interpreted as a reassuring sign of fetal well-being for the duration of the labor. However, the EFM assessment upon labor admission has not been shown to have adequate predictive value to warrant its use as an admission screening tool in women who are deemed to be either at high risk or at low risk for developing fetal acidemia during labor.[69] An admission EFM tracing does appear to increase the risk of having continuous monitoring throughout labor (RR, 1.30; 95% CI, 1.14–1.48) and a trend toward a higher risk for cesarean section (RR, 1.20; 95% CI, 1.00–1.44). The decision to perform an admission test does not affect rates of fetal or neonatal deaths.

FHR Interpretation During Labor: NICHD 3-Tier System

Overall, the positive predictive value of FHR monitoring is low, because the incidence of variant FHR characteristics is high and the incidence of neonatal acidemia is very low in the general population. The poor sensitivity and high false-positive rates found in studies that sought to correlate FHR patterns with newborn outcomes present a clinical conundrum that has not yet been solved.[70] In an effort to improve the predictive value of these data, several clinical algorithms that include three or more subcategories for interpretation have been developed.[11,71-76] Currently, the Parer–Ikeda 5-tier system appears to have the best accuracy in correlating FHR patterns to newborn acidemia.[77,78] Computer-aided models and models that incorporate risk screening are also being evaluated in research studies. None of these algorithms has been sufficiently tested in clinical settings.

Some data from this body of work do appear to be clinically useful. Category I FHR patterns signify an absence of acute fetal acidemia in 98% to 99% of fetuses. Thus, if no other risk factors are present, women with a Category I FHR pattern can be monitored with intermittent auscultation during labor. Conversely, category III includes the FHR patterns that likely reflect significant fetal acidemia; such a pattern requires urgent evaluation and preparations for emergent delivery.

Category II FHR patterns constitute a heterogenous group with differing risks for fetal acidemia and are an area of current research. When one of these patterns is present, management should be based first on the degree of FHR variability (and accelerations, if

present) and then on the presence or absence of recurrent decelerations (**Figure 26-13**). Management may also include use of auxiliary tests such as fetal scalp stimulation or vibroacoustic stimulation as well as intrauterine resuscitation techniques such as position change, intravenous fluid bolus, or oxygen administration. Because institutional resources must be taken into consideration when devising protocols, it is unlikely that one management paradigm for Category II FHR patterns will be applicable to all settings. Most importantly, when a Category II FHR pattern is present, it must be considered in conjunction with other factors in the clinical scenario that can independently reduce the fetus's ability to tolerate repeated hypoxic events (**Table 26-7**).

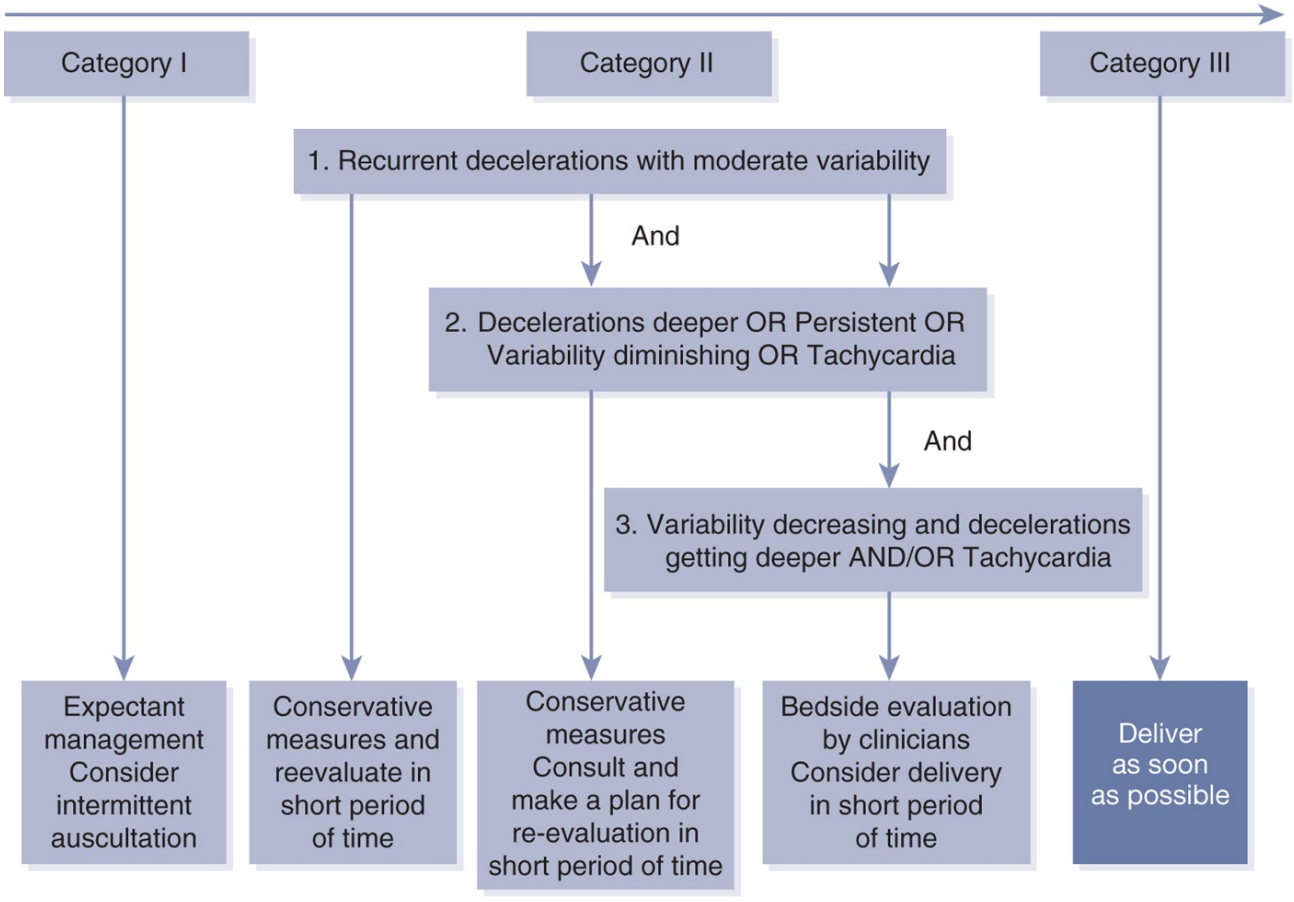

Figure 26-13 Management of FHR pattern evolution during labor.

Table 26-7	Selected Clinical Considerations That Increase the Risk for Fetal Acidemia
Maternal complications that increase the risk for uteroplacental insufficiency (e.g., preeclampsia, hypertension, diabetes, lupus erythematosus)	
Fetal factors that increase the risk for uteroplacental insufficiency (e.g., post dates, fetal growth retardation, decreased amniotic fluid index)	
Presence or absence of tachycardia and/or decreased variability (e.g., chorioamnionitis may increase vulnerability to brain damage that causes cerebral palsy)	
Success or failure of attempts to correct the underlying problem	
Acid–base status of the fetus, determined either through scalp or acoustic stimulation or via direct fetal scalp blood sampling	

Presence or absence of meconium
Gestational age (with the preterm fetus having a lower tolerance for hypoxia than the term infant)
Anticipated time until birth
Availability of consultant physician, emergency operative staff, and facility

Auxiliary Tests: Fetal Scalp Stimulation or Vibroacoustic Stimulation

Fetal scalp stimulation or vibroacoustic stimulation that elicits an acceleration provides reassurance that the fetal pH is higher than 7.2 at that time.[44] Vibroacoustic stimulation is performed using a handheld vibroacoustic stimulator (artificial larynx), which is applied to the maternal abdomen over the region of the fetal head, where it delivers a sound stimulus for 3 to 5 seconds. Approximately 50% of fetuses that do not respond with an acceleration will have a normal pH.[44] Thus, this test is useful only if the scalp stimulation, which is performed between contractions, results in an FHR acceleration. If the acceleration occurs, the clinician can be assured that the fetus is not acidemic. Conversely, when an acceleration does not occur, the presence or absence of fetal acidemia has not been determined and management must be based on other clinical factors.

Fetal scalp stimulation or vibroacoustic stimulation is most useful in the setting of minimal variability and decelerations or minimal variability without decelerations. For example, if a woman has been given opioids, the FHR variability will be iatrogenically decreased. If this woman has an FHR pattern that includes late or variable decelerations, it may be of value to perform a scalp stimulation test.

Corrective Measures for Category II FHR Patterns

Several corrective measures (also referred to as intrauterine resuscitation techniques) are used to relieve umbilical cord compression or improve uteroplacental perfusion (**Table 26-8**).[79-84] With the exception of tocolysis to decrease the frequency of uterine contractions, the evidence supporting the efficacy of these measures is not strong despite common incorporation of these techniques in most FHR management protocols.[83]

Table 26-8 Corrective Measures for Category II Fetal Heart Rate Patterns

Corrective Measure	Underlying Mechanism
Variable Decelerations	
Position change	Alters the relationship between the umbilical cord and the fetus to relieve cord compression.
Amnioinfusion	Increases the amount of amniotic fluid available in the uterus to protect the cord from compression.
Intravenous fluid bolus	Increases the amount of amniotic fluid available in the uterus to protect the cord from compression.
Open glottis pushing	Reduces the frequency and severity of variable decelerations.

Late Decelerations	
Lateral position	Increases uterine blood flow so the intervillous space is adequately perfused.
Reduction of uterine activity by discontinuing oxytocin, tocolysis	Decreases the frequency of uterine contractions so that the fetus has more time to equilibrate acid–base balance between contractions.
Intravenous fluid bolus	Increases uterine blood flow and dilutes plasma oxytocin levels.
Oxygen administration	Oxygen administration to a laboring woman increases fetal oxygenation. The effect, which lasts approximately 30 minutes after supplemental oxygen is stopped, relieves late decelerations. Because of the theoretical risk that supplemental oxygen might produce free oxygen radicals that could harm the fetus, administration of supplemental oxygen should be stopped once the FHR pattern improves.
Prolonged Decelerations	
Intravenous fluid bolus	Increases uterine blood flow and dilutes plasma oxytocin levels.
Reduction of uterine activity by discontinuing oxytocin, tocolysis	Decreases the frequency of uterine contractions so that the fetus has more time to equilibrate acid–base balance between contractions.
Correction of maternal hypotension via intravenous fluids, lateral positioning	If prolonged deceleration occurs secondary to maternal hypotension from supine positioning or following placement of regional analgesia, maternal hypotension will result in a prolonged deceleration from decreased uteroplacental perfusion. If lateral positioning and intravenous fluids do not resolve the deceleration, intravenous ephedrine can be administered.

Fetal Heart Rate Patterns and Uterine Activity

Studies of fetal oxygenation have found that an interval of approximately 60 seconds between contractions is associated with stable fetal cerebral oxygenation, whereas intervals between contractions that are less than 60 seconds are associated with lower umbilical artery pH levels.[85-87] Simpson et al. measured fetal oxygenation ($FSpO_2$) via pulse oximetry among women who were being induced at term.[85] These researchers found that when fewer than 5 contractions occurred in a 10-minute window, fetal saturation was unaffected; when 5 or more contractions occurred in a 10-minute window, fetal $FSpO_2$ dropped 20% in 30 minutes; and when more than 6 contractions occurred in 10 minutes, fetal $FSpO_2$ dropped 29% in 30 minutes.

Thus, amelioration of tachysystole can improve fetal oxygenation and mitigate the development of acidemia. In the Simpson et al. study, discontinuation of oxytocin infusion resulted in resolution of tachysystole in approximately 14.2 minutes.[85] Discontinuing oxytocin and administering an intravenous bolus (at least 500 mL) resulted in resolution in approximately 9.8 minutes. Discontinuing oxytocin, administering an intravenous bolus, and ensuring lateral positioning together resolved tachysystole in approximately 6 minutes.[85]

Administration of a tocolytic such as terbutaline (0.25 mg) will also reliably resolve tachysystole. Finally, maternal pushing with every other contraction to mitigate the effect of uterine contractions may decrease the severity or frequency of variable decelerations during second-stage pushing.

Special Populations

The fetal response to hypoxial stress can be significantly affected by fetal and maternal medical or obstetric disorders, gestational age, and in utero exposures to fetotoxic substances. For example, although the pathophysiologic pathways differ, preterm and post-term fetuses are more vulnerable to asphyxial stress than term fetuses. Furthermore, the fetus responds differently to chronic hypoxia, which is more likely to develop during the prenatal period, than to acute hypoxia, which is more likely to occur in the intrapartum period. Although a detailed discussion of these modifying factors is beyond the scope of this chapter, a brief review of the most common clinical scenarios—that is, preterm gestation, infection, and uteroplacental insufficiency—is presented here.

Preterm Fetus

The preterm fetus has different inherent FHR characteristics as compared to the term fetus. For example, the baseline heart rate is higher in the preterm fetus, averaging 155 bpm at 20 gestational weeks. FHR accelerations in association with fetal movement are a developmental process. By 28 gestational weeks, approximately 80% of fetuses will have accelerations adequate to meet the standard nonstress test criteria. Prior to 32 weeks' gestation, the amplitude of an acceleration may be only 10 bpm with a duration of 10 seconds, which satisfies the requirement for NST reactivity in a preterm fetus. Baseline variability is decreased in the preterm fetus, but no standards have been established in this regard. Short, shallow variable decelerations appear more frequently in FHR tracings of preterm fetuses.

The preterm fetus is also more vulnerable to cerebral injury from a hypoxic event and more likely to be exposed to hypoxial stress via preterm labor or infection. Thus, tachycardia should be evaluated as a possible sign of infection, even though the baseline rate in a preterm fetus may be only slightly elevated above the normal baseline rates seen in term fetuses. Pattern evolution that reflects developing acidemia, characterized by diminishing variability, deeper decelerations, and tachycardia, progresses more rapidly than the expected 1-hour duration that has been reported in term fetuses.

Infection

Infection may reduce the threshold at which hypoxia causes cerebral damage, thereby increasing the fetus's risk for subsequent cerebral palsy. Infection also increases the fetal metabolic rate, such that the fetus requires more oxygen. The cascade of pathophysiologic events linked to infection includes fetal exposure to inflammatory mediators that are introduced into the maternal and fetal circulation in response to the presence of endotoxins. Pro-inflammatory cytokines increase the permeability of the blood-brain barrier, cause endothelial damage, and increase the risk of ischemia, thrombosis, and infarction. In this way, the fetal inflammatory response to infection, in addition to the direct effects of the bacterial toxins, causes dysregulation of cerebral blood flow and subsequent hypoxic–ischemic injury.[88]

Preterm birth is closely linked to this process, as infection also initiates release of

prostaglandins, which cause preterm labor. Indeed, intra-amniotic infection is often the cause of preterm labor. The cardinal FHR characteristic associated with intra-amniotic infection is tachycardia. Treatment is reviewed in the *Complications During Labor and Birth* chapter.

Uteroplacental Insufficiency

Uteroplacental insufficiency (UPI) refers to any condition in which the placenta is not able to supply sufficient oxygen or nutrients to the fetus. It can occur at any time during the course of pregnancy, but is most often associated with preeclampsia, diabetes, maternal vascular disorders, and post dates. In the setting of uteroplacental insufficiency, the fetus can be exposed to chronic hypoxia and must balance reduced oxygen delivery with oxygen consumption. The result is a diminution of metabolic function and growth restriction. The term *intrauterine growth restriction* (IUGR) is applied when a fetus fails to reach the genetic growth potential—that is, when the fetus's estimated weight is less than 10% of the predicted weight based on gestational age.

Baseline FHR variability is generally diminished in fetuses with IUGR compared to the FHR variability commonly seen in fetuses with appropriate growth.[89-91] During labor, fetuses with UPI or IUGR are more likely to develop late decelerations than are fetuses without UPI.

Conclusion

The assessment of fetal well-being is a critical component of midwifery management of the maternal–fetal dyad during labor. Regardless of the use of intermittent auscultation, EFM, or a combination of the two, the focus must be on the care of both the woman and her fetus—not just documentation of electronically generated data.[66] Like many other areas of practice, assessment of the fetus in labor is complex, and information is being gathered continuously through ongoing research.

All midwives can use the methodologies that promote normal labor and birth while screening for and managing deviations from normal. The midwife may be the primary supporter of intermittent auscultation and the educator of other professionals in the birthing environment. Use of intermittent auscultation is a clear opportunity to blend the art and science of midwifery in a way that can make substantive positive change in clinical practice.

Intermittent Auscultation During Labor

TEKOA L. KING

© hakkiarslan/iStock/Getty Images Plus/Getty

The purpose of intrapartum assessment of the fetal heart rate (FHR) is to monitor fetal well-being over the course of labor and to identify the fetus at risk for clinically significant acidemia. Effective methods of evaluation and accurate interpretation of the FHR during labor have long been the subjects of clinical debate. Continuous electronic fetal heart rate monitoring (EFM) is the most commonly used method of intrapartum fetal surveillance, but has not been found to be more effective than intermittent auscultation (IA).[1] Professional organizations' recommendations for fetal heart rate monitoring during labor are primarily based on protocols used in randomized clinical trials conducted during the 1990s that compared IA to EFM.[1-4] Handheld Doppler or Pinard-type fetoscopes were used for the IA groups in these trials, and those women had continuous one-to-one nursing during labor. Since those studies were performed, knowledge of the relationship between specific FHR patterns and adverse neonatal outcomes has improved, so it cannot be assumed that the IA protocols currently in use reflect current knowledge about the physiology of fetal heart rate characteristics during labor.[5,6]

Intermittent auscultation is typically conducted using a handheld Doppler fetoscope. Pinard-type fetoscopes may be used prenatally, but they have limitations for intrapartum use. A handheld Doppler device can effectively monitor the fetus if the technique is performed correctly. Conversely, intermittent auscultation can miss significant fetal heart rate decelerations if the technique used is not accurate. This appendix presents the technique for intermittent auscultation, interpretation of findings from IA, and management recommendations based on current knowledge of fetal heart rate characteristics.

Intermittent Auscultation Versus Electronic Fetal Heart Rate Monitoring

Both EFM and IA have benefits and limitations. Auscultation allows the woman freedom of movement and permits fetal assessment if the woman is in water. Auscultation also requires one-to-one continuous care, but may not be technically feasible for women who have high body

mass indices (BMIs) or when women are in certain positions such as on hands and knees. EFM will monitor the fetus continuously during labor and provides a record that can be examined by others as needed, often from a central monitoring site. However, EFM limits the woman to a bed or sitting near a bed unless telemetry units are available for her use. Moreover, when a healthcare provider monitors the fetus from a central monitor, the only supportive person for the woman may no longer be in the room, and she may miss the additional advantages of having someone with her continuously throughout her labor.

The randomized controlled trials (RCTs) that compared EFM with IA did not find that either modality was a better option for improving Apgar scores, lowering the incidence of cerebral palsy, or improving perinatal mortality rates.[1] EFM was associated with a significant increase in the rate of cesarean section compared to IA. The value of these findings and limitations of the RCTs are reviewed in this chapter and extensively elsewhere.[7,8] Until another RCT comparing EFM to IA that incorporates current knowledge about which FHR patterns are associated with acidemia is published, it is unlikely that the question of which modality is superior will be answered. Therefore, the focus of this appendix is on safe use of IA based on current knowledge.

Fetal Heart Rate Characteristics Detectable on Intermittent Auscultation

Table 26A-1 lists the FHR characteristics that can be detected via IA and EFM. Auscultation can determine the baseline FHR, changes in the rhythm of the heart rate, and accelerations.[1,9-11] The *Auscultated Acceleration Test* appendix of the *Pregnancy-Related Conditions* chapter describes the methods used to identify and document FHR accelerations in nonlaboring women. Although these methods have not been assessed in a laboring population, it is reasonable to assume that they are valid. Studies assessing reliability of IA use to document accelerations during labor have not been conducted. IA cannot determine FHR variability.[6] Decelerations can be identified as a decrease in the heart rate, but specific timing of the decelerations in relation to uterine contractions cannot be determined with assurance, nor can the degree of decline of the heart rate, such as “sudden” or “gradual,” be confirmed. Thus, decelerations cannot be categorized as early, variable, or late in character. Instead, auscultation of decreases in the FHR can be described as “brief” or “prolonged” based on the auscultated duration and the slowest rate counted or registered on the Doppler device.

Table 26A-1 FHR Characteristics Determined via Fetoscope, Doppler, and Electronic Fetal Heart Rate Monitoring

FHR Characteristic[a]	Fetoscope	Doppler Without Paper Printout	Electronic FHR Monitor
Variability	No	No	Yes
Baseline rate	Yes	Yes	Yes
Accelerations	Detects increases[b]	Detects increases[b]	Yes
Decelerations	Detects decreases in FHR and duration of decrease	Detects decreases in FHR and duration of decrease	Differentiates types of decelerations as early, late or variable
Rhythm[c]	Yes, arrhythmia will be audible	Yes, arrhythmia will be audible	Yes, arrhythmia will be audible and recorded on a paper graph. The type of arrhythmia cannot be determined. May double or halve the count and report an inaccurate FHR if arrhythmia is present.
Differentiation of maternal and fetal heart rate	Yes	May detect maternal heart rate instead of fetal heart rate	May detect and record maternal heart rate instead of fetal heart rate

Abbreviations: FHR, fetal heart rate; NICHD, National Institute of Child Health and Human Development.
[a] Definitions of each FHR characteristic per the NICHD 2008 criteria.[3]
[b] Per method described by Paine et al. in pregnant women not in labor.[9,10]
[c] Determined as regular or irregular. None of these devices can diagnose the type of fetal arrhythmia.
Modified with permission from Intermittent auscultation for intrapartum fetal heart rate surveillance: American College of Nurse-Midwives [erratum, *J Midwifery Womens Health.* 2016;61(1):134]. *J Midwifery Womens Health.* 2015;60(5):626-632.[2] © 2015, with permission from Wiley.

Moderate FHR variability is the most reliable indicator that a fetus is not experiencing clinically significant acidemia. As a consequence, the inability of IA to detect FHR variability or to discriminate between types of FHR decelerations must be addressed. Despite the fact that it cannot detect FHR variability and despite the lack of direct scientific study of this technique, IA is considered a viable option for low-risk women at term for several reasons:

- IA is recommended only for women who do not have an a priori risk (known risk) for developing fetal acidemia during labor. The incidence of clinically significant metabolic acidemia in newborns in a healthy population of women is approximately 3 per 1000 births.[12,13] Of these infants, only a small proportion will have adverse outcomes. A priori risk screening is a critical step in identifying women who are candidates for this method of fetal surveillance. Further evidence that supports risk screening comes from large population-based studies of out-of-hospital birth. Very-low-risk women at term who are monitored with IA during labor have a very low risk for adverse maternal and newborn outcomes during labor and birth.[14-18]
- When significant fetal acidemia does develop during the intrapartum period in a previously healthy fetus, it occurs over a period of time during which the fetus will develop recurrent FHR decelerations that are detectable on IA[19] or as an acute unremitting bradycardia. Although the incidence of acute bradycardia in a rigorously screened low-risk population is quite low, this is an important fact that needs to be included in shared decision making when a woman is choosing a mode of fetal surveillance.
- Randomized controlled trials of IA included one-to-one nursing care, which may have an

independent positive effect on labor outcomes. Thus, use of IA presumes continuous labor support is in effect.

- IA will not detect a sinusoidal FHR pattern if decelerations are not also present. This rare FHR pattern is associated with placental abruption, Rh isoimmunization, and maternal–fetal hemorrhage. A woman with symptoms of one of these conditions is not a candidate for IA.

Professional Guidelines for Intermittent Auscultation

The American College of Nurse-Midwives (ACNM) has published a clinical bulletin that summarizes the technique and interpretation of IA.[2] The method described in this appendix is concordant with the ACNM guidelines. Individual institutions or practices may develop protocols specific to their settings and populations. Protocols for IA should define the method of conducting IA, frequency and duration of IA, indications for IA, and indications for transfer to EFM.

Frequency, Timing, and Technique for Intermittent Auscultation for Women in Labor

ACNM recommends auscultating the FHR every 15 to 30 minutes in the active phase of labor and every 5 minutes in the second stage of labor.[2] The frequency and timing of IA are based on the frequency and timing used in the RCTs comparing EFM with IA. However, the protocols designed for RCTs were not tested for effectiveness and have some important limitations.

Frequency

Strict adherence to a 15- or 30-minute interval fails to account for changes in labor status that could potentially affect the FHR. The frequency of auscultation should be individualized based on labor characteristics such as the frequency of contractions, clinical signs of fetal descent (e.g., spontaneous rupture of membranes, bloody show, urge to push, nonrecurrent decelerations), and institution of hydrotherapy or other interventions that may affect the FHR.

Duration of Auscultation

The original RCTs recommended auscultating between contractions, and for many years professional organizations' guidelines maintained this recommendation. However, listening between contractions can result in missing clinically significant variable decelerations that occur during a contraction and resolve as the contraction ends. For this reason, the current guidelines recommend listening through a contraction and for a period of time after the contraction ends.[1,4] If no FHR decreases are noted, in subsequent assessments the midwife may begin auscultation at the peak of a contraction and continue listening for 30 to 60 seconds after the contraction is over. Listening between contractions is not effective and should not be part

of the technique.

Multicount Strategy

A multicount technique has been shown to be more reliable than counting once throughout the period of assessment.[20] In a study conducted by Shiffrin et al., the multicount strategy identified approximately 93% of FHR decelerations; by comparison, a single-count strategy identified 74% of the FHR decelerations.[15] When using a multicount strategy, the listener counts the FHR for a period of 6, 10, or 15 seconds several times over the course of the listening period. A defined rest period of 5 or 10 seconds occurs between each count. Each count is then multiplied by the appropriate number to obtain an FHR-per-minute rate. The counts can be plotted to diagram the FHR changes over the course of the auscultation period, as shown in **Figure 26A-1**. Some anecdotal evidence suggests that this technique will reveal FHR variability, but this relationship has not been evaluated scientifically.

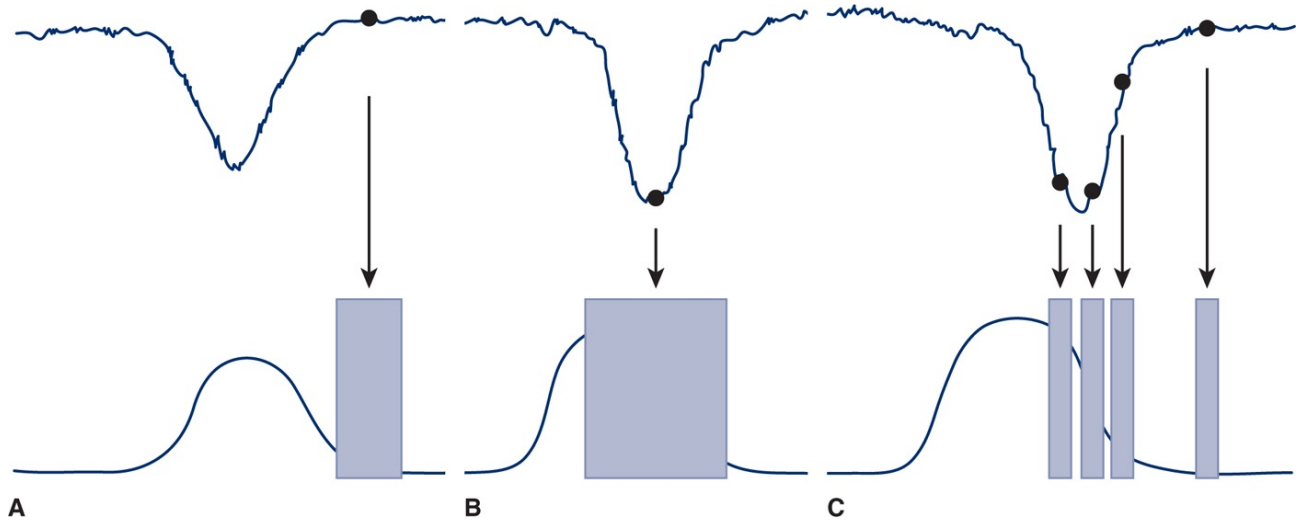

Figure 26A-1 Multicount strategy for assessing the fetal heart rate via intermittent auscultation. **A.** Single count strategy for < 1 minute between contractions may miss a deceleration. **B.** Single count strategy for 30–60 seconds that starts after the peak of the contraction will detect presence of a deceleration qualitatively. **C.** Multicount strategy for 10 seconds with a 5–10 second break between counts allows the clinician to graphically sketch the deceleration.

Interpretation of Intermittent Auscultation Fetal Heart Rate Characteristics

FHR changes identifiable on IA have been evaluated in concert with the 2008 National Institute of Child Health and Human Development (NICHD) interpretative categories for EFM for use in the United States. FHR changes detected on IA are classified as either Category I or Category II, as outlined in **Table 26A-2**.[2] There is no Category III when using IA, because Category III FHR patterns have no variability and cannot be detected via IA.

Table 26A-2	Interpretation of Auscultation Findings Relative to NICHD 3-Tier Categories
Category 1 FHR Characteristics by Auscultation	**Category II FHR Characteristics by Auscultation**
FHR baseline between 110 and 160 bpm with regular rhythm No FHR decelerations from the baseline FHR increases (accelerations) of 15 seconds in duration and amplitude from the baseline may or may not be present, but should be assessed for and documented if present	Tachycardia (baseline > 160 bpm) or bradycardia (baseline < 110 bpm) Audible irregular rhythm Presence of FHR decreases or decelerations from the baseline

Abbreviations: FHR, fetal heart rate; NICHD, National Institute of Child Health and Human Development.

Management of Category II Fetal Heart Rate Changes on Intermittent Auscultation

Category II FHR changes require increased surveillance. A longer listening period may be initiated, the frequency of auscultation increased, or transfer to EFM undertaken. If recurrent decelerations are noted or if the FHR is bradycardic, several commonly performed interventions should be initiated. The woman should be turned to her side and the FHR immediately reevaluated. Oxygen therapy and intravenous fluids may be initiated. If the Category II FHR pattern does not resolve in a short period of time, frequent auscultation and documentation of results should continue while transferring the woman to a setting where EFM and operative delivery are available.

Documentation of Intermittent Auscultation

The type of Doppler technology used and the multicount procedure employed are documented in the health record. The graph for documentation of IA should be simple and straightforward, to facilitate documentation.

Fetoscopes

Several Pinard-type stethoscopes are available, but all rely on bone conduction from the listener's cranium to amplify the sound. The most commonly used alternative is the Allen fetoscope, with either short or long tubing. The DeLee-Hillis fetoscope has a headpiece that fits over the listener's head, which facilitates the bone conduction.

The Pinard-type fetoscopes identify the sounds associated with the opening and closing of ventricular valves and must be placed on the maternal abdomen where the fetal heart is closest, over the fetal scapula or chest (**Figure 26A-2**). If used, the bell must be placed tightly against the maternal abdomen to achieve a good air seal, and the headpiece must be placed against the listener's forehead to take advantage of bone conduction

Figure 26A-2 Pinard-type fetoscopes. **A.** Allen fetoscope with short tubing. **B.** Allen fetoscope with long tubing. **C.** DeLee-Hillis fetoscope. **D.** Pinard fetoscope.

Although some of the RCTs of EFM versus IA used a Pinard-type fetoscope during labor, these devices are not good choices for detecting the FHR during a contraction. Given current knowledge about the role of FHR decelerations as a reflection of developing fetal acidemia, most midwives in developed nations do not use these devices for monitoring the FHR during labor today, and they are not recommended by the authors of this text.

Doppler Fetoscopes

Doppler devices use ultrasound to detect the movement—that is, opening and closing—of the ventricular valves by noting the change in ultrasound wave length that is caused by heart movement. The device converts the wavelength change into a visual digital recording and audible sound.

Doppler devices require use of a gel between the face of the transducer and the maternal skin to ensure transmission of sound without air interference. Some handheld devices will generate a printout record. Most Doppler fetoscopes are waterproof and can be used to record the FHR when a woman is in water.

Technique for Performing Intermittent Auscultation

1. Determine the fetal lie to optimize the quality of the heart sounds. Listening through the fetal back provides the clearest sound.
2. Determine the duration and frequency of uterine contractions.
3. Determine baseline FHR:
   a. If using a Doppler device, check the maternal radial pulse at the same time to be certain the Doppler fetoscope is detecting the FHR. The maternal heart rate may be documented in the woman's record.
   b. Perform the initial auscultation for a minimum of 60 seconds, between contractions, to determine the baseline FHR and to listen for regularity of the rate.
   c. Listen between contractions for several intervals within a 10-minute period to confirm consistency of the FHR and to identify the baseline.

   d. Count for 6 to 10 seconds several times, with a 5- or 10-second pause between counts; then multiply each count by 10 or 6, respectively, to obtain the FHR-per-minute numeric value.
4. Listen for the presence of FHR accelerations. Noting the presence of FHR accelerations can be done qualitatively or quantitatively. Accelerations do not need to be present to identify the FHR as Category I if the FHR rate has a normal baseline and no decelerations are present. However, FHR accelerations are a sign of fetal well-being when present and should be assessed for and documented if auscultated. The *Auscultated Acceleration Test* appendix in the *Pregnancy-Related Conditions* chapter describes the procedure for detecting FHR accelerations quantitatively.
5. Determine the presence of FHR decelerations. Begin listening at the peak of the contraction and continue for at least 30 to 60 seconds after the contraction is over.
   a. If a deceleration is heard, listen through successive contractions or several contractions in a 10-minute window to determine whether they are recurrent or nonrecurrent.
   b. Use a multicount method to document the drop in FHR baseline and depth of the decrease.
6. Document the FHR-per-minute rate for each assessment and inform the laboring woman and her support team of the findings.

Fetal Scalp Electrode

TEKOA L. KING

© hakkiarslan/iStock/Getty Images Plus/Getty

A fetal scalp electrode (FSE) is a very small, thin, spiral electrode that, when attached to the fetal scalp, enables fetal electrocardiogram (ECG). The FSE is attached to a cord that connects to an electronic fetal monitor, which turns the ECG into an audible and written continuous recording. An FSE requires that membranes are ruptured and the cervix is at least 1 to 2 centimeters dilated.

This device is not recommended for routine use. An FSE is used *only* when a continuous legible recording is considered necessary as a basis of clinical management and an external Doppler fetoscope is *not* able to supply such a record. Although there are no specific indications for use of an FSE in the United States, it is commonly used when an external Doppler device is unable to continuously detect the fetal heart rate (FHR) and the fetus is at risk for metabolic acidemia or perinatal death. Examples of such situations include severe preeclampsia or prior cesarean section birth such that an increased risk for uterine rupture is now present.

First-generation electronic monitors exaggerated FHR variability when the abdominal Doppler device was used, so an FSE would be applied to provide a more accurate rendition of FHR variability. Today, however, electronic fetal monitors have an autocorrelation feature that allows portrayal of FHR variability with an accuracy almost equal to that obtained when an FSE is used.[1] Thus, the need to better assess variability is rarely an indication for use of an FSE if a continuous legible tracing is present. Nevertheless, it is important to note that the external Doppler device can erroneously detect a maternal heart rate or double or halve the signal, which can, in rare situations, confound interpretation of its output.[1,2] In turn, doubt about the Doppler signal's accuracy in portraying a fetal heart rate is another indication for use of an FSE.

The FSE penetrates into the fetal scalp approximately 2 mm. Use of this device is contraindicated in women who have infections that might potentially be vertically transmitted to the fetus, such as active herpes, hepatitis, or human immunodeficiency virus (HIV). An FSE is also contraindicated if the fetus has a known or possible coagulation disorder. Some clinicians consider chorioamnionitis to be a relative contraindication to the use of an FSE.

This type of electrode should not be attached if the fetus is in a face presentation, or if the presentation is unknown. Likewise, it should not be placed on genitalia in breech presentations, or over the fontanelle in a vertex presentation.[1]

Complications following FSE use may include scalp laceration, localized infection, and (rarely) abscess. Some case reports describe facial injury, or insertion in the eye or ear when the FSE is placed without accurate diagnosis of fetal position. An FSE provides a potential pathway for ascending infection. Early studies found a correlation between prolonged use of an FSE (more than 12 hours) and neonatal sepsis, but subsequent retrospective analyses determined that FSE alone is not associated with an increased risk for neonatal sepsis.[3-5] To date, none of the studies conducted have been sufficiently powered to definitely answer this question. When attachment of an FSE is done in a known vertex presentation and the procedure is performed under aseptic conditions, complications are very rare.

Mechanism of Action

The FSE spiral electrode contains two electrodes in close proximity. One penetrates the fetal scalp to the depth of approximately 2 mm, with vaginal secretions providing electrical conduction between the two wires; the difference in voltage between the two electrodes is then measured and recorded. A third reference electrode that helps eliminate electrical interference is placed on the maternal thigh.

Contraindications to Use of Fetal Scalp Electrode

- Active infection such as HIV, herpes, or hepatitis B or C
- Placenta previa
- Unknown fetal presentation or position
- Face presentation

Do not place on genitalia or a fontanel.

Equipment

- Sterile fetal spiral electrode
- Sterile gloves
- Electronic fetal monitor
- Leg plate with Velcro strap or adhesive patches and cable to fetal monitor
- Water-based lubricant

Procedure for Attaching a Fetal Scalp Electrode

1. Explain to the woman the indication for use of an FSE, and review the procedure, along with its benefits and risks. Answer any questions the woman or her support personnel have. Obtain an informed consent prior to placement.
2. Perform hand hygiene.
3. Attach the leg plate to the woman's thigh.
4. Prepare a site, often on the woman's bed, for the material needed.
5. Open the FSE packaging.
6. Put on sterile gloves.
7. Remove the wires from between the drive tube and the guide tube, keeping the materials sterile.
8. Perform a vaginal examination; confirm lie, presentation, and position. Keep the examining hand on the area of the presenting part where the FSE will be applied.
9. Select the FSE with the nonexamining hand. Verify that the spiral end of the electrode is withdrawn so it is completely within the guide tube. This assures that the device will not inadvertently injure any tissue of the woman or the examiner (**Figure 26B-1**).
10. Advance the guide tube between the examining fingers, and position it firmly against the fetal presenting part, avoiding sutures, fontanels, or genitalia. If uncertain about the exact presentation, do not attach the FSE.
11. Advance the drive tube until it touches the fetal presenting part.
12. Maintain pressure on the guide tube so that it remains touching the fetal presenting part, and rotate the drive tube clockwise approximately 1.5 rotations until mild resistance is felt and the drive tube recoils. Rotating causes the tip of the spiral electrode to penetrate the fetal scalp and be attached.[1]
13. Release the end of the electrode wires from the locking device at the end of the drive tube grip.
14. Carefully retract the guide tube a few inches and check the placement of the scalp electrode with the examining hand.
15. Remove the guide tube from the woman's vagina and dispose of it per institutional policy.
16. Remove and discard gloves.
17. Attach the electrode wires to the leg plate and the cable from the leg plate to the fetal monitor.
18. Evaluate the FSE recording of FHR for at least 5 to 10 minutes before leaving the room.
19. Explain the findings to the woman and her support team.

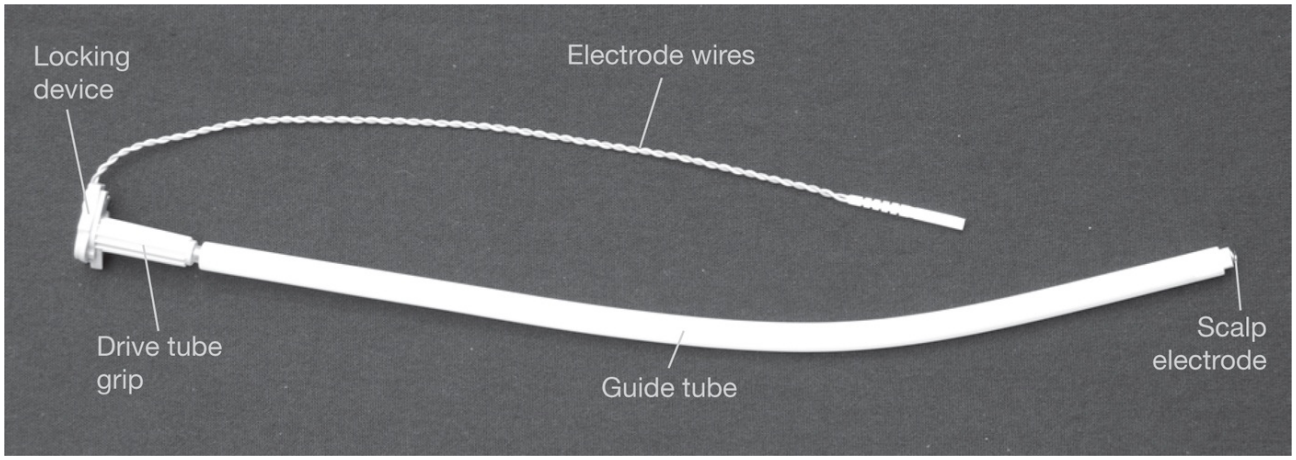

Figure 26B-1 Fetal monitoring spiral electrode assembly.

Procedure for Removing a Fetal Scalp Electrode

1. To detach the electrode, put on sterile gloves.
2. With the examining hand on the electrode, rotate it counterclockwise until it is free of the fetal presenting part.
3. Do not pull the electrode directly, as this could cause a scalp laceration.

CHAPTER

27

Support for Women During Labor

ELIZABETH NUTTER

The editors acknowledge Kimberly K. Trout and Ladan Eshkevari, who were the authors of this chapter in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

Every labor and birth is unique, and a woman's interpretation of labor pain is highly individual. The actions of care providers can have a strong effect in how a woman copes with labor pain and views her experience of labor.[1] A woman's memory of each labor and birth persists for many years, and likely for her lifetime.[2] This chapter divides coverage of support for women during labor into three sections: (1) a review of the physiology of labor pain and factors that influence the experience of labor and birth, (2) nonpharmacologic techniques for supporting women in labor, and (3) pharmacologic techniques used to support women during labor.

Physiology of Pain

Pain is the result of a complex interplay between physical, biological, psychological, and sociocultural factors, each of which contributes to the overall perception of the experience.[3,4] The formal definition of pain used in health care today comes from the International Association for the Study of Pain:

> *Pain is an unpleasant sensory and emotional experience. . . Pain is always subjective. Each individual learns the application of the word through experience related to injury early in life.*[5]

Pain Physiology: Receptors and Pathways

Pain is generally characterized as either acute or chronic, and is further characterized as somatic (deep or superficial) or visceral. Deep somatic pain is dull and aching but poorly localized, whereas superficial somatic pain is sharp and well localized. Visceral pain is caused by ischemia or inflammation in visceral structures (internal organs). Over the course of labor, visceral, deep somatic, and superficial somatic pain can all be experienced.

Pain is caused by stimulation of nociceptors—that is, sensory neurons that detect noxious substances. The pain impulse is transmitted from nociceptors in the periphery or viscera via fast, lightly myelinated A-delta fibers and slower, unmyelinated C fibers (**Figure 27-1**). Pain traveling along the A-delta fibers is perceived within 0.1 second, whereas pain transmitted along the C fibers takes longer—approximately 1 second or more to be perceived by the individual. Numerous types of stimuli, such as mechanical, thermal (temperature related), inflammatory mediators, and chemical agents, can stimulate nociceptors. For example, uterine stretching during labor causes mechanical pain, but lactic acid in uterine muscle can also stimulate uterine pain. Chemical mediators of pain include substance P, glutamate, bradykinin, acetylcholine, serotonin, and histamine. Pain management during labor is aimed at minimizing or allaying the effects of both mechanical and chemical mediators.[6]

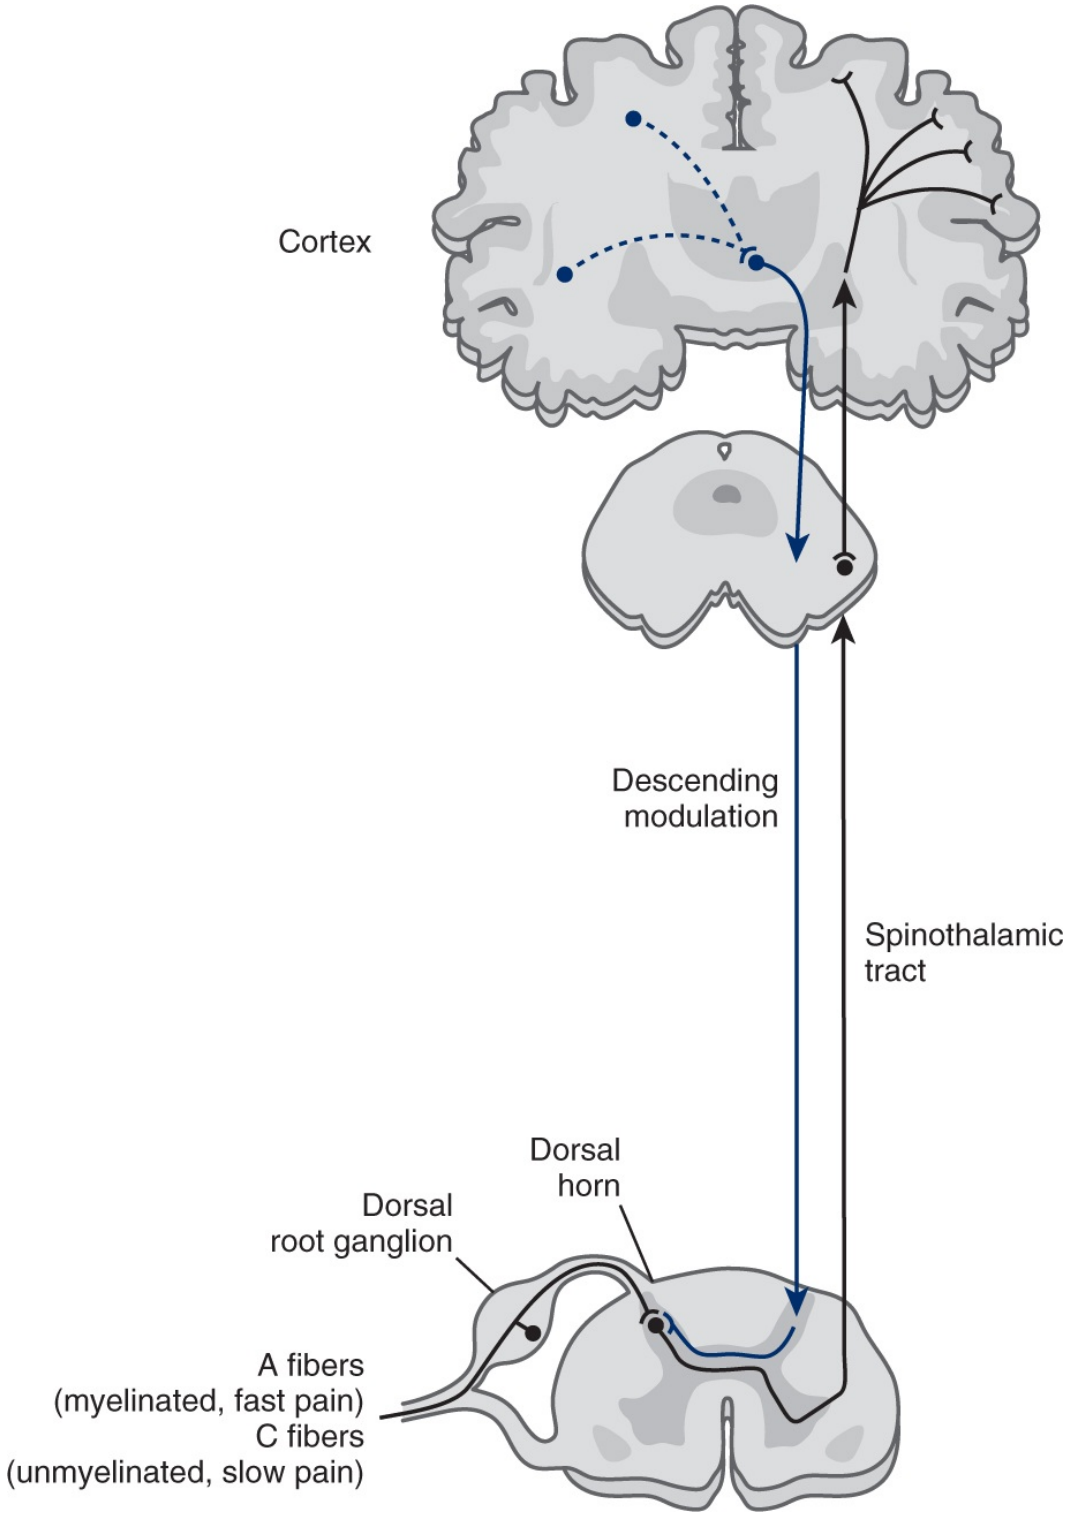

Figure 27-1 Transmission of pain periphery to the central nervous system.

Once pain is transmitted from the nociceptors at the anatomic source of the pain, the impulse is transmitted via A-delta and C fibers to the dorsal column of the spinal cord, where these fibers synapse with other neurons in the cord. During the first stage of labor, the pain fibers from the contracting uterus enter the spinal cord at the T10 to L1 levels, whereas during the second stage the pain fibers enter the spinal cord at the S2 to S4 level.[7] Nerves within the dorsal horn of the spinal cord transfer the impulse to the contralateral spinothalamic tract,

where nerves ascend to the cerebral cortex.

Prior to ascending to the central nervous system (CNS), the pain impulse crosses from one side of the dorsal horn to the other. The impulse can be modulated by several different mechanisms in the dorsal horn. The gate-control theory of pain modulation is the hypothesis that stimulation of A-delta fibers via massage, sterile water injections, or transcutaneous electric nerve stimulation (TENS) results in impulses rapidly traversing to the dorsal horn, where they effectively close a “gate” that blocks impulses from the slower C fibers that transmit deeper pain signals.[3,4] This theory, which was proposed in 1965 by Melzack and Walls, is not exactly correct in its details; notably, the mechanism for how the small and larger fibers interact is more complex.[8] Nonetheless, the gate-control theory of pain correctly identified the general process and set the stage for subsequent research that has greatly expanded knowledge of pain pathways and the factors that influence them.

The pain impulse travels to the brain via two pathways: the neospinothalamic tract and the paleospinothalamic tract. Most of the fibers of the neospinothalamic tract terminate in brain areas such as the brain stem and the thalamus, where the pain signal is transmitted to basal areas of the brain as well as the somatosensory cortex, causing the parturient to “feel” pain. The paleospinothalamic tract fibers terminate in the brain stem, in the areas of the medulla, pons, mesencephalon, and periaqueductal gray region. These lower regions of the CNS also play a role in the perception of pain. Thus, the perception of pain is the result of CNS integration of pain impulses in the thalamus, lower brain areas, and the cortex.

The pathways of pain perception are bidirectional. The CNS also has the capability of modifying the perception of pain. First, inhibitory neurons in the CNS can dampen the pain sensation via activation of an endogenous opiate system. The brain has a fairly elegant analgesic system that varies from person to person, which partially explains some of the individual differences in pain perception across the population. In addition, the periaqueductal gray and the periventricular areas (the areas around the third and fourth ventricles of the brain) possess neurons that transmit anti-nociceptive impulses to the dorsal horns of the spinal cord. The impulses from these fibers block the ascending pain impulse before it is relayed to the brain, via release of neurotransmitters such as enkephalin and serotonin at their terminus in the dorsal horn of the spinal cord. Serotonin promotes release of enkephalin, which is known to inhibit both presynaptic and postsynaptic type C and A-delta pain fibers at the dorsal horns. Several other naturally occurring physiologic opioids, such as beta-endorphin and dynorphin, also play roles similar to that of enkephalin. Most of the opioids now used exogenously to treat pain are derived from opium, a naturally occurring opioid whose structure resembles that of the endogenous opioids found in the brain and dorsal horn of the spinal cord.

Labor Pain

Labor pain is felt in three general physical locations. Virtually all women in labor experience lower abdominal pain, approximately 74% experience contraction-related back pain, and approximately 33% experience continuous low back pain.[9] In Melzack's classic study of 42 nulliparous women and 37 multiparous women who completed hourly pain assessments throughout labor, there was a wide amount of variability between individuals in the spatial distribution of where pain was felt.[10]

In addition to spatial variation, variation in intensity of labor pain is apparent. Generally, nulliparous women report higher average intensity levels of pain than multiparous women on the McGill Pain Questionnaire, especially nulliparous women who have had no preparation for childbirth.[10] However, there is variability in the pain reported at hourly intervals by individuals, just as there is a great deal of variability among different women. Although for most women, the average intensity of pain increases as labor progresses, nulliparous women often report more pain in early labor whereas multiparous women tend to report more pain in active labor. In addition, many women report periods during active labor where pain does not increase or when it actually decreases for a short time.

In summary, despite the general observation that labor pain increases as cervical dilation increases, labor pain can be independent of cervical dilation for both nulliparous and multiparous women, and there is interindividual variability in the location, intensity, and progression of pain during labor.[9-11]

Physiologic Response to Labor Pain

Pain during the first stage of labor is generally believed to be caused by mechanical distension of the lower uterine segment, cervical dilation, and perhaps acidemia in uterine muscles that develops as a result of recurrent uterine contractions.

A number of physiologic systems are affected by pain. One of the first responses is that of the sympathetic nervous system, which releases stress-related hormones such as cortisol, catecholamines (norepinephrine and epinephrine), and cytokines. Concomitantly, the levels of angiotensin II, antidiuretic hormone, growth hormone, and glucagon increase. The effect of these changes is heightened alertness, increased cardiac output, increased heart rate, increased respiratory rate, elevated blood pressure, higher serum glucose levels, and more extracellular fluid in the periphery and lungs. Increased levels of catecholamines also slow gastrointestinal and genitourinary motility and alter coagulation and immune responses.

The relationship between catecholamine release and uterine contractility during labor is poorly understood. It has long been theorized and noted in observational studies of small numbers of laboring women that the uterus does not contract well when catecholamine levels are very high.[12] Epinephrine is a known tocolytic and increases proportionately more than does norepinephrine during labor, although there is a great deal of interindividual variability. Poorly controlled pain can cause anxiety and fear, which in turn further stimulates the hypothalamic–pituitary axis and exacerbates the stress response, leading to the release of even more catecholamines and cytokines. Despite some known physiologic mechanisms, the exact effects

of stress and fear on uterine contractility during labor have not yet been clearly delineated.[12]

Factors That Affect Perception of Labor Pain

To help account for the significant interindividual variability in the perception and response to pain, Melzack expanded the gate-control theory so it evolved into the neuromatrix theory of pain.[3,4,13] According to this theory, the perception of pain by any individual, including the laboring woman, is a dynamic process with physical, psychological, and behavioral components.

The interplay of psychological preparation, expectations, past experience of pain, fear of childbirth, and emotional support during labor are just a few of the factors that affect the degree of pain perceived by a woman during labor. Expectations appear to play a large role in a woman's perception and ability to cope with the pain of labor.[13] In a review of this body of work, Lally et al. found that, in general, there is a significant gap between expectations and experience, with most women reporting more pain than expected and expectations that were not met.[14]

The effects of race, ethnicity, and culture on pain perception are complex.[6] Culture does not appear to influence perception of pain, but does affect behavioral responses to pain.[6] Genetic variability in opioid receptors can affect pain sensation, with specific polymorphisms in opioid receptors occurring more frequently in some racial/ethnic groups.[15,16] Unfortunately, interethnic differences in opioid receptors do not predict pain perception well enough to be of clinical value at this time.[16]

Genetic differences in the microsomal enzymes involved in metabolizing drugs can play a clinically important role in a woman's ability to metabolize the opioids used for pain management during labor.[17] For example, the cytochrome CYP2D6 has several polymorphisms that adversely affect the metabolism of codeine in individuals who have the polymorphism phenotype.[17]

Women's Experience of Labor

Multiple demographic characteristics of women are associated with increased severity of labor pain as well as the experience of labor. For example, women who have severe dysmenorrhea are more likely to have severe labor pain. This outcome may be related to increased prostaglandin synthesis, which results in intense uterine contractions.[6] Pain tends to be worse at night than in the daytime, and unfamiliar settings increase self-reports of pain intensity. Fear of labor and lack of self-efficacy are also associated with severe labor pain. A woman's ability to use mental strategies to cope with labor pain appears to be related to her self-confidence in being able to use those strategies, although this is probably a simplification that does not fully account for the many factors involved.[6] Finally, severe labor pain and a traumatic birth are associated with the development of chronic pain and post-traumatic stress syndrome.[18] Given these factors lead to different experiences of labor, the importance of providing individualized care and support for women during labor cannot be emphasized strongly enough.

Prenatal Factors That Influence Labor Pain

Knowledge of the physiology of labor pain and the ability to assess how a woman is coping with labor pain are important but not enough to ensure a midwife has the ability to support women sufficiently in labor. Multiple antecedents may affect labor pain, and knowledge of these factors can inform the therapeutic approach for an individual woman.

Women with Childbirth Fear or Anxiety

Fear of childbirth can range from mild anxiety to avoidance of childbearing because the fear is so great; the latter extreme is defined as *tokophobia*. Most of the research on fear of childbirth has been conducted in Northern Europe. Although there is a paucity of data on this topic from the United States, significant fear appears to be more common than previously thought.[19,20] Studies that have examined pregnant women's fear of childbirth have found increased fear is associated with nulliparity, young maternal age, preexisting psychological conditions, low-self-esteem, and a history of abuse.[19-21] Fear of childbirth is also associated with increased severity of labor pain.[21,22]

History of Sexual Abuse

In the United States, approximately one in every five women has a history of sexual abuse.[23] The experience of labor and birth can be traumatic for women who have a history of sexual abuse. Although most studies of this topic are small qualitative analyses of women's experiences, findings consistently show that care practices during labor can result in victimization and trauma.[23,24] A safe, trusting relationship with caregivers and trauma-informed support is an essential approach for caring for women who have a history of abuse.

Childbirth Education

Starting with the first edition of Grantly Dick-Read's classic *Childbirth Without Fear* published in the 1930s, various childbirth preparation programs have evolved to assist women in preparing to give birth. By the 1970s, childbirth education classes had become the *de rigueur* means of preparing for labor and birth. The initial focus of these classes was on reducing the fear–pain–tension cycle by providing women with knowledge about the labor process so pain medications could be avoided during labor. Dick-Read postulated that fear generates physical tension, which in turn increases pain; he also suggested that fear could be alleviated with knowledge and skills. Subsequently introduced natural psychoprophylactic methods of childbearing have varied in the emphasis they place on preparatory muscular and breathing exercises, but all educate the woman about the processes of labor and various means of coping with pain, thereby reducing fear.

A Cochrane review of the effects of childbirth preparation classes was not able to identify how childbirth classes affect labor pain, self-efficacy, or knowledge acquisition, with the researchers citing multiple methodological flaws in the trials that made up their systematic review of this topic.[25] A subsequent large randomized trial that involved intention-to-treat analysis found some significant benefits of childbirth education. In this study, women were randomly assigned to a group that received 9 hours of formal childbirth education versus a group that received usual care. The researchers found that women in the usual-care group were less likely to be admitted in active labor (relative risk [RR], 1.45; 95% confidence interval [CI], 1.26–1.65) and less likely to use epidural analgesia for labor (RR, 0.84; 95% CI, 0.73–0.97).[26]

Intrapartum Factors That Influence the Experience of Labor

In 2002, Hodnett performed a systematic review that analyzed results from 137 studies (both qualitative and quantitative) involving more than 14,000 women to determine the major factors that influence birth satisfaction.[13] This analysis identified four major components of birth satisfaction: (1) prenatal expectations, (2) support from caregivers, (3) quality of the caregiver–woman relationship, and (4) involvement in decision making. These results have been validated and replicated in multiple studies since the publication of this seminal analysis. Surprisingly, adequate pain relief is not one of the four factors that affect birth satisfaction. Hodnett concluded:

> *The influences of pain, pain relief, and intrapartum medical interventions on subsequent satisfaction are neither as obvious, as direct, nor as powerful as the influence of the attitude and behaviors of the caregivers.*[13(pS160)]

Coping During Labor

The work of Hodnett and others has greatly expanded our knowledge of women's experiences of labor, including clarifying the point that mitigation or diminution of pain and coping with labor are not the same thing. Research suggests that for the laboring woman, the ability to cope

is more important to birth satisfaction than relief of pain.[27] Yet, adequate pain relief is considered an important patient right by The Joint Commission (formally the Joint Commission on Accreditation of Hospitals). In most acute care settings in the United States, a numerical rating scale (where 0 is no pain and 10 is the worst possible pain) is used to assess pain, plan interventions, and evaluate the effect of those interventions. Such a numeric rating scale of pain does not, however, capture how well a woman in labor is coping with this experience.[27,28]

Fortunately, alternative algorithms have been developed to assess the more important variable of "coping" for the laboring woman. Gulliver et al. developed a Coping with Labor Algorithm that was pioneered at the University of Utah to capture the variable of coping for the laboring woman, while at the same time complying with The Joint Commission standards.[28,29] This algorithm is presented in **Figure 27-2**. Simply asking "How well are you coping on a scale of 1 to 10?" instead of "How bad is your pain on a scale of 1 to 10?" can generate the information that the midwife needs most to help a woman during labor.

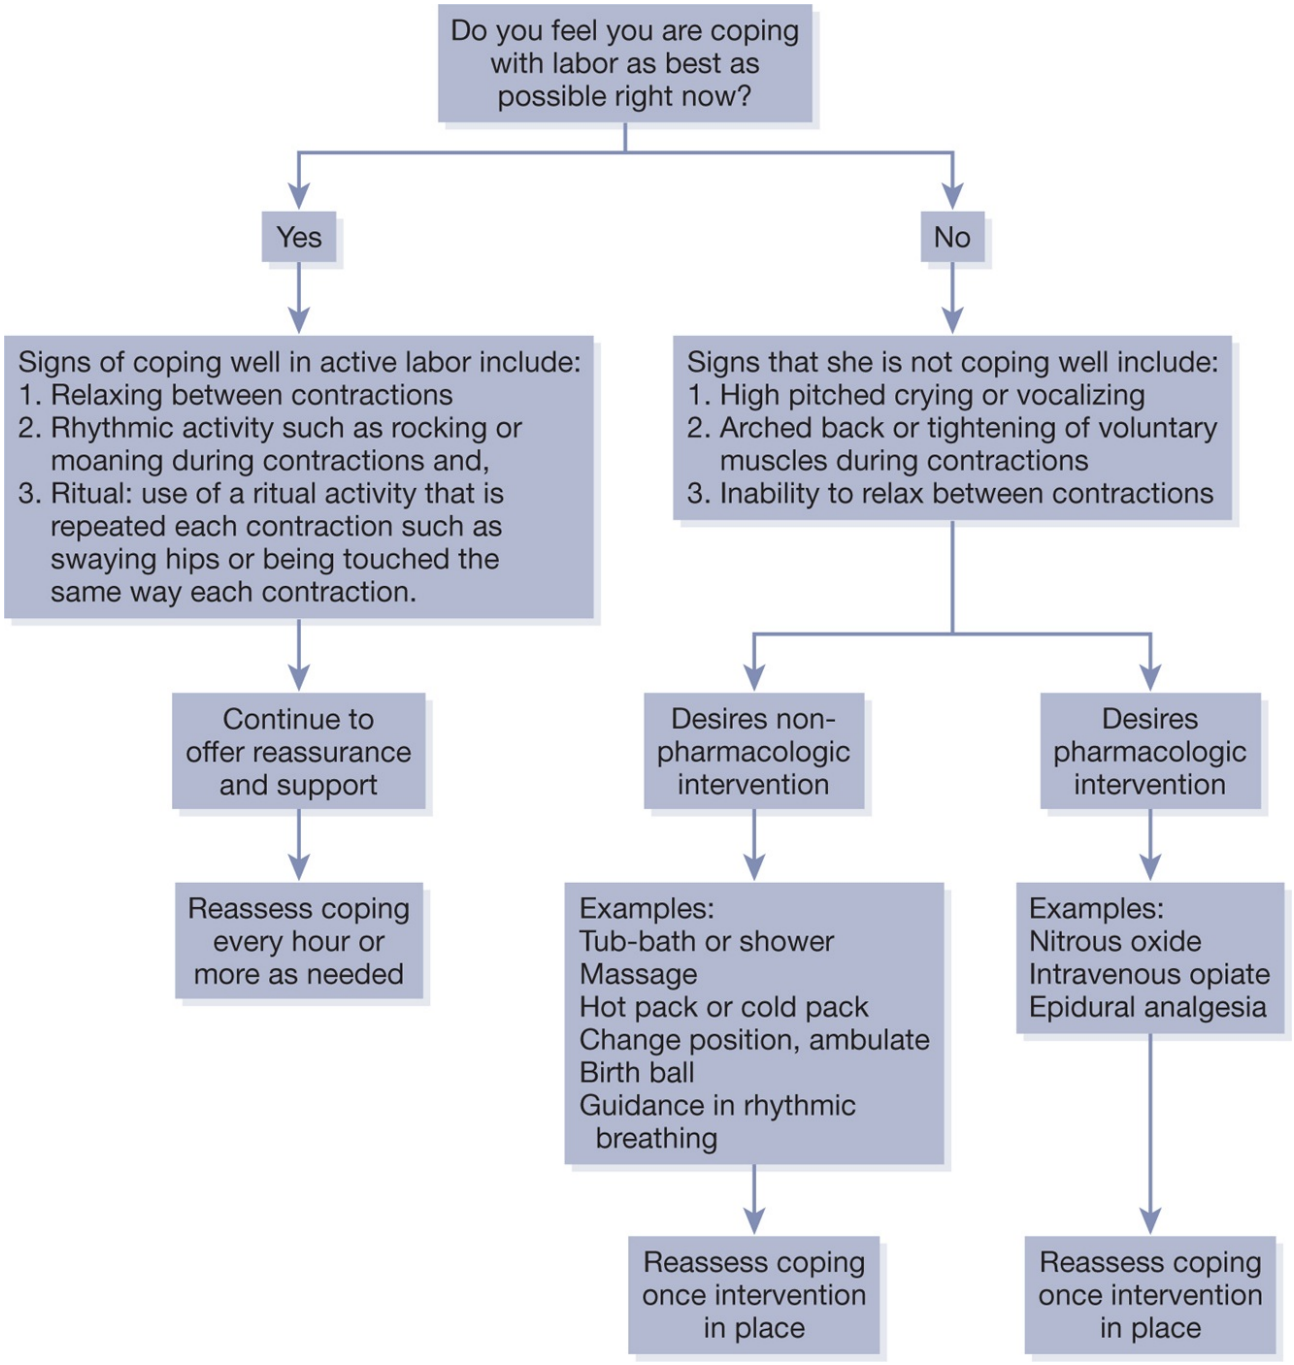

Figure 27-2 Coping with labor algorithm.

Simkin analyzed the behaviors of women who were coping well in labor and found three consistent behaviors that serve as cues in addition to what the woman tells her caregivers: (1) relaxation during or between contractions, (2) use of a ritual (repeated use of a meaningful rhythmic activity), and (3) rhythmic activity (breathing, rocking, swaying).[30] If a woman is coping well with the pain of labor, then one can reliably presume she is not suffering or experiencing acute emotional distress. Simkin and Bolding stated:

> *Although pain and suffering often occur together, one may suffer without pain or have pain without suffering. . . one can have pain coexisting with satisfaction, enjoyment and empowerment. Loneliness, ignorance, unkind or insensitive treatment during labor, along with unresolved past psychological or physical distress, increase the chance that the woman will suffer.*[1(p489)]

Signs of not coping well or signs of suffering include crying, rapid shifts in position, and inability to focus. Performing a secondary analysis of data from the National Institutes of Health–funded Second Stage Labor Project, Bergstrom et al. reviewed videotapes of 23 women in the second stage of labor who eventually gave birth vaginally. The researchers observed four broad categories of behavior during the second stage: (1) no pain or distress, (2) low-level pain, (3) focused working, and (4) severe pain.[31] In all but the last category, women were able to maintain their sense of self-control. When pain was severe and women were not able to maintain a sense of self-control, an effective technique identified by the researchers was the "talking down" method. This method has three distinct steps: (1) calling out (getting the woman's attention), (2) positioning very close to the woman's face (en face position), and (3) talking in a low tone of voice so that the woman has to be quiet to hear. The researchers found that when the "talking down" method was used, women went back to a lower level of pain intensity that allowed them to maintain their sense of control.[31]

The Postpartum Effect of Traumatic Birth Experiences

Approximately 1% to 6% of women have symptoms consistent with the diagnosis of post-traumatic stress disorder (PTSD) in the immediate postpartum period following birth and approximately 2% continue to have symptoms of PTSD at 6 months postpartum.[32] More recently, a review of data from the Listening to Mothers II survey found the rate of PTSD after childbirth in women who gave birth in the United States to be approximately 9%.[33] Traumatic births are positively associated with PTSD, depression, and chronic pain. Several prepregnancy factors, such as preexisting anxiety disorders, are independent predictors of both traumatic birth and postpartum PTSD, which makes it difficult to determine the independent effect of labor experiences on these outcomes. Nonetheless, traumatic experiences during labor can have long-lasting negative effects. Consistent predictors of PTSD after birth include obstetric procedures, negative woman–staff interactions, and feelings of loss of control over the birth. This topic is reviewed in more detail in the *Mental Health Conditions* chapter.

General Principles for Assessment of Labor Pain and Provision of Labor Support

Care providers are not very accurate in assessment of a woman's discomfort or pain during labor. Studies that have compared provider assessments to women's assessments have found that the care provider's estimate of a woman's degree of pain is consistent with her estimate only approximately 50% of the time.[34] Approximately 25% of women have their pain overestimated by providers and 25% have their pain underestimated.[34] Multiparous women are more likely to have their pain underestimated by providers, and cultural differences between providers and women also increase the likelihood that pain will be underestimated.[35] In addition, one study found that midwives estimated women's pain fairly well when the woman reported mild or moderate pain but were likely to underestimate her pain when the woman reported experiencing severe pain.[36] Another study found that midwives' personal experiences influenced their estimation of a woman's degree of pain in labor.[37] Although these investigations entail small studies from different countries, they offer a cautionary tale. A woman's report of her experience is the most critical piece of data needed before offering any form of labor support.

The general support and comfort measures listed in **Table 27-1** summarize several general principles that form the foundation of supporting a woman during labor.

Table 27-1 General Support and Comfort Measures to Mitigate Pain During Labor

Basic Principles
Ensure privacy and prevent exposure
Use calm, quiet, purposeful communication
Physical Care Activities
Support relaxation to prevent fatigue
Help the woman maintain an empty bladder
Keep the perineum clean and dry
Offer oral liquids and lip moisteners for oral care
Change positions regularly and support extremities with pillows

Assurance of Privacy and Prevention of Exposure

Assurance of privacy and prevention of exposure are of particular importance in a hospital.[38] Ideas of modesty vary widely, often according to the woman's culture. Some women may not feel the need to be carefully draped to prevent exposure of external genitals, whereas other women will be uncomfortable exposing their body to anyone other than their partner and need as much draping as possible. Walburg et al. found that a limited number of personnel present at the time of exposure of external genitalia, a professional and kind attitude from providers, and

explanation of procedures may minimize feelings of embarrassment.[39]

Prevention of Exhaustion and Provision for Rest

Prevention of exhaustion and provision for rest between contractions are also important general support and comfort measures. Unnecessary exhaustion can be prevented by the following means:

- Have the woman use the most relaxed form of breathing possible. For example, panting is a physically taxing type of breathing, and should be used only when the goal is to help a woman not bear down. Controlled types of breathing, whether Lamaze or abdominal, can also be tiring if used in early, latent-phase labor before they are needed.
- Organize or plan procedures so that as many as possible are done sequentially in the shortest possible time (or number of intervals between contractions).
- Control the environment in accord with what is most restful to the individual woman. This includes controlling lighting, air, external noises, restriction of loud noises, and room arrangement.

Labor Pain Relief Methods Used in the United States

Laboring women can choose many methods of mitigating labor pain. **Table 27-2** presents findings from the second and third national Listening to Mothers surveys (LTM II and LTM III), which were conducted in 2006 and 2012, respectively.[33,40] These surveys interviewed women who gave birth in the previous year and provide a wealth of information about birth practices in the United States. Although epidural anesthesia is consistently rated as very helpful by women who use this technique to mitigate pain, other pharmacologic methods such as opioids are not rated as highly as some nonpharmacologic methods such as immersion in water.[33]

Table 27-2 **Methods of Pain Relief Used by Women in the United States**

Technique	Who Used This Technique 2012 (%)	Who Used This Technique 2006 (%)	It Was Helpful or Somewhat Helpful 2006 (%)	It Was Not Helpful 2006 (%)
Epidural or spinal analgesia	67	76	91	9
Breathing techniques	48	49	77	22

Nonpharmacologic Methods of Mitigating Pain

Some nonpharmacologic techniques for addressing labor pain are quite simple, whereas others require specialized training to perform. Techniques are reviewed here in the general order of the strength of evidence for their use, although in some cases comparisons are difficult due to different outcome measures, populations, and experimental designs used in the various studies. **Table 27-3** reviews the purported mechanisms of action for each of the following nonpharmacologic methods of labor pain relief.

Table 27-3 Mechanism of Action for Reducing Pain via Selected Nonpharmacologic Methods

Mechanism	Acupuncture/Acupressure	Aromatherapy	Breathing/Focus	Childbirth Education	Cold	Emotional Support	Heat	Hydrotherapy	Hypnosis	Intradermal Water Block	Massage/Touch	Movement and Positioning	Music/Audioanalgesia	Relaxation	TENS
Counter-irritation analgesia					✓					✓					✓
Increases endorphins	✓									✓			✓		✓
Provides stimuli from peripheral sensory receptors to inhibit pain awareness		✓			✓		✓	✓			✓		✓		✓
Increases joint mobility							✓	✓				✓			
Alters pressures within pelvis and on soft tissue								✓			✓	✓			
Improves energy flow along meridians crucial to labor progress and comfort	✓				✓*										
Decreases muscle tension	✓				✓		✓	✓	✓		✓			✓	
Alters nerve conduction velocity (slows pain transmission to central nervous system)					✓										
Decreases anxiety/fear, provides reassurance		✓	✓	✓		✓			✓		✓	✓	✓	✓	
Increases woman's sense of control, reducing pain perception			✓	✓		✓			✓			✓	✓	✓	✓

Continuous Labor Support/Doula Care

Multiple randomized controlled trials (RCTs) have shown that continuous labor support improves labor outcomes and has a positive influence on a woman's childbirth experience.[1,41,42] The word "continuous" refers to one support person who provides care to one woman and is physically present throughout labor. Doulas are trained nonmedical persons who provide continuous support for women in labor. The primary role of the doula is to provide continuous nonmedical care, including physical comfort, emotional support (reassurance and encouragement), information (nonmedical advice, anticipatory guidance), and facilitation of communication with healthcare providers. The word *doula* is derived from the Greek word *doule-*, meaning "one who serves." Doulas can provide many of the comfort measures during labor that are detailed in this chapter.

The effects of continuous labor support were evaluated in a systematic review of 27 RCTs that included 15,858 women from high- and middle-income countries.[41] This review revealed that continuous labor support during labor is associated with the following outcomes:

- Increased likelihood of spontaneous vaginal birth (relative risk [RR], 1.08; 95% confidence interval [CI], 1.04 to1.12)
- Lowered risk of cesarean births (RR, 0.75; 95% CI, 0.64 to 0.88)
- Shorter duration of labor (mean duration: –0.69 hour; 95% CI, –1.04 to –0.34)
- Reduced need for pharmacologic pain relief (RR, 0.90; 95% CI, 0.84 to 0.96)
- Less likely to have negative perceptions of childbirth experiences (RR, 0.69; 95% CI, 0.59 to 0.79).
- Reduced risk for low 5-minute Apgar scores (RR, 0.62; 95% CI, 0.46 to 0.85)

No significant differences were found in the use of synthetic oxytocin, newborn admission to a special care nursery, or breastfeeding at 1 to 2 months postpartum.[41]

The randomized trials found that continuous labor support is most effective when provided by doulas rather than by partners, other relatives, nurses, or midwives.[41-43] Nevertheless, smaller nonrandomized studies that employed midwifery students, nursing students, or trained relatives as doulas (following some training) have found positive birth outcomes as well.[44]

Hodnett[45] and Hofmeyr et al.[46] have described two theoretical explanations for the effectiveness of labor support. Both theories posit that labor support increases women's sense of being in control and self-efficacy. Hofmeyr et al. hypothesized that continuous companionship serves as a buffer to the stressors of labor, particularly in a hospital environment. Hodnett suggested labor support enhances fetal passage by promoting mobility and upright positions with improved comfort of the mother. Labor support may also reduce anxiety and fear, thereby decreasing the stress response.[46]

Intrapartum Hydrotherapy

Intrapartum hydrotherapy is the therapeutic use of water for pain relief and relaxation during childbirth. This practice may reduce a laboring woman's perception of pain by transmitting a therapeutic temperature into targeted tissues, changing the state of irritant receptors.[47,48] Intrapartum hydrotherapy can be provided in a shower, bathtub, pool, or any body of water available to a laboring mother.

Intrapartum immersion is the term used to signify hydrotherapy via submersion in a pool/tub that is deep enough for the water to cover the woman's abdomen. More specifically, intrapartum immersion can be divided into water labor and waterbirth. Water labor is defined as use of immersion during some portion of labor, but the actual birth does not take place while the woman is in the tub. Waterbirth is defined as birth of the neonate underwater.[47] Intrapartum immersion causes an increase in the woman's hydrostatic pressure and shift of extracellular fluid into her circulation, which provides a central blood volume bolus, increases cardiac output, and subsequently decreases circulating catecholamine levels. It is postulated that the improved blood flow results in improved uteroplacental perfusion and increased uterine

efficiency.[48,49]

The Cochrane Collaboration completed a systematic review of the effects of intrapartum immersion on labor and birth by examining 12 clinical trials involving more than 3400 women.[50] Water immersion during the first stage of labor was associated with a reduction in the use of epidural/spinal analgesia (RR, 0.90; 95% CI, 0.82–0.99) and a shorter first stage of labor (mean difference [MD]: –32.4 minutes; 95% CI, –58.67 minutes to –6.13 minutes) and no difference in the risk for chorioamnionitis (RR, 0.99; 95% CI, 0.50–1.96). There were no differences in the use of oxytocin, operative vaginal birth, or adverse neonatal outcomes.[50] In addition, intrapartum immersion has been associated with increased mobility, lower episiotomy rates, decreased likelihood of third- and fourth-degree perineal lacerations, and increased patient satisfaction, although the studies yielding these findings were small and the data not yet considered conclusive.[51]

Timing of intrapartum immersion warrants consideration. Immersion is recommended after active labor is established.[52] Immersion in water during latent labor may result in longer labors that can require pharmacologic intervention and oxytocin augmentation.[50,52] The American College of Nurse-Midwives has developed a model template for hydrotherapy in labor that describes eligibility for this therapy, techniques, and recommended policies.[52]

Acupressure/Acupuncture

Traditional Chinese medicine recognizes acupuncture as a means to correct imbalances in vital energy known as Qi (pronounced “chee”). Acupuncture involves the needling of specific points along meridian pathways, thereby promoting the circulation of blood and stimulating the flow of Qi to promote harmony of yin and yang. Acupuncture is thought to stimulate the body to produce endogenous opioids (endorphins), and to secrete neurotransmitters that maintain the normal physiology and provide comfort. Minimizing the stress response may be another mechanism of action underlying acupuncture’s efficacy.[53–55] Acupuncture should be performed only by a qualified practitioner, and most states require a diploma from the National Certification Commission for Acupuncture and Oriental Medicine for licensing to practice acupuncture.

An alternative to acupuncture is acupressure, whereby firm steady pressure is applied to acupoints with a thumb or finger instead of needles (**Figure 27-3**). Although no license is required to administer acupressure, training and education in these techniques are recommended.[55] Commonly cited acupoints utilized to help difficult or slowed labor progress and/or labor pain are Sanyinjiao/spleen 6 (SP6), Hoku or Hegu/large intestine 4 (LI4), bladder 67 (BL67), and gallbladder 21 (GB21).[53] Midwives with appropriate training, in combination with clinical judgment and practice, can incorporate acupressure into care for a laboring woman.

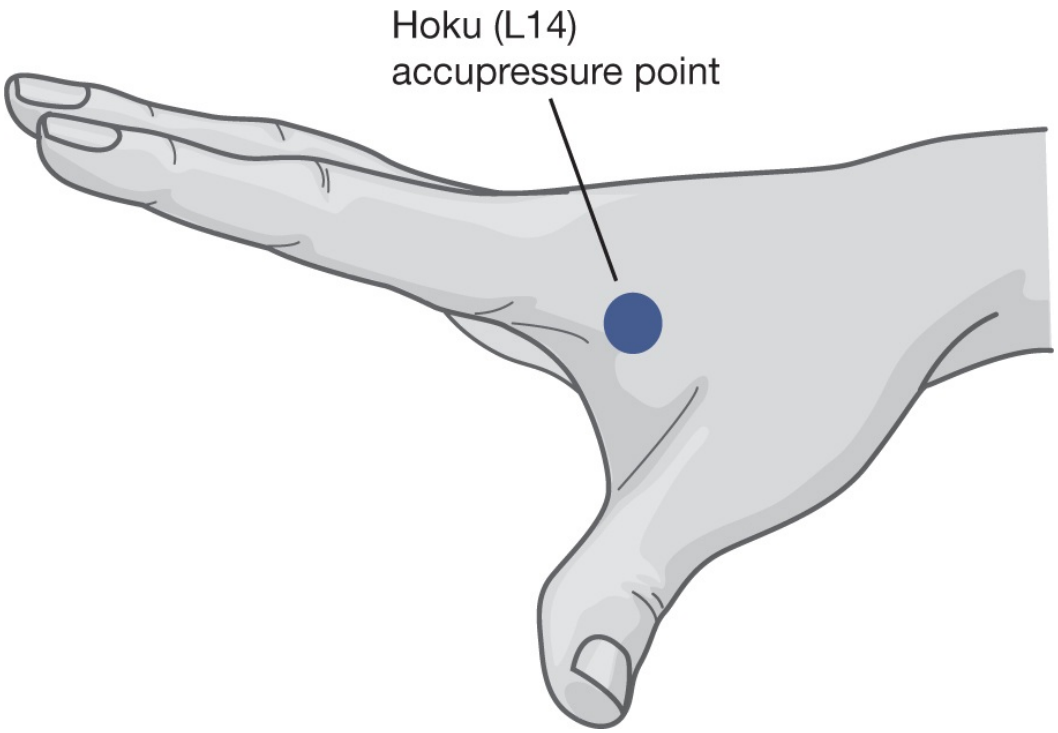

Figure 27-3 Correct positioning of small ice bag for massage stimulation of LI4.

Reproduced with permission from Waters BL, Raisler J. Ice massage for the reduction of labor pain. *J Midwifery Womens Health*. 2003;48:317-321.[55]

Although there is some heterogeneity in the trials of acupuncture or acupressure, results consistently show that these techniques reduce labor pain when compared to no intervention or placebo acupuncture/acupressure.[53-55] A theoretical risk of acupuncture is possible infection if sterile needles are not used, although licensed practitioners would be expected to use sterile needles, usually disposable.

Acupuncture/acupressure has also been evaluated for effectiveness in improving uterine contractility and labor induction. These studies have found a modest increase in cervical ripening (as measured by a Bishop's score) in women exposed to acupuncture, but have not adequately assessed other clinically important variables such as time to onset of labor. Nonetheless, contraindications to use of acupressure during labor may include fetal intolerance of labor, uterine tachysystole, tetanic contractions, preterm gestation, or any other clinical condition in which uterine contractions are contraindicated (e.g., placenta previa).[53]

The most current Cochrane meta-analysis of 14 RCTs of acupressure/acupuncture for pain relief in labor[54] identified the following results:

- Less intense pain with acupuncture compared with no intervention (standardized mean difference [SMD], –1.00; 95% CI, –1.33 to –0.67)
- Increased satisfaction with pain relief compared with placebo control (RR, 2.38; 95% CI, 1.78 to 3.19)
- Reduced use of pharmacologic analgesia when acupuncture is used compared with placebo, and compared with standard care (RR, 0.72; 95% CI, 0.58 to 0.88)
- Fewer operative vaginal births when acupuncture is used compared with standard care

(RR, 0.67; 95% CI, 0.46 to 0.98)
- Reduced pain intensity with acupressure compared with a placebo control (SMD, –0.55; 95% CI, –0.92 to –0.19)

Sterile Water Injections

Sterile water injections, or sterile water papules, involve intradermal injections of sterile water administered in four places in the lower lumbosacral area of the back to form papules. The therapeutic goal is to relieve back pain in labor. Since cutaneous afferent nerves from the lower back converge to the dorsal horns in the same segments, pain may be referred to the lower back. It is speculated that sterile water injections work by the gate-control theory, whereby stimulation of specific areas can relieve this referred pain. The mechanism has been described as counter-irritation, a process by which localized pain felt in one part of the body may be relieved by irritating the skin in an adjacent part of the body. Sterile water injections are thought to cause distension in the skin, which stimulates nociceptors and mechanoreceptors, thereby providing noxious stimulation of nociceptors. This effect results in a subsequent release of endorphins and stimulation of A-delta fibers, which overwhelm the visceral sensations transmitted to the brain by the slower C fibers.[56]

A 25-gauge needle containing 0.6 to 1.0 mL of sterile water, not saline, is used to inject 0.1 to 0.3 mL of sterile water intradermally at each of the four sites adjacent to the Michaelis rhomboid, where referred pain from uterine contractions is usually felt. Women experience an intense stinging sensation for approximately 30 to 90 seconds during (and immediately following) the injection and then relief from their back pain for approximately 45 minutes to 3 hours.[57] **Appendix 27A** reviews the procedure of sterile water papule injection.

Sterile water injections have been found to significantly reduce severe back pain. However, the overall need for additional pain medication is not reduced, presumably because the effect dissipates before the labor is concluded. When Derry et al. performed a meta-analysis of seven RCTs, they concluded that the evidence is insufficient to recommend this practice, due to perceived limitations of the studies involved.[56] In contrast, the meta-analysis of eight RCTs performed by Hutton et al. found sterile water papules were associated with a significant reduction in Visual Analog Scores (VAS) for pain in women and a decreased rate of cesarean births in the sterile water group (4.6%) versus the comparison groups (9.9%) (RR, 0.51; 95% CI, 0.30–0.87).[55]

Position Changes/Ambulation

When women are not confined to bed or acculturated to believe they should be in bed during labor, they frequently change positions throughout the intrapartum course, gradually limiting the number of position changes as labor progresses, and with the incidence of ambulation and sitting diminishing during active labor.[58] Upright positions are likely to improve maternal comfort during labor via several mechanisms. First, pelvic dimensions are wider in upright or squatting positions, and maternal movement is thought to facilitate optimal fetal positioning (**Figure 27-4**).[59,60] Second, optimal feto-pelvic relationships may decrease the pain associated

with malpositions.[1] Third, uterine contractility may be improved with upright positions, which could shorten the duration of labor.[59] Finally, upright positions may enhance a woman's sense of control and self-efficacy, which may make coping with labor easier.

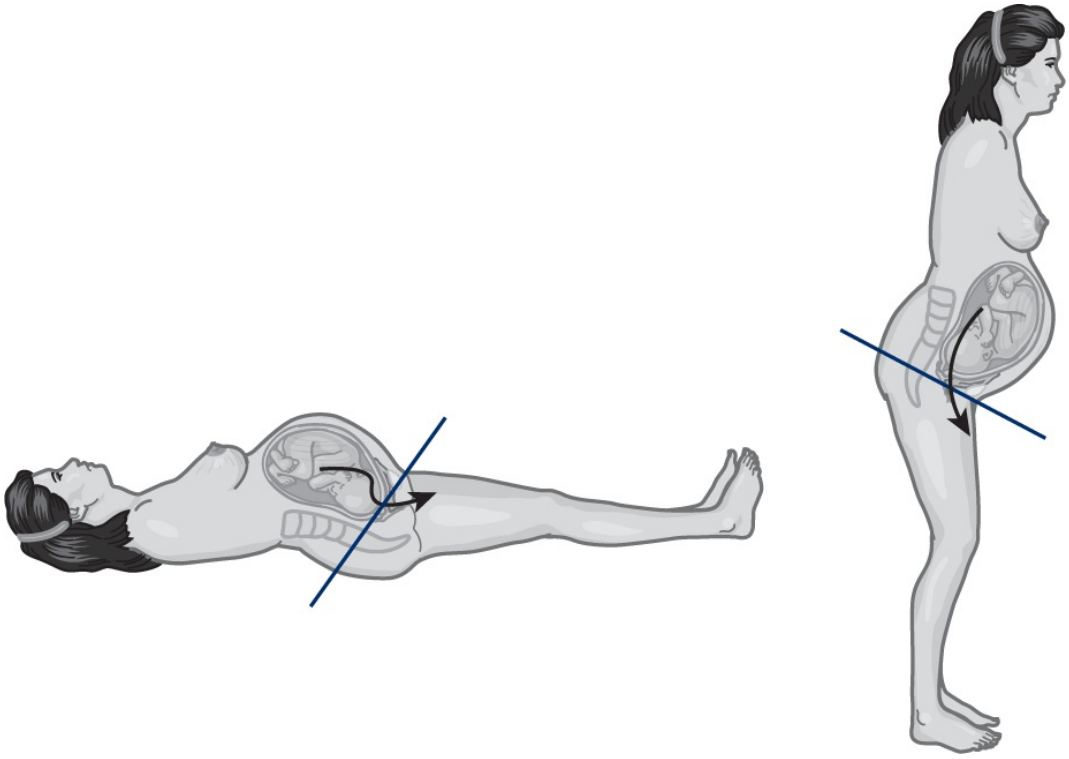

Figure 27-4 When a woman is supine or standing, the plane of the pelvic brim is not perpendicular to the spinal axis. Spinal flexion reduces the lumbar curve, providing the fetus with a straighter path through the birth canal. Note that the S-curve is simplified to a C-curve, allowing pressure on the fundus by the upper trunk.

Reproduced with permission from Fenwick L, Simkin P. Maternal positioning to prevent or alleviate dystocia in labor. *Clin Obstet Gynecol.* 1987;30(1):83-89.[59]

Atwood's 1976 article remains the key reference defining the different positions women may assume during labor or birth.[60] Atwood described maternal positions for labor or birth as either standing or neutral. The four standing positions are standing, sitting, kneeling, and squatting. Each of these positions places the maternal pelvis perpendicular to the spine and vertical plane of the uterus. Neutral positions include supine, lithotomy, lateral, prone, Sims, and semi-recumbent. In each of these positions, the woman's weight is primarily supported by her back, but by changing the position of her legs, she can alter the feto-pelvic relationship. The reader is referred to the articles listed in the Resources section at the end of this chapter for detailed descriptions of maternal positions.

Lawrence et al. conducted a Cochrane meta-analysis (n = 5218; 25 RCTs) of studies involving women in the first stage of labor who labored in an upright position as opposed to recumbent position. Upright positions were associated with a shorter labor by approximately 1 hour and 22 minutes (average MD, –1.36; 95% CI, –2.22 to –0.51).[61] Women who were upright were more likely to experience a vaginal birth, and were less likely to have a cesarean birth, epidural analgesia, or admission of their neonate to the neonatal intensive care unit

(NICU). There were no significant differences between groups in the duration of the second stage of labor, nor in other outcomes related to the well-being of women and newborns between the groups who were upright versus those who were recumbent during the first stage of labor.[61]

A Cochrane meta-analysis of studies involving women who did not have epidural analgesia and who assumed upright positions in the second stage of labor (n = 9015; 32 RCTs) revealed fewer operative vaginal deliveries, fewer abnormal fetal heart rate patterns, fewer episiotomies but no change in cesarean section rates, and an increased risk of an estimated blood loss of more than 500 mL.[62] The difference in estimated blood loss may be related to differences in estimating rather than differences in actual blood lost. By comparison, another Cochrane meta-analysis assessed studies involving women who utilized epidural analgesia in the second stage of labor (n = 879; 5 RCTs) and revealed no statistically significant difference between upright and recumbent positions on mode of birth, duration of the second stage of labor, trauma to the birth canal requiring suturing, operative birth for fetal distress, low cord pH, or admission to a NICU.[63] Although this body of work is limited by heterogeneity in study designs and small numbers of participants, the findings suggest that upright positions may benefit women who do not receive an epidural, but that preserving the perineum may be technically more difficult at the time of birth.

Contraindications to ambulation and movement are rare but may include ruptured membranes with high fetal station with the presenting part not well applied to the cervix, or any other condition for which bed rest is necessary.

Birthing Balls

A physiotherapy ball is a 65-centimeter ball that can be adjusted for individual “fit” by adding or letting out air so that the ball is firm but gives to the touch, and rolls easily, with the woman’s legs being bent at a 90-degree angle when sitting on the ball. Women sit on the birthing ball with their feet approximately 2 feet apart and flat on the floor. This puts the woman in an upright position from which she can rotate her hips in ways that relieve back pain and encourage fetal descent. A woman can also sit on the ball and lean forward, or can use the birthing ball to lean against either in a kneeling (ball on floor) or standing (ball on a bed or table) position (**Figure 27-5**). These positions support the woman’s body and provide a position in which she can rest. They also align the long axis of the uterus and the fetus with the mother’s pelvis and facilitate occiput anterior positions. The hypothesized mechanism of action with regard to mitigating pain is similar to the purported mechanisms for upright positions.

Figure 27-5 Positions for laboring women using a birthing ball.

Research on the effects of birthing balls on pain is limited to a few RCTs with a small number of subjects. A meta-analysis (n = 220; 4 RCTs) found that birthing balls provided statistically significant improvements in labor pain when compared to women who did not use such a ball during labor (pooled MD,–0.92; 95% CI, –1.25 to –0.56; p > 0.0000005).[64]

Another type of birthing ball is known as the "peanut ball." As the name implies, it is shaped like a peanut shell, with the middle circumference being smaller than the circumference at the ends. The peanut ball can be placed between a woman's legs or under her legs while in the bed. This positioning widens the diameter of the pelvic outlet, thereby allowing more room for fetal descent or repositioning of the fetus.

One RCT evaluated the impact of the peanut ball on duration of the first and second stages of labor in women who were scheduled for elective induction of labor at 39 weeks' gestation or more and who were planning epidural pain management. The researchers found that use of a peanut ball reduced the duration of the first stage of labor for primiparous women (P = 0.018), but did not lead to any significant difference (reduction) in the length of first-stage labor for multiparous women (P = 0.057). Because the authors did not report actual differences in time, it is not clear how clinically significant these findings are. Use of the peanut ball did not alter the duration of second-stage labor in either group in women undergoing induction of labor.[65]

A second RCT evaluated use of the peanut ball in women who received epidural analgesia, compared to standard care with epidural analgesia and no peanut ball. The researchers found that the peanut ball decreased the duration of labor (first stage, 29 minutes; P =.053 and second stage, 11 minutes; P <.001), and decreased the incidence of cesarean deliveries (10.3% versus 21.1%, respectively, P =.011).[66]

Although these studies suggest that both the birthing ball and the peanut ball have positive impacts on labor outcomes, more research is needed to determine the evidence of effectiveness of these techniques.

Touch and Massage

Massage, which refers to purposeful manipulation of soft tissues for therapeutic purposes, is

widely utilized during labor. Massage is applied to a specific body part, such as the hands, feet, scalp, shoulders, or back. Touch can be firm or light and repeated in a specific pattern (e.g., effleurage), or it can consist of still pressure or kneading. A specific form of touch often used to aid women with back pain is firm, steady counterpressure applied to the center of the sacroiliac portion of the back during a contraction. With counterpressure, the amount of pressure increases during the contraction and decreases as the contraction wanes. Massage can be performed with use of the hands or with massage devices, and with or without lotions, oils, and powders.[67]

Touching and massage will be effective only if the woman is comfortable being touched, as cultural views of touch appropriateness vary. This technique's probable mechanism of action in reducing pain is an increase in the endogenous release of endorphins and oxytocin. A meta-analysis (n = 225, 6 RCTs) evaluating massage and touch demonstrated a statistically significant reduction in pain intensity during the first stage of labor (SMD, –0.82; 95% CI: –1.17 to –0.47).[68] A subsequent trial that compared a specific form of massage/counterpressure over the sacrum and lower back, applied for 30 minutes at three different times during labor, found a significant decrease in reported lower back pain and increased satisfaction with the birth experience among the women in the massage group.[69]

While these studies demonstrate that massage may have a positive impact on laboring women, research into massage or touch has examined many different methods. Thus, it is not clear which massage or touch techniques are the most helpful.

Hypnosis

Hypnosis employs specific mind–body techniques that are used to induce profound relaxation. The goal of using hypnosis during labor is to help the woman achieve a state of deep relaxation within a state of focused attention, thereby reducing perception of external stimuli and increasing receptivity to specific suggestions by the hypnotist. The ability to experience hypnosis varies, but hypnotic susceptibility has generally been found to increase during pregnancy.[70] Hypnosis can involve a hypnotist or can be self-administered as self-hypnosis, whereby women can be trained to guide themselves through a hypnotic state.

Studies evaluating hypnosis during childbirth have yielded conflicting findings to date. Women who practice self-hypnotic techniques during the prenatal period may reduce their need for analgesia during labor and may have shorter labors when compared to women who use other childbirth preparation techniques.[71-73] The beneficial effects of introducing hypnosis for the first time to women in labor, however, have not been confirmed.[73] A Cochrane meta-analysis (n = 2954; 9 RCTs) reported no difference between women in the hypnosis group and those in the control groups in regard to sense of coping with labor, mode of birth, or satisfaction with pain relief.[72] Further research is needed to assess the value of hypnosis as a pain management technique during labor and birth. Notably, this technique is contraindicated for women with a history of psychosis or severe mental health condition.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) units are handheld, battery-operated devices that use low-voltage electric current to reduce pain in labor. TENS has been used in childbirth to help reduce labor pain since the 1970s. With this technique, stimulation electrode pads are placed on the skin over the low back on the paraspinal muscles, on either side of the spine, at the vertebral positions of T10 and S2, which correspond to the nerve pathways through which the pain signal from the uterus enters the spinal cord. With the pads in place, the TENS unit emits low-voltage impulses. The frequency and intensity of the nerve stimulation can be controlled by the woman. The low-voltage sensation is not painful, but rather is often experienced as a tingling or buzzing feeling at the site of the electrodes.[74]

The mechanism of action of TENS is based on the gate-control theory of pain, as well as a theory that painful stimulation results in the release of neurotransmitters. TENS units are believed to induce the release of endorphins. Endorphins' primary function is to inhibit the transmission of pain signs, similar to the effect produced by opioids.

The effectiveness of TENS for treating labor pain remains unclear. A Cochrane meta-analysis (n = 1466; 17 trials) of women who used TENS units in labor was unable to find consistent evidence that TENS units have any impact on interventions or labor outcomes.[74]

Application of Heat and Cold

Heat and cold therapies are simple, safe, and inexpensive nonpharmacologic pain relief methods. Application of cold for minimizing pain is based on gate-control theory; cold therapy effectively blocks neural transmission via sensory fibers, thereby elevating the pain threshold. Cold therapy can also lead to a reduction in pain by inducing numbness, decreasing muscle tension, and offering distraction. Heat therapy, in addition to the same mechanisms of action related to application of cold, stimulates heat receptors in the derma and deeper tissues, which purportedly leads to closure of the gate, thereby subsequently impeding neural impulses from reaching the brain. Topical application of heat increases circulation to the area, thereby combating pain from tissue anoxia.

Most studies of heat or cold therapy published to date have been small and hindered by differing methodologies. In general, though, the studies published have found some benefits to heat or cold therapy with regard to decreasing labor pain.[75,76]

Caution is warranted when using heat or cold packs, as burns can be caused by using too high a temperature or by putting heat on an area to which creams, oils, or ointments have already been applied. Using a microwave to heat hot packs can be particularly dangerous, as microwaves heat elements at different temperatures; thus, the hot pack can be differentially heated in various places within the pack. It is recommended that at least one layer of cloth be placed between the woman's skin and hot or cold pack, and that the pack be tested on an arm or other portion of skin by someone other than the laboring woman before being placed against her skin. Use of heat or cold should also be avoided in the dermatomes anesthetized by an epidural due to concerns that women may not be able to perceive if the temperature is too hot or cold.

Fever is a contraindication to using heat. Contraindications to use of cold include sickle cell anemia, cold hypersensitivities, cryoglobulinemia, Raynaud's phenomenon, and cultural

proscriptions.[1]

Breathing and Relaxation Exercises

Breathing and relaxation exercises can help a woman in labor by decreasing her anxiety and fear, and by increasing her sense of control or self-efficacy.[1] Use of these techniques is directly related to childbirth satisfaction, and they are essential components of most childbirth education programs.[1] Approximately 48% of women in the United States use breathing and relaxation methods during labor, and 77% of those women report that these techniques were either somewhat helpful or very helpful.[33] Practice may play a large role in how well these techniques work. Specific breathing techniques work best in early labor but do not help women cope with labor if introduced for the first time during active labor.

Breathing techniques that focus on progressive relaxation may be more effective than those that focus on specific types of breathing patterns. Progressive relaxation can be practiced prenatally, so that the woman can quickly relax between contractions during labor. A knowledgeable caregiver can also teach some relaxation techniques during labor.

Audioanalgesia

Audioanalgesia was originally defined as a technique whereby auditory stimulation (e.g., music, white noise, and/or environmental sounds) is provided to create distraction and decrease perception of pain by activating regions of the brain that are responsible for mediating reward and anxiolytic effects. These areas of the central nervous system overlap with regions of the brain involved with analgesia.[77]

Audioanalgesia is common in dental practice, but research on its effectiveness during labor has yielded mixed results. Some small studies have found audioanalgesia may be beneficial during latent and active labor and may positively affect pain perception via elevation of mood and an increase in pain tolerance.[78,79] However, Cochrane systematic reviews of these studies have found insufficient evidence to support the effectiveness of audioanalgesia for labor pain management.[1,80] The wide variation in personal choices may account for the lack of sufficient evidence to make recommendations for the use of music for labor pain management.

Aromatherapy

Aromatherapy refers to the medicinal or therapeutic use of essential oils absorbed through the skin or olfactory system. Essential oils are derived from plants and are utilized to enhance physical and psychological well-being. Clinical aromatherapy is the controlled use of pure essential oils to achieve a desired measurable outcome based on the chemical constituents of an oil. Every essential oil comprises a variety of chemical constituents (e.g., esters, alcohols, phenols, aldehydes, ketones, terpenes, sesquiterpenes) that may have therapeutic effects.

Research into the effectiveness of aromatherapy in reducing pain during childbirth has yielded inconsistent results. A Cochrane review of two RCTs (n = 535 women) found no difference between groups in terms of pain intensity, assisted vaginal birth, cesarean section,

use of pharmacologic pain relief, spontaneous vaginal birth, duration of labor, or augmentation in women using clary sage, chamomile, lavender, ginger oil, or lemongrass essential oils compared to women receiving standard care.[81] In contrast, a combined systematic review and meta-analysis identified a significant positive effect of aromatherapy (compared to placebo or usual treatment controls) in reducing pain reported on a visual analogue scale. This study found that aromatherapy was effective in treating nociceptive, acute, postoperative, and obstetric and gynecologic pain ($P < 0.0001$).[82]

Essential oils are generally considered safe for use in childbirth. Midwives wanting to integrate essential oils into their clinical practice should seek additional training on the clinical application of essential oils during labor and birth prior to their utilization in practice. Midwives using essential oils in clinical practice need to understand relevant essential oil physiology, chemistry, and pharmacology, and must know how to blend and administer the oils safely and appropriately.

Pharmacologic Methods of Mitigating Labor Pain

Women can be knowledgeable and prepared; want active participation in the natural, normal process of childbearing; and yet still desire to use medication to mitigate labor pain. Medications may be used during labor to relieve pain, decrease anxiety and apprehension, provide sedation, or control nausea and vomiting. All medications used by laboring women should be evaluated for (1) effectiveness, (2) safety for the laboring woman, (3) safety for the fetus and newborn, and (4) effects on labor progress. Prior to administering any medication during labor, a careful assessment of the woman's vital signs, fetal heart rate pattern, other medications being used, and stage of labor is made and documented in the health record. The choice of medication will be tailored to the degree of pain relief the woman wants to attain and what is safe for her stage of labor.

Two types of pain relief drugs exist: analgesics and anesthetics. Analgesia is the relief of pain without total loss of feeling or muscle movement. Analgesics do not always stop pain completely, but rather tend to lessen pain. Anesthesia refers to blockage of all sensation, including pain. In most cases, analgesia is offered to women in labor or after surgery or birth, whereas anesthesia is used during cesarean birth. Pharmacologic management can also be classified as either systemic or neuraxial (e.g., epidural, spinal). Drugs placed in the epidural space (neuraxial) can induce *epidural analgesia* (reduces but does not obliterate all sensation) or *epidural anesthesia* (all sensation and motor ability is inhibited). Epidural analgesia is used to treat labor pain and epidural anesthesia is used for surgery when all sensation needs to be blocked.

Systemic Analgesic Medications

Systemic medications were the mainstay agents used to assist laboring women for most of the first half of the twentieth century. These medications are utilized by women who prefer less physically invasive pain management techniques; they can also be administered to women for whom regional neuraxial techniques are contraindicated or unavailable. Systemic medications are given by intravenous, intramuscular, or inhalation routes. The most popular of these agents are opioids, mixed opioid agonist–antagonists, sedatives, and hypnotics. Systemic analgesics act on the entire nervous system, rather than a specified area. The primary drawback of these drugs is that they adversely affect the fetus to varying degrees.

Sedatives and Hypnotics

Various sedatives and hypnotic agents are used during childbirth to induce sedation, decrease anxiety, and decrease pain. Non-opioid agents commonly utilized in labor are listed in **Table 27-4**. These drugs are usually administered in combination with opioids to decrease nausea and vomiting, both of which are often side effects of opioids. In clinical practice, they are typically used to induce sedation and stop contractions for women who are experiencing a prolonged latent phase of labor.

Table 27-4 **Sedatives and Hypnotics for Management of Pain During Latent Labor**

Generic (Brand)	Drug Class	Dose/Route	Onset	Duration	Comments
Promethazine (Phenergan)	Phenothiazine	25–75 mg IV/IM	10–20 minutes	3–4 hours	Commonly used with opioids to mitigate nausea and vomiting; induces sedation; may produce hypotension
Hydroxyzine (Vistaril)	Antihistamine	25–50 mg IM	30 minutes	4 hours	Commonly used with opioids to mitigate nausea and vomiting; induces sedation; not to be used intravenously; painful for IM injection
Diphenhydramine (Benadryl)	Anticholinergic antiemetic	10–50 mg IV	5–10 minutes	6–8 hours	Commonly used with opioids to mitigate nausea and vomiting; induces sedation; maximum daily dose 400 mg
Prochlorperazine (Compazine)	Dopamine receptor antagonist	5–10 mg IV/IM	5–10 minutes	3–4 hours	Commonly used with opioids to mitigate nausea and vomiting; induces sedation

Abbreviations: IM, intramuscular; IV, intravenous.

Sedatives such as promethazine (Phenergan) and hydroxyzine (Vistaril) do not induce sufficient analgesia when used alone, but are often used in combination with opioids in an attempt to potentiate the opioid effect.[83] Controversy exists regarding the effect of sedatives on labor pain. Promethazine, for example, can produce significant sedation, which results in the woman appearing as though she is in less pain but may actually just prevent her from communicating her level of pain. Thus, although anecdotally the combination of an opiate with a sedative results in pain relief potentiation, a potentiation effect has not been definitely proven.

Opioids

Women desiring pain relief during labor may be offered opioids when neuraxial analgesia is contraindicated or unavailable. The opioids most commonly used to treat labor pain in the United States are listed in **Table 27-5**.[83] These drugs are readily available, easy to administer, fast acting, and less invasive than neuraxial analgesia.

Table 27-5 **Pharmacokinetic Profiles of Selected Opioids**

Drug (Brand)	Usual Dose	Onset/Peak Effect	Duration of Action/Elimination Half-Life	Clinical Implications
Butorphanol (Stadol)	IV: 1–2 mg every 3–4 hr IM: 1–2 mg every 3–4 hr	IV: 2–3/5–10 min IM: 10–20/30–60 min	IV or IM: 4–6 hr Half-life: 2.5–3.5 hr in adults	Kappa agonist and sigma agonist; may precipitate acute withdrawal syndrome in an opiate-dependent mother and baby Maternal ceiling effect on respiratory depression and analgesia Fetal transient pseudo-sinusoidal FHR pattern
Fentanyl (Sublimaze)	IV: 50–100 mcg/hr IM: 50–100 mcg/hr	IV: 1 min/5 min IM: 7–15 min/ 10–20 min PCA: 10–25 mg with a lockout of 3–12 min and a set maximum 1-hr dose	IV: 30–60 min IM: 1–2 hr Half-life: Adults: 3–4 hr Neonates: 75–440 min	Pure agonist at mu receptors,[a] kappa receptors,[b] sigma receptors,[c] and delta receptors[d] Short-acting; less effective than morphine or Demerol, but very few side effects noted With higher doses or prolonged infusions, fentanyl becomes longer acting Transient decreased FHR variability or pseudo-sinusoidal pattern Maximum cumulative labor dose is usually 500–600 mcg when given IV or IM
Meperidine or pethidine (Demerol)	IV: 25–50 mg every 1–2 hr IM: 50–100 mg every 2–4 hr	IV: 5 min/5 min IM: 10–20 min/ 30–60 min	IV: 2–4 hr IM: 2–5 hr Half-life: Maternal: 3–7 hr Neonates: 18–23 hr	Fetal exposure is highest 1–4 hr after maternal administration with associated neonatal respiratory depression; highest 2–3 hr after administration May temporarily decrease FHR variability Normeperidine is an active metabolite of meperidine that has a half-life of 21 hours in the woman and 63 hours in the neonate; normeperidine accumulates in maternal plasma after multiple doses and adversely affects newborn neuroadaptive scores and breastfeeding behaviors

Morphine	IV: 2–5 mg every 4 hr IM:10 mg every 4 hr	IV: 5 min/0.5–1 min IM: 10–20 min/20 min	IV: 1–3 hr IM: 3–5 hr Half-life: Maternal: 43 min Neonates: 6.5 ± 2.8 hr	Pure agonist at mu[a] and kappa[b] receptors Faster absorption when administered in deltoid muscle compared to gluteal muscle Use lower doses for women with impaired ventilation or asthma Side effects include pruritus, nausea and vomiting, and urinary retention; has an active metabolite that can cause respiratory depression as the dose accumulates[e] The active metabolite of morphine is morphine-6-glucuronide; this metabolite has a half life of 2–4 hours in the woman and 13.9 hours in the neonate, and produces greater analgesic effect than morphine; can accumulate with repeated doses
Nalbuphine (Nubain)	IV or IM: 10 mg every 3 hr	IV: 2–3 min/30 min IM: <15 min/30–60 min	IV: 2–4 hr IM: 4–6 hr Half-life: 2–5 hr in adults	Mu antagonist and kappa partial agonist Maternal ceiling effect on respiratory depression and analgesia at 30 mg May precipitate acute withdrawal syndrome in an opiate-dependent mother and baby
Remifentanil (Ultiva)	PCA administration with varying dosing	1–1.5 min/2 min	20 min Half-life: 9 min in adults	Potent maternal respiratory depressant; this agent's use in clinical practice is controversial Dose at beginning of uterine contraction to maximize peak effect during contraction

Abbreviations: FHR, fetal heart rate; IM, intramuscular; IV, intravenous; PCA, patient-controlled analgesia.

[a] Mu-receptor stimulation causes slowed gastrointestinal motility, nausea and vomiting, respiratory depression, spinal and supraspinal analgesia, sedation, urinary retention, pruritus, and euphoria.
[b] Kappa-receptor stimulation causes sedation, spinal analgesia, and miosis.
[c] Sigma-receptor stimulation causes dysphoria, hallucination, and mydriasis.
[d] Delta-receptor stimulation causes spinal and supraspinal analgesia.
[e] Morphine causes more pruritus and urinary retention when administered via epidural or intrathecally. Maternal respiratory depression can be a late effect in epidurally administered morphine sulfate secondary to slow uptake into the central nervous system.

Based on Anderson D. A review of systemic opioids commonly used for labor pain relief [erratum, *J Midwifery Womens Health*. 2011;56(4):411-418]. *J Midwifery Womens Health*. 2011;56(3):222-239.[83]

Opioids can be administered by the intramuscular, intravenous, or subcutaneous routes, or via a patient-controlled analgesia (PCA) pump. The intramuscular and subcutaneous routes involve potentially painful injections, delayed onset of action, and variable absorption, which can lead to unpredictable plasma levels. Intravenous injections have a faster onset, with less variability of peak concentrations. PCA pumps allow women to self-administer a programmed dose of the opioid intravenously with minimum intervals between doses. PCA pumps provide rapid onset of action, better control of pain relative to side effects compared to parenteral

opioid injection, and a sense of control for the woman.[84] In general, PCA administration of fentanyl in labor may provide the best combination of effective pain relief with low risk of side effects or neonatal effects. A fentanyl PCA regimen of 10–25 mcg every 5–10 minutes has been found to provide effective analgesia with fewer side effects than morphine, meperidine, or alfentanil PCA regimens.[84-87]

Historically, meperidine (Demerol) was the most frequently used opioid for treating labor pain worldwide; now, however, it has largely fallen out of favor in the United States. Meperidine does not provide strong pain relief and when women who have used it are asked, more than half report that it was ineffective.[88] Meperidine has a long half-life and active metabolites, so its use is associated with a high risk of neonatal respiratory depression.

Morphine and fentanyl (Sublimaze) are the two mu-opioid receptor agonists most frequently used for labor pain in the United States. Morphine is most often used to treat prolonged latent labor, as it decreases uterine activity prior to active labor but does not inhibit active labor contractions.[89] A common combination for treating prolonged latent-phase labor is 10 mg of morphine sulfate and 50 mg of promethazine (Phenergan) given intramuscularly. Because morphine has active metabolites that can cause maternal or newborn depression, it is generally contraindicated for use in the later stages of labor and is replaced by fentanyl if an opioid is considered for a woman in active labor.

Fentanyl has a short half-life, so it has not been associated with neonatal respiratory depression. Due to its short duration of action it is well suited for administration toward the end of the first stage of labor or for intravenous PCA administration when neuraxial analgesia is contraindicated or unavailable.

Remifentanil is the shortest-acting opioid available. It is used only in PCA infusions, and primarily for women who cannot use neuraxial analgesia for some reason. Remifentanil does not have active metabolites, and is associated with fewer side effects or neonatal effects when compared to other opioids. Because it can cause significant maternal respiratory depression, its use in laboring women remains controversial, and research on this indication continues.[90]

Butorphanol (Stadol) and nalbuphine (Nubain) are kappa-receptor agonists and mu-receptor antagonists. They have a longer half-life and, anecdotally, have been reported to provide better pain relief than fentanyl. Both are contraindicated for use by women who have a history of drug abuse or addiction because the mu-receptor antagonist effect can elicit withdrawal symptoms.

One of the first systematic reviews of parenteral opioids found that this therapy provides limited pain relief and leads to moderate satisfaction with analgesia, with two-thirds of women reporting moderate or severe pain and/or poor or moderate pain relief one to two hours after parenteral opioid administration.[88] Furthermore, comparative effectiveness studies have not found one opioid to be better than another in mitigating labor pain. Research has also demonstrated there is no apparent effect on labor progress if an opioid is administered during the active phase of labor. Some women feel an unwelcome loss of control after being given an opiate, although this experience is not common. The more common side effects of such therapy include euphoria and sedation. Potential side effects include nausea and vomiting and urinary retention. Adverse effects include respiratory depression, but this outcome is rare with the doses and methods of administration typically used to treat labor pain. All of the opioids have

some drug–drug interactions that can be clinically significant in some populations.[83]

All opioids are lipid soluble, so they readily cross the placenta and concentrate in the fetus. Fetal effects include decreased fetal heart rate variability and neonatal respiratory depression; in addition, there is controversy about whether opioids adversely affect early neurobehavioral scores in the newborn.[91] Naloxone (Narcan) is the opiate/opioid antagonist given to the newborn to reverse the respiratory depression effect of opiates administered to the woman during labor. Naloxone must be available whenever opiate and opioid medications are used. The dose is 0.01 mg/kg of body weight, and the effect becomes evident 2 to 5 minutes after an intramuscular injection and 1 to 2 minutes after an intravenous injection. The peak effect occurs in 5 to 15 minutes.[91]

Inhaled Analgesia: 50:50 Nitrous Oxide/Oxygen

Nitrous oxide inhalation analgesia for labor pain management consists of 50% nitrous oxide and 50% oxygen (N_2O/O_2). This therapy has only recently been reintroduced in the United States, but it has been in widespread use in Northern Europe and Canada for decades. This gaseous agent is widely considered both safe and effective.[86,92-101] Nitrous oxide is a weak anesthetic when used in high doses and has analgesic and anxiolytic effects at low doses.[92] N_2O/O_2 can be used as the sole analgesic, or it can be administered in combination with opioids or opioid agonist–antagonists. The gas mixture is blended in a machine attached to nitrous oxide and oxygen tanks or attached to piped nitrous oxide and oxygen if the hospital has these gases available in labor rooms (**Figure 27-6**). It is then self-administered by the woman via a handheld facemask over her nose and mouth or via a mouthpiece (**Figure 27-7**). A demand valve opens with inhalation and closes with exhalation. Self-administration is not only empowering for the woman, but also acts as a safety mechanism because it is almost impossible to overdose with N_2O/O_2 when it is self-administered. Guidelines for use of this agent are listed in **Table 27-6**.[92]

Table 27-6 **Clinical Application of 50% N_2O/O_2 for Labor Analgesia**

Steps	Description
Precautions	1. Determine that there are no contraindications, such as inability to hold the face mask, impaired

	oxygenation, or hemodynamic instability. 2. Use with caution if other sedating drugs are administered concomitantly.
Preparation	1. Inform the woman of the potential side effects of nausea, vomiting, and/or dizziness. 2. Instruct her on how to hold the mask so it creates a seal; instruct her on timing of inhaation. 3. Review with the woman and any labor support persons that only the woman can hold the mask. a. Sedation from N_2O/O_2 is possible only if the woman continues to inhale the gas after she can no longer hold the mask tightly to her face. N_2O/O_2 dissipates rapidly with exhalation and the effects resolve very quickly. b. Self-administration gives the woman personal control of management of pain, and this control may potentiate the analgesic effect.
Procedure	1. The woman holds the mask over her mouth and nose, creating a seal that allows activation of a second-stage regulator. 2. She begins breathing the gas 30 seconds before a contraction starts; the onset of action is approximately 30 seconds, and the full analgesic effect occurs in 50 seconds. It often takes three to four contractions to learn the correct technique. 3. The woman exhales into the mask to facilitate scavenging.
Intermittent versus continuous inhalation	1. Intermittent inhalation 30 seconds prior to the onset of contraction maximizes the peak effect of N_2O/O_2 so the peak analgesic effect occurs during the peak of the uterine contraction. 2. Continuous inhalation is easier to initiate, but in this scenario the woman is exposed to the effects of the gas between contractions when the central nervous system effects of dizziness or dysphoria could be bothersome.

Reproduced with permission from Rooks JP. Safety and risks of nitrous oxide labor analgesia: a review. *J Midwifery Womens Health*. 2011;56:557-565.[92] © 2011, with permission from Wiley.

Women have generally reported high degrees of satisfaction with the use of N_2O/O_2 for pain relief in labor even when they report lower or moderate degrees of pain relief. This finding may relate to maternal control of the agent, or possibly some anxiolytic effect of the agent, or a mixture of analgesia, anxiolytic effect, and increased self-efficacy.[86,98] The analgesic effect of N_2O/O_2 is relatively mild with the doses used for labor, but in combination with the anxiolytic effect, it effectively reduces the perception of pain.[94] Approximately 40% to 60% of women who start using N_2O/O_2 convert to neuraxial analgesia later in labor.[99,100] N_2O/O_2 can also provide effective analgesia for placement of a Foley bulb for labor induction, postpartum suturing, or manual removal of the placenta, as well as gynecologic procedures such as a difficult insertion of an intrauterine contraceptive device.

Potential side effects of N_2O/O_2 include nausea in 5% to 40% of women and vomiting in as many as 15%, dizziness, and dysphoria, although the occurrence of these side effects is rare.[96] Administration of N_2O/O_2 must occur in settings where scavenging of the exhaled gases occurs so it does not exit out into the air. No fetal heart rate abnormalities have been attributed to its use, and this agent does not affect uterine contractility.[86,93-96] The half-life in the neonate is

approximately 3 minutes, and no neonatal adverse outcomes have been found following maternal use during labor.[86] Adverse effects on the fetus or newborn have not been seen in the extensive history of this agent as a labor analgesic, although some theoretical risks are associated with higher doses than those used for labor analgesia that have not been well studied. Likewise, there are no risks to healthcare personnel who are in a room where N_2O/O_2 is being used.[94]

In the body, nitrous oxide oxidizes an active form of cobalamin (vitamin B_{12}). Cobalamin is used in the enzymatic reaction of methionine synthase that converts homocysteine into methionine. Methionine uses folate to synthesize myelin, DNA, and RNA. Acting through this pathway, prolonged use of nitrous oxide has resulted in neurodegeneration in animal studies. Thus, despite a long record of safety in the concentrations and total amounts used by laboring women, there is some controversy about use of N_2O/O_2 by pregnant women.[94] Contraindications to use of N_2O/O_2 are rare but include persons with extreme vitamin B_{12} deficiency, or other conditions that might lead to vitamin B_{12} deficiency. Other contraindications include inability of the woman to hold the mask, impaired oxygenation, or hemodynamic instability.[94]

Neuraxial Analgesia

Neuraxial analgesia encompasses both epidural and spinal analgesic techniques. Neuraxial analgesia must block T10 to L1 during the first stage of labor and extend to S2 to S4 during the late first stage and second stage of labor if it is to block sensory input from the uterus and perineum. Neuraxial analgesia is performed by anesthesia specialists (nurse anesthetists and anesthesiologists), and the specific technique depends on the needs of the laboring woman as well as the availability and choice of the anesthetist. Regional analgesic techniques include spinal (intrathecal injection), epidural, and combined spinal/epidural injections. The effect depends on where the medication is placed, which medications are used, and which dose is administered. Absolute contraindications to neuraxial analgesia are rare but include coagulopathy, infection of the lower back, and increased intracranial pressure.

Spinal Analgesia

To induce spinal anesthesia, a single injection of opioid is administered in the intrathecal (subarachnoid) space that contains cerebrospinal fluid, spinal nerves, and blood vessels, all of which are enclosed by the membrane of the dura mater. The onset of action with this therapy is rapid, but its duration is limited to the duration of the specific opioid used.

Spinal analgesia has no effect on motor ability, so women can ambulate or assume any position they want. This therapy is often called “the walking epidural” despite the fact that this technique does not deliver analgesia into the epidural space. Spinal analgesia is associated with transient fetal heart rate abnormalities such as prolonged decelerations and a transient increase in uterine contractions and uterine tone.[102] As a consequence, close observation of the fetal heart rate is necessary for a period of time after the injection. The major drawback to spinal analgesia is that it requires a dural puncture, which is not safe to do more than once.

Therefore, a spinal can be performed only once. Because it is not easy to predict when during labor a woman will need analgesia the most, spinal analgesia is not used as often as is epidural analgesia. Spinal analgesia is most appropriate for women who are having a rapidly progressing course of labor without the need for an extended block (epidural).

Side effects of intrathecal analgesia may include pruritus or nausea and vomiting, which occur secondary to the effect of the opioid rather than the technique itself. Pruritus (skin itching) is the most common side effect, occurring in varying degrees of severity in 50% to 90% of women.[103] Diphenhydramine (Benadryl 25 mg given intravenously) can be of value in this situation, or in severe cases naloxone (Narcan) can be administered with caution. If naloxone is needed, the anesthetic effect of the spinal analgesia will also be reversed. Urinary retention and respiratory depression are less common side effects.

Spinal analgesia is more often used today as part of a combination spinal/epidural, wherein the spinal technique is used to inject a small dose of opioid and, as the needle is withdrawn, a catheter is placed in the epidural space. When the spinal analgesia wears off, medication is injected to initiate epidural analgesia.

Epidural Analgesia

Epidural analgesia provides the most effective relief of labor pain compared to opioids and inhalation anesthetics. Women using epidural analgesia have lower pain scores and are more satisfied with their analgesia than women using parenteral opioids when the experience of pain is evaluated.[104] The most recent study that compared the effectiveness of epidural analgesia to that of N_2O/O_2 found that women who relied on N_2O/O_2 alone (without converting to neuraxial analgesia) reported higher scores of satisfaction compared to women who used epidural analgesia, despite lower scores of actual pain diminution.[99] This finding confirms the observation that direct analgesia is not the only factor associated with birth satisfaction. Over the past three decades, the use of epidural analgesia/anesthesia for managing labor pain has increased dramatically, reflecting improvements in the administration techniques, greater access to the procedure, and consumer demand.

Mechanism of Action

The epidural space is located exterior to the dura mater, bounded posteriorly by the ligamentum flavum (**Figure 27-8**). It contains nerve roots, fat, lymphatics, and blood vessels. When an anesthetic drug is placed in this space, impulses traveling in the sensory and motor nerves in contact with the drug are blocked. The effect of epidural analgesia depends greatly on the drug, the dose placed in the epidural space, and the administration technique (i.e., intermittent versus continuous infusion).

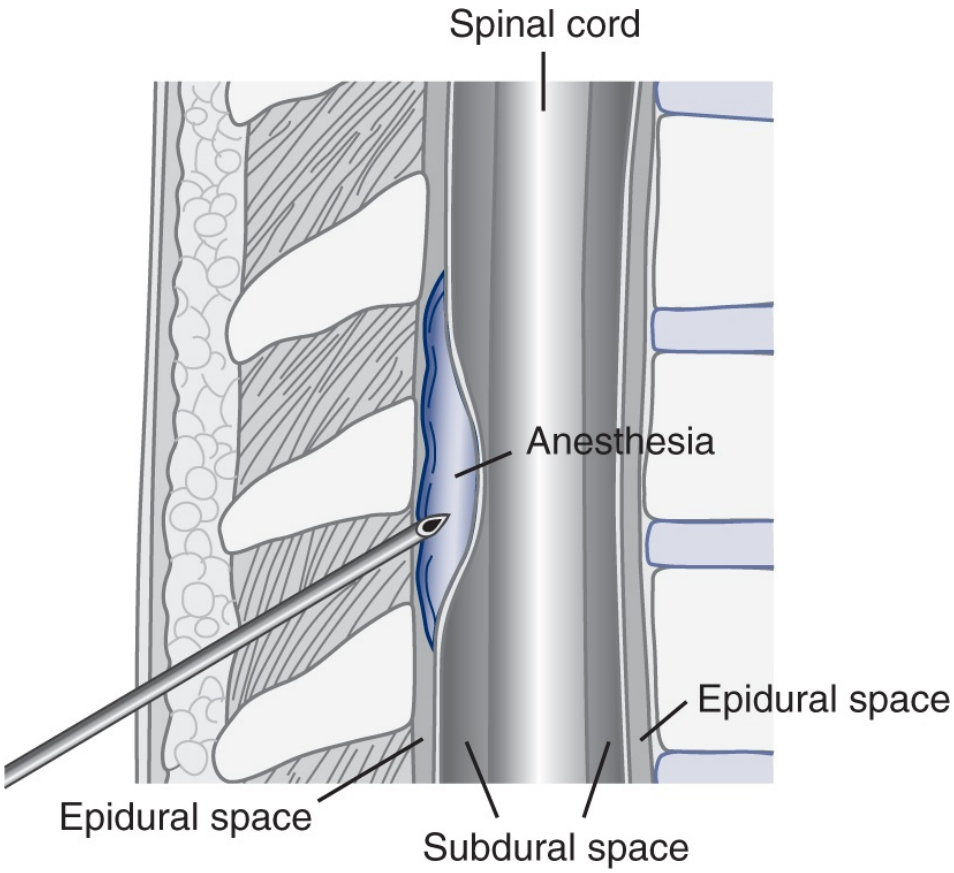

Figure 27-8 Epidural space.

The anesthetic agents most commonly used in epidural analgesia are bupivacaine (Marcaine) and ropivacaine (Naropin). Fentanyl or morphine can be added to potentiate the analgesic effect and allow smaller doses of the anesthetic drug. Often epinephrine is added to the local anesthetic solution because it prolongs the duration of action. Bupivacaine, an amide anesthetic with a long duration of action, provides an excellent sensory block, while preserving some motor function when used at low doses. A concentration of 0.25% or 0.5% is often used for labor analgesia. Fentanyl and remifentanil are synthetic opioids with potency 100 times greater than that of morphine; one of these opioids is frequently added to the anesthetic to augment the analgesic effect.

Some of the individual differences noted in the quality of neuraxial blocks, despite use of consistent technique, may reflect individual anatomic variations that occur in the epidural space. For example, differences in nerve root size or the presence of membranes in the epidural space that disallow equal spread of the medication to all nerves passing through the epidural space may lead to variable effects in individual women.

Indications and Contraindications

Indications for the use of epidural analgesia/anesthesia include relief of pain at any time during labor following maternal request, operative vaginal birth, cesarean section, and need to diminish maternal expulsive efforts (e.g., maternal cardiac or ophthalmologic disease). If a woman’s medical or obstetric condition places her at increased risk for needing an emergent

cesarean section, placement of an epidural catheter may be recommended to avoid loss of time if the emergency does, in fact, occur. This “double setup” is often done, for example, if membranes are to be ruptured when the fetal presenting part is not in the pelvis, for a vaginal breech birth, or for a woman with a multifetal gestation.

Effective epidural analgesia may be particularly helpful for some women who have a history of sexual abuse. For some of these women, labor can induce anxiety about painful stimuli in the vaginal/rectal area or flashbacks of abusive events. Thus the “numbing” effect of epidural analgesia can mitigate some aspects of the post-traumatic stress caused by labor and birth.

Absolute contraindications to epidural or spinal anesthesia include refusal, inability to cooperate, skin or soft-tissue infection at the site of needle placement, frank coagulopathy, untreated sepsis, and maternal hemodynamic instability. Relative contraindications include heparin therapy or thrombocytopenia, and neurologic disease of the spinal cord. In addition, women with the conditions listed in **Table 27-7** should be offered consultation with an anesthesia provider prior to labor.[105] Contrary to popular belief, a tattoo is not a contraindication to epidural analgesia.

Table 27-7 Indications for Anesthesiology Consultation

The following are some of the most common indications for consultation with an anesthesiologist during the antenatal period or peripartum period. In many cases, a phone consultation may be sufficient; in other cases, a face-to-face consultation will be appropriate.
Cardiac Disease
Congenital and acquired disorders such as repaired tetralogy of Fallot and transposition of the great vessels
Cardiomyopathy
Valvular disease such as aortic and mitral stenosis, tricuspid regurgitation, and pulmonary stenosis
Pulmonary hypertension and Eisenmenger syndrome
Rhythm abnormalities such as supraventricular tachycardia and Wolff–Parkinson–White syndrome
Presence of an implanted pacemaker or defibrillator
Hematologic Abnormalities or Risk Factors
Immune and gestational thrombocytopenia
Coagulation abnormalities such as von Willebrand disease
Current use of anticoagulant medications
Jehovah’s Witness
Spinal, Muscular, and Neurologic Disease
Structural vertebral abnormalities and prior surgeries such as vertebral fusion and rod placement
Prior spinal cord injury
Central nervous system problems such as known arterial–venous malformation, aneurysm, Chiari malformation, or ventriculoperitoneal shunt
Major Hepatic or Renal Disease
Chronic renal insufficiency
Hepatitis or cirrhosis with significantly abnormal liver function tests or coagulopathy
History of or Risk Factors for Anesthetic Complications
Anticipated difficult airway

Obstructive sleep apnea
Previous difficult or failed neuraxial block
Malignant hyperthermia
Allergy to local anesthetics
Obstetric Complications That May Affect Anesthesia Management
Placenta accreta
Nonobstetric surgery during pregnancy
Planned cesarean delivery with concurrent major abdominal procedure
Miscellaneous Medical Conditions That May Influence Anesthesia Management
Body mass index of 50 or greater
History of solid organ transplantation
Myasthenia gravis
Dwarfism
Sickle cell anemia
Neurofibromatosis

Side Effects and Adverse Effects of Epidural Analgesia

The anesthesia provider will review the risks, benefits, side effects, adverse effects, and alternative therapies prior to initiating the procedure. Midwives who care for women who are administered epidural analgesia need to know the effects of this procedure and be prepared to manage complications. Often the anesthesia provider focuses on maternal risks associated with the procedure or the block, while the maternity care provider addresses the effect of neuraxial analgesia on labor progress and the fetus or newborn.

The primary side effect related to performance of this procedure is postdural puncture headache following accidental dural puncture. If the epidural needle inadvertently pierces the dura and cerebrospinal fluid leaks into the epidural space, the drop in intrathecal pressure can cause a positional headache, which increases in severity when the woman is in the sitting or standing position. Resolution of the headache occurs spontaneously within 4 to 5 days. If not severe, this headache may be treated with oral hydration, caffeine, and simple analgesics such as acetaminophen (Tylenol) or ibuprofen (Motrin, Advil). If the headache is severe or prolonged, it can be treated with a blood patch, which is an epidural injection of the woman's blood that seals the leaking membrane.

Back pain is a common side effect of labor and birth, with or without an epidural. When lower back pain occurs following regional analgesia, the back pain may be attributed to the epidural. However, it is not known if the etiology of back pain following use of epidural analgesia for labor and birth is related to physiologic changes of pregnancy, effects of labor itself, or the epidural and resulting regional block.[106,107]

Adverse effects related to performance of the epidural analgesia procedure are rare, but include epidural abscess (fewer than 1 in 60,000), epidural hematoma (1 in 250,000), and

serious neurological injury (1 in 36,000).[106] Inadvertent intrathecal (subarachnoid) or intravascular placement can result in toxicity (**Table 27-8)**. Total spinal anesthesia occurs in 0.03% of women when the level of the anesthesia rises dangerously high, resulting in paralysis of the respiratory muscles including the diaphragm (1 in 4000).[106] When this effect occurs, the woman will experience numbness of the hands and fingers, as well as dyspnea. Treatment is accomplished with assisted respiration until the anesthesia resolves.

Table 27-8	Signs of Intrathecal or Systemic Toxicity Following Epidural Injection
Placement of Anesthetic	**Signs and Symptoms of Toxicity**
Intrathecal	Rapid cephalad spread of anesthesia
	Profound hypotension
	Respiratory depression
	Loss of consciousness
Intravascular	Tinnitus
	Dizziness
	Metallic taste in the mouth
	Disorientation
	Seizures
	Cardiac dysrhythmias
	Cardiac arrest

Side effects of local anesthetic placed in the epidural space include hypotension, urinary retention, and leg numbness and weakness. Local anesthetics cause a sympathetic blockade that leads to decreased vascular tone, peripheral vasodilation, and subsequent drop in blood pressure. Hypotension (defined as a systolic blood pressure less than 100 mm Hg) is noted in approximately 10% of women following administration of epidural analgesia.[108] Significant complications are uncommon, but blood flow to the uterus diminishes with hypotension, and fetal heart rate decelerations (e.g., prolonged deceleration or late decelerations) frequently appear for a short time 10 to 20 minutes after the epidural is emplaced. These fetal heart rate patterns are associated with moderate fetal heart rate variability, usually resolve spontaneously or following a bolus of intravenous fluids, and are not associated with adverse newborn outcomes. In rare cases, ephedrine is required to elevate maternal blood pressure and restore blood flow to the uterus. This is most commonly accomplished with incremental doses (5–10 mg administered intravenously) of ephedrine, a mixed catecholamine agonist that increases blood pressure and heart rate without constricting uterine blood vessels.

Bladder distension can occur when the woman experiences loss of the sensation to void, relaxation of overall bladder tone, and loss of control of the urinary sphincter. Intermittent catheterization during labor and/or at the time of birth is common. If many hours will elapse between initiation of an epidural and birth, and the woman is unable to void on her own, an indwelling catheter or intermittent catheterization may be indicated. The catheter should be discontinued during the second stage of labor.

An increase in the incidence of maternal fever, defined as a body temperature equal to or

higher than 38°C (100.4°F), has been demonstrated in women who have epidural analgesia during labor.[109] Women who develop temperature elevations tend to have increases that start immediately after the epidural is initiated and average 0.18°C (0.33°F) per hour. The occurrence of fever equal to or higher than 38°C (100.4°F) is apparent after approximately 4 hours.[110,111] Most likely, epidural-related fever is attributable to thermoregulatory alterations such as a decrease in heat dissipation secondary to sympathetic block of sweating. Some women who develop a fever after epidural initiation, however, may have subclinical chorioamnionitis.[110,111] Unfortunately, it is not possible to distinguish fever of benign versus infectious origin, so all women who develop a fever in labor are treated for chorioamnionitis. Newborns of women who develop a fever during labor are more likely to be subjected to evaluations for sepsis in the first few days of life.[111]

A secondary analysis of data from a large study that followed women in labor to determine fetal position confirmed the increased incidence of a rise in temperature in women who have an epidural.[112] This analysis found that a rise in temperature was positively associated with increased incidence of occiput posterior position at birth despite the groups having a nonsignificant difference in the incidence of occiput posterior position at the onset of labor.[112] Furthermore, the incidence of occiput posterior position at birth and cesarean section increased proportionately as the maternal temperature increased (17.2% vs 9.2% in women with and without fever respectively; odds ratio [OR], 2.0; 95% CI, 1.5–2.8).[112] This finding remained significant after controlling for confounding factors such as body mass index, gestational age, birth weight, and length of labor (OR, 1.5; 95% CI, 1.1–2.1).[112]

Effect of Neuraxial Analgesia on Labor Progress

During the many years over which epidural analgesia has been in use, there has been a great deal of controversy regarding the potential effects of this therapy on the course and outcomes of labor.[107,113] The effect of epidural analgesia on duration of labor is difficult to determine due to many confounding variables. Retrospective studies have found the use of epidural analgesia to be associated with longer first and second stages of labor. The largest and most recent of these studies, which was conducted by Zhang et al. (n = 62,400), found the 95th percentile was approximately 50 minutes longer for the second stage in nulliparous women.[113] This extended duration is presumed to occur secondary to the lack of sensation for bearing down and perhaps the relaxation of the levator ani muscles that make up the pelvic floor. The meta-analyses of RCTs that compared labor outcomes in women with and without epidural analgesia have not found epidural analgesia to be associated with a prolongation of the second stage of labor in the aggregate (MD, 13.66 minutes; 95% CI, 6.67–20.66; 11 trials; 2981 women).[109] In addition, it appears that lower concentrations of anesthetic are less likely to cause longer durations of the second stage of labor.[114]

However, the aggregate mean values for duration of labor do not tell the full story. In general, epidural analgesia is often associated with a slow rate of cervical dilation in the first stage of labor, especially if such analgesia is initiated during the latent phase of labor. Women who need epidural analgesia in the latent phase of labor for pain relief, however, may have an

underlying uterine dysfunction that results in a longer labor. Thus, it is not clear if the analgesia slows the first stage of labor or if women who need epidural analgesia have inherent differences that result in slower labors.

Conversely, some women experience an accelerated course of labor after epidural analgesia is initiated. This effect may be due to improved uterine contractility after previous inhibition from markedly elevated catecholamine levels in women who had severe pain. Alternatively, the higher level of pain that initiated the request for epidural analgesia might have reflected rapid dilation that occurred spontaneously. Thus, the combination of some women whose labors are slowed by epidural analgesia with some women whose labors are faster after epidural analgesia is initiated results in an aggregate mean duration of the first stage that is no different than the duration of the first stage in women who do not use epidural analgesia. Given these offsetting groups, it is difficult to draw clinically meaningful conclusions from these data.

Epidural analgesia is not associated with an increase in cesarean births, but women who have epidural analgesia are more likely to have an operative vaginal birth (RR, 1.42; 95% CI, 1.28–1.57).[109] The incidence of instrumental deliveries can be reduced with the use of a more dilute solution of local anesthetic.[115] Some practitioners have advocated cessation of epidural analgesia during second-stage labor to enable the woman to experience the urge to push and to be able to actively participate in expulsive efforts. For a few women, this is a successful approach; for many others, the reoccurrence of severe pain and anxiety may interfere with their ability to push. Discontinuing the epidural infusion is not recommended.

Fetal and Neonatal Side Effects and Adverse Effects of Neuraxial Analgesia

Both anesthetic drugs and opioids are highly lipid soluble and can cross into the fetal circulation in small amounts, depending on the quantity found in the maternal circulation. Nevertheless, neonatal outcomes such as poor 5-minute Apgar scores and low umbilical artery pH have not been shown to be significantly different between women using epidural analgesia and those using intravenous opioids or no medications.[113] Neurologic studies of epidural analgesia-exposed infants, opioid-exposed infants, and nonmedicated infants have not identified significant differences in performance between any of these groups.

The effect of epidural analgesia on breastfeeding outcomes has also been controversial. Women cannot be randomized prospectively to epidural analgesia or no-epidural analgesia groups, and because women who have epidural analgesia tend to have longer second stages, more fevers, and a higher rate of operative birth, it is not clear if lower rates of breastfeeding initiation occur secondary to the epidural analgesia or to the labor course. Overall, rates of breastfeeding initiation and continuation through 6 weeks postpartum appear to be unchanged regardless of the method of analgesia.[107]

Pudendal Block

A pudendal block is used to alleviate pain stemming from the perineum and vagina during the second stage of labor.[116] Before the widespread adoption of epidural analgesia for mitigating labor pain, pudendal blocks were the preferred analgesic technique for birth. A pudendal block

can be an effective form of analgesia if the woman has a contraindication to neuraxial anesthesia and an anesthetic is needed for a low vaginal or perineal procedure. The lower vagina, perineum, and vulva obtain most of their sensory and motor innervation from sacral nerve roots 2, 3, and 4 via the pudendal nerve. Infiltration of a local anesthetic around the pudendal nerve at the level of the ischial spine results in analgesia of these areas. Pudendal nerve blocks do not decrease the pain associated with uterine contractions or cervical dilation. The appendix in the *Second Stage of Labor and Birth* chapter describes the procedure for performing a pudendal block in detail.[116]

Pudendal blocks are simple to perform and provide satisfactory analgesia in many cases. However, 10% to 50% of bilateral pudendal blocks are ineffective on one or both sides. Pudendal blocks do not interfere with uterine contractions, so they have no adverse effects on labor progress or maternal or fetal well-being. Neonatal local anesthetic toxicity after maternal pudendal block is extremely rare. A case report described three cases of neonatal lidocaine intoxication, which manifested as transient hypotonia, apnea, seizures, mydriasis, cyanosis, and need for mechanical ventilation; all of the neonates recovered completely.[117] Potential complications are rare, but may include post-block fetal bradycardia, systematic toxicity after intravascular administration, lower-extremity paresthesia, vaginal hematoma, and infection.[116-117]

General Anesthesia

General anesthesia refers to the use of an inhaled anesthetic agent to induce sleep for obstetric applications, primarily for emergency cesarean birth. Induction of anesthesia is accomplished with short-acting agents that render the woman unconscious, such as thiopental or propofol. After the induction agent is administered, a muscle relaxant such as succinylcholine is typically administered to facilitate intubation.

Intubation generally proceeds without complications; however, in pregnant women, intubation is several times more complicated than in the nongravid person. For this reason, general anesthesia is avoided when possible, due to maternal and fetal side effects that are undesirable and possibly life threatening. General anesthesia complications due to inability to intubate and maternal aspiration remain leading causes of anesthesia-related maternal mortality.[118] Even so, true emergencies such as cord prolapse and acute placental abruption may necessitate the use of general anesthesia if neuraxial anesthesia is not already in place. For many clinical situations where a surgical birth becomes necessary, there is adequate time for placement of spinal anesthesia, which has less potential for maternal–fetal complications.

Conclusion

Unmedicated or medicated, easy labor and birth or complicated labor and birth, the midwife sets the tone for all involved in the care of the laboring woman. Speaking in a low voice, dimming bright lights, and making all involved as comfortable as possible help women feel cared for and supported. The midwife always has a special opportunity to make each birth experience one that shows respect for birth, even if the birth takes place in the midst of a high-technology environment. Providing support to the woman in labor and facilitating her choices for coping with the pain of labor are key responsibilities for the midwife, regardless of birth setting.

APPENDIX

27A

Injection of Intradermal Sterile Water Papules for Relief of Low Back Pain in Labor

TEKOA L. KING

The editors acknowledge Saraswathi Vedam and Carolyn L. Gegor for contributions to this appendix in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

Approximately 30% of women experience severe continuous low back pain in labor.[1] Back pain in labor, especially when caused by an occiput posterior position, is one of the most challenging conditions for the midwife to treat effectively. The tension caused by this pain has been associated with prolonged labor, increased need for pain medication, and prevention of the spontaneous rotation of the vertex to an anterior position. Several techniques have been reported to be helpful, including massage, counterpressure, applied heat or ice, transcutaneous electrical nerve stimulation (TENS), and hydrotherapy. However, most of these measures offer only partial relief with constant application by another person.

Several randomized controlled trials (RCTs)[1-6] and two meta-analyses[7,8] have shown that intradermal sterile water papule injections have greater analgesic effects than massage, TENS, or counterpressure. The pain relief has been shown to last approximately 1 to 3 hours in 85% to 90% of women,[2–6] and intradermal injections appear to reduce pain by approximately 60%.[7,8] This technique offers the advantages of needing minimal, readily available equipment; moreover, it is adaptable to any birth setting and simple to administer. There are no systemic maternal or fetal side effects. Laboring women are able to ambulate and move freely. There is no need for additional fetal heart rate monitoring or other supplemental interventions. The main disadvantage is the sensation of intense burning or stinging at time of application—an effect that lasts 30 to 90 seconds. Uneven or inadequate relief of pain is also an undesirable side effect.[7-9]

The mechanism of action seems to be primarily counter-irritation, which is thought to inhibit

multireceptive neurons to the brain.[10] The gate control mechanism of pain control may also be involved in the effectiveness of this procedure.[7,11,12]

The onset of relief occurs within 2 minutes of injection and usually lasts 2 to 3 hours. The technique may be repeated up to three times, but some women will decline reapplication because of the initial burning. Some women will experience no relief or only partial relief. The exact location of the injected papules can influence the effectiveness of this technique. Hence, prior to injecting the sterile water, the midwife assesses both the fetal position and the woman's preferred focal points for pressure.

Method to Inject Sterile Water Papules

1. Prior to beginning the procedure:
   a. Prepare a 1-cc syringe with 0.6 mL of sterile water (do not use normal saline) and a 25-gauge needle. Use two syringes if two midwives will do the injections simultaneously.
   b. Gather alcohol swabs, pen(s) for marking the skin, and sterile gloves to avoid introduction of pathogens and to protect the provider from exposure to the woman's blood.
2. Explain the procedure to the woman and her support persons.
   a. Benefits include relief of back pain, lack of systemic maternal or fetal side effects, and continued ability to ambulate or move as desired.
   b. Risks include intense burning pain at the injection sites for 30 to 90 seconds and less effective pain relief than desired.
   c. Relief occurs by 2 minutes of completion of injections. Prepare the woman and her support persons with methods of maintaining a stable position and coping with discomfort during the procedure.
3. Place the woman in a sitting, kneeling, or standing position, stabilizing herself with her arms and hands as she leans forward slightly. The injection sites in the sacral area will be more visible when the woman leans forward and flattens her back.
4. Expose the woman's lower back enough to visualize the sacral dimples, which correspond to the dorsal sacral foramina. Place and press the pads of the thumbs on the superior iliac spines. Mark these landmarks with a pen. Place the index finger at these marks and move the thumbs about 3 to 4 cm down and 1 to 2 cm inward into the sacral dimples so that the fingertips touch the corners of a trapezoid (**Figure 27A-1**); mark these points as well.[12] Put pressure on these four points, moving them very slightly laterally and vertically until the woman indicates the points of greatest relief.[8]

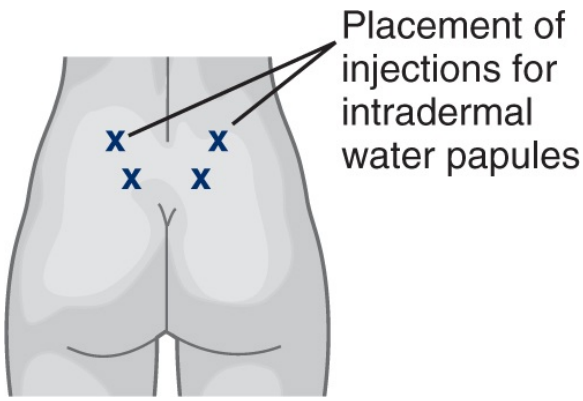

Figure 27A-1 Injection sites for sterile water papules.

5. To mark the points of greatest relief most accurately, ask an assistant to place an X or draw a half-circle around the provider's fingertips while they remain in place.
6. Clean the sites with an alcohol swab, taking care not to erase the circular marks around the area to be injected. Put on sterile gloves. Remind the woman that she will feel temporary burning and stinging as the papules are placed.
7. Plan to do the injections quickly during a contraction unless the woman prefers having the injections done between contractions.[7]
   a. Inject 0.1 to 0.15 mL intradermally in each of the four points delineated (within the half-circle mark) until the distended skin forms a blanched 1-cm bleb or papule.
   b. If possible, have another clinician inject two papules simultaneously to reduce the burning episodes. Do not touch or rub the injection sites when complete.[7]
8. Onset of relief should occur within 2 minutes.
9. If the relief is uneven, the area of less analgesia is often consistent with a bleb that is noted to absorb too quickly, is misplaced, or was injected too deeply. Replacing the papule slightly laterally or vertically often achieves the desired effect.
10. Reevaluate the areas with finger pressure as initially applied, and then repeat the injection.
11. Once the effects have worn off (in 1 to 3 hours, depending on the woman and the fetal position and station), the papules may be replaced with the woman's consent. More than three applications may not be advisable.
12. Document the woman's consent for the procedure. Also document the time of injections and patient pain scores both before and after the procedure.

CHAPTER

28

Second Stage of Labor and Birth

LISA KANE LOW AND KATHRYN OSBORNE

The editors acknowledge Tia Cole, Debra A. Erickson, and Judith S. Mercer for contributions to this chapter.

Introduction

Midwives create a circle of support and safety during labor and birth that encourages, rather than disrupts, the normal processes that facilitate healthy outcomes for families. In this capacity, the role of the midwife has best been described as watchful waiting or "the art of doing 'nothing' well."[1] The midwife anticipates needs and provides vigilance in the assessments conducted for women and their support persons during labor and birth, while remaining cognizant of the wide range of what constitutes normal and where the boundaries of abnormal begin. All persons involved participate in shared decision making, with the midwife being responsive, rather than reactive, and supportive, rather than directive. This chapter reviews midwifery management during the second stage of labor and through the event of birth.

Definition of Second-Stage Labor

Anatomically, second-stage labor is defined as beginning with complete dilation of the cervix (10 cm) and ending with expulsion of the fetus. However, the clinical and physiologic demarcation between the final dynamics of first-stage labor and the beginning of second-stage labor is less distinct. Subtle changes indicative of the second stage may appear near the end of the active phase of the first stage of labor, or there may be a lull in the frequency and intensity of contractions at the end of first-stage labor prior to the onset of active second-stage labor.[2] Although the anatomic definition is the one most commonly used in clinical practice, from a physiologic perspective second-stage labor may be defined as the onset of the urge to bear down until the birth of the infant. Using this definition, second-stage labor is initiated when the vertex or presenting part of the fetus has descended to a station wherein an involuntary maternal urge to bear down occurs. The physiologic urge to push typically occurs when the fetal presenting part reaches +1 station.

Normal Course of the Second Stage of Labor

Observations of women in labor without epidural analgesia who are not coached to push, regardless of whether they have an urge to do so, have revealed that most women experience two or three distinct phases of the second stage of labor.[2,3] If the fetus is above 0 station when the cervix becomes completely dilated, the first phase may consist of a short lull or pause during which uterine contractions are less frequent and there is no urge to push. This is followed by an expulsive phase or phase of active pushing, during which the urge to push and bearing-down efforts become progressively stronger to accomplish the necessary fetal rotation and descent. The final perineal phase occurs when the fetal head is visible at the introitus. During this last phase, a strong sense of pressure combined with a sensation of stretching often results in pushing efforts even without contractions.[2]

Signs and Symptoms of Second-Stage Labor

The most common symptom that heralds the onset of the second stage is an urge to push or bear down. Women who are not using epidural analgesia usually have an irresistible need to push or bear down, but this is not universally true.[4] Many women interpret this feeling as needing to have a bowel movement. Signs of second-stage labor also include finding the fetal heart rate (FHR) in progressively lower locations on the maternal abdomen, rectal bulging, perineal bulging, and progressive visibility of the fetal head at the vaginal introitus. In addition, there may be an increase in bloody show, and the FHR pattern may demonstrate variable decelerations secondary to the vertex descending with maternal bearing-down efforts. Interestingly, an almost infallible signal of imminent birth is the woman saying, “The baby’s coming!”—a verbal expression that occurs in most cultures and languages.

Fetal Descent During Second-Stage Labor

During the second stage of labor, the fetus descends. Internal rotation often takes place during the late first stage or in the second stage. Birth of the head occurs first with flexion of the fetal neck, followed by extension and external rotation. This process can occur very quickly, especially for women who have given birth before, or it can occur over a period of time, which is more common when a woman is experiencing her first birth. A detailed description of the cardinal movements that describe fetal passage through the birth canal during labor and birth is found in the *Anatomy and Physiology During Labor and Birth* chapter.

Duration of Second-Stage Labor

For several decades, the norms used to define duration of second-stage labor were based on investigations conducted in the 1950s and early 1960s by Emanuel A. Friedman.[3] During that era, labor management strategies were quite different from contemporary practice: Approximately 55% of the women in Friedman’s observations had their labors terminated by application of low or mid-forceps. As a result, Friedman’s analysis of second-stage duration

was more an observation of practice patterns at the time than an investigation of the natural course of the second stage. According to Freidman, the average length of the second stage was 46 minutes for a woman having a first vaginal birth and 14 minutes for women having subsequent births.[3]

The parameters used to define the duration of second-stage labor have changed, in part due to the widespread use of epidural analgesia for pain management and the effect of epidural analgesia on maternal bearing-down efforts. Women who enter the second stage of labor with effective epidural analgesia have diminished or absent pelvic and rectal sensation and, therefore, experience lessened or no urge to push, often resulting in a second stage that is longer than the parameters established by Friedman. Studies examining the maternal and fetal effects of a longer second stage and delayed pushing for women with epidural analgesia began to appear in the literature more than 30 years ago. Recent retrospective and prospective study results suggest that the normal duration of second stage labor is at least 1 to 2 hours longer than the duration described by Friedman.[5-7] The findings of research examining the relationship between second-stage labor duration and perinatal outcomes have been conflicting, and are reviewed later in this chapter.

The factors that influence the duration of the second stage of labor are listed in **Table 28-1**. For women who have no medical or obstetric complications at the onset of labor, the three factors that have the strongest effect on the duration of the second stage are parity, fetal position, and the presence or absence of regional analgesia.

Table 28-1	Factors That Influence the Duration of the Second Stage of Labor
Parity	
Fetal position	
Epidural analgesia	
Fetal station at complete cervical dilation	
First-stage labor dystocia	
Uterine contraction activity: strength and frequency of contractions	
Presence or absence of infection	
Effectiveness of maternal pushing efforts	
Pelvic architecture	
Birth weight	
Maternal weight or high body mass index	
Induction of labor	
Maternal fear or anxiety	
Maternal pain or discomfort	
Maternal history of sexual abuse or trauma	

Second-stage labor abnormalities have traditionally been categorized as prolonged duration or abnormalities in the process of descent and/or rotation. Abnormalities in the process of descent can be further subdivided into protracted descent, failure of descent, or arrest of descent.

Prolonged Duration of Second-Stage Labor

There are three clinically significant questions related to prolonged duration of the second stage: (1) What is the time frame during which the woman's chance of successful vaginal birth declines? (2) What are the maternal outcomes? (3) What are the fetal outcomes?

Using Friedman's criteria, prolonged second-stage labor has been defined as second-stage labor lasting longer than 2 hours for a primigravida and longer than 1 hour for a multigravida.[3] In 1989, Kilpatrick and Laros published the first analysis of the duration of labor in women (*n* = 6991), both with and without epidural anesthesia, who had a spontaneous vaginal birth at term without the use of oxytocin.[8] They concluded that longer durations should be used to define prolonged second-stage labor when an epidural is in place. Their work became the "1-2-3 Rule," which established the limits of normal for second-stage labor as 1 hour for multiparous women without an epidural, 2 hours for multiparous women with an epidural and for nulliparous women without an epidural, and 3 hours for nulliparous women with an epidural.[8] The Kilpatrick and Laros study was conducted prior to the introduction of "laboring down"—that is, the use of passive descent (without maternal bearing-down efforts) as a strategy for second-stage labor management in the presence of an epidural. Later studies have provided evidence to support even longer durations of the second stage, particularly when passive descent has been used as a management strategy.[9-11]

In a secondary analysis of a randomized controlled trial (RCT) in which 94% of the participants had an epidural, Rouse et al. found that 85% of women who pushed for less than 1 hour had a spontaneous vaginal birth. Among women who pushed between 1 and 2 hours, 78.7% had a spontaneous vaginal birth; among women who pushed between 2 and 3 hours, the rate was 59.1%; and among women who pushed between 3 and 4 hours, the rate was 24.7%. When women pushed 5 hours or more, the vaginal birth rate was 8.7%.[12] Thus, it appears there is a positive correlation between duration of the second stage and spontaneous vaginal birth rates. Furthermore, there is also a second-stage labor duration at which the chance of vaginal birth diminishes significantly. The authors concluded that duration of second-stage labor could be safely extended for some women, but that decisions to terminate the second stage should not be made based on duration alone.[12]

To date, no prospective randomized trial has been conducted to address the question of "how long is too long" for the duration of second-stage labor; retrospective cohort studies and secondary analyses have been conducted that support longer durations.[13] The debate is ongoing in the literature, with some investigators advocating caution in regard to extending the duration beyond 2 hours for multiparous women and 3 hours for nulliparous women because of concerns about increased maternal and neonatal morbidity.[14] Other investigators have identified that the parameters for second-stage labor duration can be safely extended without an increase in adverse maternal or fetal outcomes and recommend a reexamination of the definition of prolonged second-stage labor.[11]

Maternal Complications Associated with Prolonged Second-Stage Labor

A prolonged duration of second-stage labor is associated with an increased risk of maternal

morbidity. Specifically, actively pushing for more than 2 to 3 hours has been associated with an increased risk for intra-amniotic infection postpartum hemorrhage, operative birth, and third- and fourth-degree lacerations.[12,14,15] Prolonged pushing may also contribute to long-term adverse outcomes in the pelvic floor such as levator ani muscle tears, which are associated with pelvic floor disorders later in life.[16-19] In multiparous women, those with a prolonged second stage had a higher risk of shoulder dystocia. It is not clear if prolonged duration of the second stage results in intra-amniotic infection or if intra-amniotic infection adversely affects uterine contractility sufficiently to cause a prolonged duration. Intra-amniotic infection may be both a cause and effect of prolonged labor.

Fetal Complications Associated with Prolonged Second-Stage Labor

Most of the research on second-stage labor has not found a significant relationship between second-stage duration and perinatal mortality, 5-minute Apgar scores of less than 7, neonatal seizures, or admission to the neonatal intensive care unit (NICU) as long as the FHR pattern does not indicate an increasing risk for fetal acidemia.[14,15,19] A large epidemiologic analysis of women who gave birth between 2002 and 2008 (n = 59,605) shed more light on these relationships. Using guidelines that defined prolonged second-stage labor as longer than 3 hours for nulliparous women with an epidural, longer than 2 hours for nulliparous women without an epidural and multiparous women with an epidural, and longer than 1 hour for multiparous women without an epidural, Laughon et al. found a positive association between a prolonged second stage and neonatal morbidity with regard to several outcome measures.[14] In particular, prolonged second-stage labor was associated with a significant increased risk for 5-minute Apgar score less than 4, neonatal sepsis, admission to the NICU, and perinatal mortality. The findings were stratified by parity and epidural use. The incidence of neonatal sepsis was 2.6% versus 1.2% (adjusted odds ratio [aOR], 20.08; 95% confidence interval [CI], 1.60–2.70) and incidence of 5-minute Apgar scores less than 4 was 0.5% versus 0.2% (aOR, 2.71; 95% CI, 1.20–1.60) in nulliparous women with an epidural who had a prolonged second stage versus those in the same cohort who did not have a prolonged second stage. Nulliparous women without an epidural and multiparous women with and without an epidural had similar findings with regard to neonatal outcomes, although adverse newborn outcomes were less common in multiparous women. Although these are statistically significant increased odds, the absolute risk of adverse neonatal outcomes was quite low for all the newborn outcomes. Nonetheless, as second-stage labor progresses beyond the recommended guidelines, ongoing fetal assessment should be part of the consideration in balancing the risks versus the benefits of a spontaneous vaginal birth.[14]

In summary, the criteria for a diagnosis of prolonged second-stage labor has evolved from the strict limitations described by Freidman to the latest recommendations listed in **Table 28-2**,[7] which offers greater latitude in evaluation of the ongoing progress of rotation and descent and identification of prolonged second-stage labor. In brief, in the absence of maternal exhaustion, other maternal complications, or signs that the fetus is developing acidemia, there are no clear reasons for rigidly adhering to any preset time limit for duration of second-stage labor. Instead, emphasis should be placed on evidence of progress in rotation and descent of

the presenting part in response to maternal pushing efforts, maternal stamina, and fetal well being.

Table 28-2 Definition of Prolonged Second-Stage Labor

No progress in descent or rotation for:

- ≥ 4 hours in nulliparous women with an epidural
- ≥ 3 hours in nulliparous women without an epidural
- ≥ 3 hours in multiparous women with an epidural
- ≥ 2 hours in multiparous women without an epidural

Based on Spong CY, Berghella V, Wenstrom KD, Mercer BM, Saade GR. Preventing the first cesarean delivery: summary of a joint Eunice Kennedy Shriver National Institute of Child Health and Human Development, Society for Maternal–Fetal Medicine, and American College of Obstetricians and Gynecologists Workshop. *Obstet Gynecol.* 2012;120(5):1181-1193.[7]

Ongoing assessment during second-stage labor includes continuous evaluation and documentation of fetal descent, rotation, other aspects of fetal position such as asynclitism, and the degree to which the fetus and the woman in labor are tolerating the vigorous work of the second stage. Most women will progress through second-stage labor by following their physiologic urges and sensations without the need for intervention. The point in time at which the midwife first consults the physician for suspected (or anticipated) prolonged second-stage labor varies from practice to practice and is influenced by the circumstances under which the midwife works. For example, a midwife practicing in a rural hospital with the physician colleague 25 minutes away would likely need to consult the physician sooner than a midwife whose physician colleague is available in the hospital at all times. The prudent midwife–physician team has preestablished parameters, relative to prolonged second stage and consultation, that meet the unique needs of the women served by that practice.

In general, the midwife stays with the woman and continues to offer support when physician consultation becomes necessary. During the consultation, the midwife and the physician establish a plan of care that often involves co-management, such that the midwife provides ongoing care and assessment of the woman, and gives periodic updates to the physician. Critical elements of a second-stage labor consultation note are presented in **Table 28-3**.

Table 28-3 Critical Elements of a Second-Stage Labor Consultation Note

Element	Description
Subjective Data	Describe what the woman says about second-stage labor. This description generally includes comments about how she is tolerating pushing and the sensations she feels.
Objective Data	Describe status of the labor (frequency, duration, and intensity of contractions; time of complete cervical dilation; time that the woman began active pushing); status of the fetus (fetal heart tones, particularly the presence or absence of any changes in baseline or decelerations); fetal position (station and orientation of the fetal head); and maternal status (maternal vital signs and other objective findings).
Assessment	Describe the midwife's assessment of maternal and fetal status and progress (descent and rotation)

	made during second-stage labor; document total time in second-stage labor and total time actively pushing.
Plan	Document the time of the physician consultation and the plan established—specifically, the plan for continued pushing or a period of rest and the specific plan for reevaluation (who will conduct the assessment and when).

Descent Abnormalities in Second-Stage Labor

Descent abnormalities in second-stage labor can occur secondary to malpositions such as persistent occiput posterior or asynclitism, uterine hypocontractility, cephalopelvic disproportion, or maternal fatigue. Failure of descent is present if the fetal presenting part makes no descent after 1 to 2 hours of adequate contractions and maternal pushing efforts. Relative cephalopelvic disproportion may also manifest as protracted descent and prolonged second stage. Protracted descent is more common than failure of descent or arrest of descent, and malpositions are a common cause of protracted descent. The process of rotation and descent should be regularly assessed to determine whether progress is ongoing or has stopped. Assessment of station, fetal position, and presentation at the onset of second-stage labor is critical in determining the amount of progress that has been made over time, particularly if concerns about duration arise. From a clinical standpoint, it is important not to confuse molding or caput with true descent. Physician consultation should be obtained when second stage progress is protracted.

Protracted Descent and Persistent Occiput Posterior Position

One of the most common reasons for protracted fetal descent is persistent occiput posterior (OP) position. When the fetus remains in a persistent OP position during descent in the second stage of labor, the cardinal movements of labor are slightly different as described in the *Anatomy and Physiology During Labor and Birth* chapter. Flexion of the vertex (fetal chin touching fetal chest) may be incomplete, so that the larger occipitofrontal diameter is the anterior-posterior diameter that descends through the pelvis (**Figure 28-1**). When the fetus is in an occiput anterior (OA) position, the occiput descends and flexes so the chin is against the chest as the occiput moves down the 5-cm anterior–posterior diameter of the posterior inferior portion of the symphysis pubis, and then, once the occiput is out from under the symphysis, the head is born by extension of the neck. In contrast, when the fetus is in an OP position, the occiput descends along the 10-cm distance between the top of the sacrum to the bottom of the coccyx and the final few centimeters along the floor of the birth canal before the fetal head is born via flexion, with the occiput presenting in the lower portion of the introitus, then extension on the fetal head occurring only as the occiput fully exits the vagina.

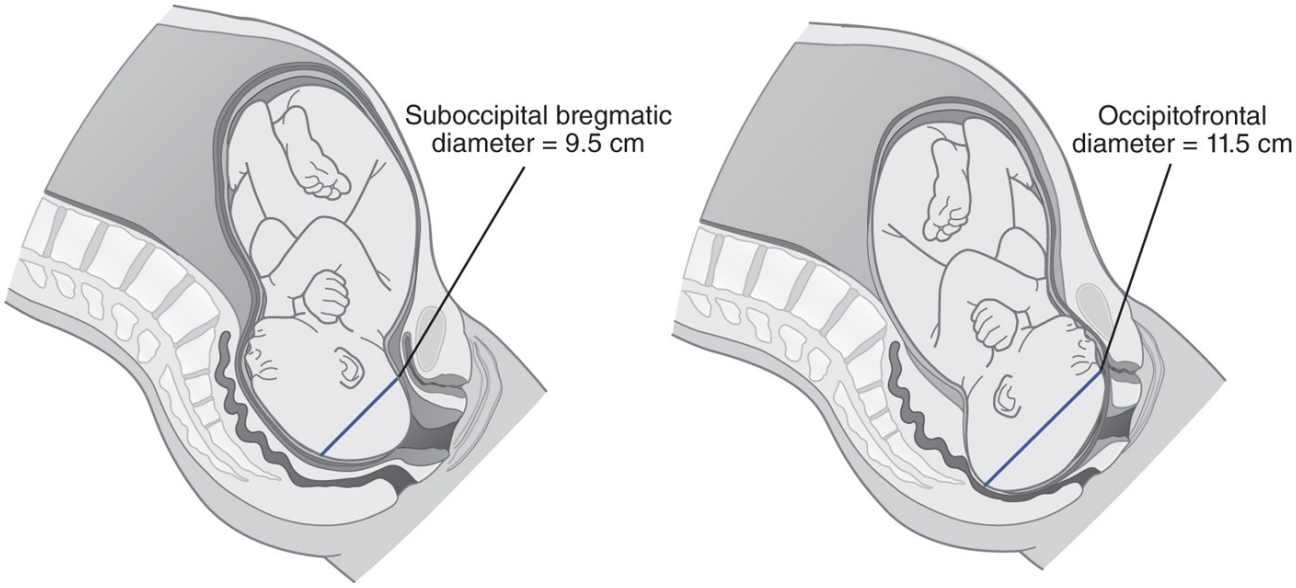

Figure 28-1 Presenting anterior posterior fetal skull diameters in occiput anterior and occiput posterior positions.

Approximately 15% to 25% of fetuses are in an OP position prior to labor, yet only 5% to 7% of fetuses are born in this position.[7,20] Most fetuses in an OP position during the first stage of labor rotate to OA position during the second stage. Anecdotally, it has been reported that women experience more intense back pain when the fetus is in an OP position, although the veracity of this supposition has been neither proven nor disproven.[21]

The occiput posterior position is more likely in women who have an epidural in place. It is not conclusively known if this association occurs secondary to relaxation of pelvic musculature caused by the epidural, or if women with a fetus in an OP position have more painful labors and, therefore, are more likely to choose epidural analgesia. A few studies have examined the relationship between OP position at the time of epidural placement and outcomes.[22,23] Lieberman et al. examined fetal position at the time of epidural placement and position just prior to birth (n = 1562) and found that there were no differences in fetal position at the time of epidural placement, but that more fetuses were in the OP position after the epidural was administered (12.9% with an epidural versus 3.3% with no epidural; P = 0.002).[22] Thus, it appears that epidural analgesia does have an independent effect in increasing the incidence of OP position.

Persistent occiput posterior position is associated with several adverse outcomes, including prolonged first-stage labor, arrest disorders in second-stage labor, a twofold increase in the risk for operative birth, and an increased incidence of perineal lacerations.[7,21,23] Newborn outcomes include higher rates of acidemic umbilical cord blood gases, meconium-stained amniotic fluid, and NICU admission. Some of these outcomes are influenced by the increased incidence of caesarean and operative modes of vaginal birth associated with a persistent OP position.[23]

Diagnosis of an OP position can be made via digital examination or with a combination of transvaginal and transabdominal ultrasound.[21,24] There is a high degree of discordance between digital and ultrasound determinations, however. Although ultrasound is more accurate

than digital examination, approximately 6% to 10% of ultrasounds are not able to determine the fetal position, particularly when the fetal head is deep into the pelvis.[20,21] Diagnostic quandaries aside, the real clinical question is treatment of the OP position once it is diagnosed.

Management of Persistent Occiput Posterior Position

Practices purported to assist internal rotation of an OP fetus to the OA position include having the woman labor on her hands and knees for a period of time, digital rotation with the examiner's fingers, and manual rotation with the examiner's hands. Studies have been conducted that assessed the effect of placing the woman in an asymmetric lateral decubitus position and hands-and-knees positions. Although the number of studies is small and methodologies cannot be compared easily, the asymmetric lateral decubitus position did not increase the incidence of internal position change from OP to OA in one RCT.[25] In another RCT of hands-and-knees positioning during labor, 16% of the OP fetuses rotated to OA position in the hands-and-knees group versus 7% in the control group, although these results were not statistically significant (relative risk [RR], 2.4; 95% CI, 0.88–6.62).[26] In this study, the women who assumed a hands-and-knees position reported less back pain and high satisfaction with laboring in this position. Other maternal maneuvers—for example, lunging, asymmetric kneeling, walking, or side-lying—have not been rigorously studied. Although study findings to date are inconclusive, there is a logical basis in maternal anatomy and physiology for the use of these strategies, and theoretical positive effects on pelvic diameter that may aid the fetus in finding the "best fit."[25] Frequent changes of position such as occur during use of the traditional Mexican rebozo technique may be more useful than any single specific position.[27] It is not known if frequent maternal position changes have an effect on fetal position in the first stage of labor compared to the second stage of labor.

Both digital and manual rotation reduce the incidence of OP birth.[28] The techniques for digital and manual rotation are described in **Table 28-4**. Although there is a theoretical risk of umbilical cord prolapse or trauma to the fetal neck with use of these techniques, these complications appear to be rare and the procedures are considered safe. Manual rotation should not be performed prior to the second stage of labor or if the fetus is at a high station. However, some evidence suggests this technique is more successful if performed prophylactically before arrest of descent occurs.

Table 28-4	Technique for Digital and Manual Rotation of Occiput Posterior Position
For Both Techniques	
Using a process of shared decision making review the risks and benefits of the procedure and obtain informed consent. Make certain the bladder is empty.	
Digital Rotation	**Manual Rotation**
1. Place the tips of the gloved index and middle fingers in the anterior portion of the lambdoidal suture near	1. Place four gloved fingers behind the posterior parietal bones with the palm and fingers resting on the

the posterior fontanelle. 2. Place the thumb of the same hand over the parietal bone. 3. Move the fetal head up toward the pelvic brim slightly and flex it with upward pressure from the two fingers. 4. Rotate the fetal head to the occiput anterior position via the shortest arc during a contraction and when the woman is pushing (i.e., if the fetus was right OP, then rotate to right OA). 5. If the fetal head does not rotate with the above mechanism, rotation of the fetal head can be attempted when the woman is not pushing, again following the short arc.	occipital bone. 2. Place the thumb of the same hand over the anterior parietal bone. 3. Flex and rotate the fetal head anteriorly during a contraction and when the woman is pushing. Mild upward pressure of the fetal head toward the pelvic brim may facilitate rotation.

Abbreviations: OA, occiput anterior; OP, occiput posterior.

Assessment of Maternal and Fetal Well-Being in Second-Stage Labor

Assessment during the second stage of labor includes evaluation of maternal well-being, fetal well-being, and progress of labor, as described in **Table 28-5**.

Table 28-5	Midwifery Assessment During Second-Stage Labor
Maternal vital signs and well-being	Blood pressure: Taken between contractions every 15 minutes, unless more frequent evaluation is indicated. Temperature, pulse, and respirations: Check hourly, unless more frequent evaluations are indicated. Maternal pulse normally increases during contractions. Assess bladder for distension periodically during the second stage. Intermittent catheterization may be needed if the woman is unable to void spontaneously. If an indwelling catheter is in place at the onset of the second stage, it should be removed when the woman is pushing to minimize trauma to the urethra when the fetal head compresses it. Assess hydration and nutrition. Dehydration can contribute to ineffectual uterine activity. Frequent intake of small amounts of oral fluids is recommended. Assess pain, comfort, and coping. Does there appear to be any fear or anxiety about giving birth? Are the comfort measures being used effective? Evaluate coping versus suffering behaviors. Assess level of fatigue. Maternal pushing efforts will become less effective if the woman becomes too fatigued after pushing for a prolonged period of time.
Fetal well-being[a]	Assess fetal heart rate every 5–15 minutes. Increase frequency as the presenting part descends, unless more frequent evaluation is indicated. Document findings in the medical record.
Labor progress	Assess contraction pattern (frequency, duration, intensity). Assess progress with a sterile digital cervical examination when the findings will inform a change in management. Assess each of the following: Fetal position Fetal station Fetal descent or rotation in response to maternal pushing effort Fetal adaptation to the pelvis including: Synclitism or asynclitism Molding or caput succedaneum Rotation, malposition

[a] A detailed discussion of fetal assessment can be found in the *Fetal Assessment During Labor* chapter.

Vital Signs

Maternal blood pressure is taken between contractions and is, on average, 10 mm Hg higher in the second stage than values obtained during the first stage of labor if the woman has been pushing. Similarly, the maternal pulse increases during contractions.

Bladder

The use of epidural analgesia results in reduced ability to void and leads to increased risk for urinary retention and distension. In women who have had an epidural, the bladder often contains larger volumes of residual urine compared to women who have not had an epidural; this retention may occur secondary to larger urine volume that follows use of intravenous fluids to maintain systemic blood pressure following the sympathetic block induced by the epidural.[29,30] If an indwelling Foley catheter is in place when the woman starts bearing down, the catheter should be removed to avoid undue stress on the urethra.

If the woman has a distended bladder and is unable to void, intermittent catheterization can be performed. If catheterization must be performed during second-stage labor and the fetal head is in the true pelvis, the direction of catheter insertion is different from usual. The urethra is displaced by the fetal head and conforms to the contour of the fetal head. Therefore, immediately after inserting the catheter into the urethra, it is necessary to direct it upward and over the fetal head to guide the catheter into the bladder. Sometimes it is helpful to splint the urethra by placing a finger into the vagina, below the urethra, as the catheter is being inserted.

Hydration

The second stage of labor requires active physical work; in turn, the risk for maternal dehydration increases. Prolonged fasting in labor is associated with increased production of ketones, which may result in ketosis for the laboring woman. Consequences of limited fluid intake or limited nutritional intake can include a rising maternal pulse rate and limited energy or fatigue. Theoretically, ketosis can cause dysfunctional uterine contractions, although this has not been definitively shown.

In 2016, the American Society of Anesthesiologists revised its position to recommend that women whose labors are progressing normally be offered modest amounts of clear liquids.[31] Clear liquid options include water, fruit juices without pulp, carbonated beverages, clear tea, black coffee, and sports drinks.[31,32] The midwife can encourage oral hydration by offering clear liquids or ice chips in between pushing efforts.[32] If the woman is unable to maintain oral hydration, intravenous fluids may be indicated. The presence of an epidural should not alter the recommendation to maintain oral hydration during labor if the woman desires.[32]

Assessment of Pain and Coping

During the second stage of labor, new physical sensations occur as the woman nears the time of birth. Anticipatory guidance as the second stage progresses can help the woman cope with pushing sensations, perineal stretching, and the potentially uncontrollable urge to bear down.

If a woman is crying out rather than grunting and bearing down, or is unable to sustain any

position of comfort, she may be suffering acute distress instead of actively coping.[33] Some women will experience sudden fear and anxiety with the sensations of vaginal stretching, and pain relief that ameliorates this perineal sensation may be necessary so she can push. A pudendal block can be used if an epidural is not available or desired. Women who have experienced past sexual abuse or assault may be at particular risk for fear or panic that escalates when the presenting part induces new sensation in the pelvic floor or perineum.[34]

Maternal Fatigue

The amount of added energy a woman requires for the process of pushing varies greatly, as does the average duration of second-stage labor. Some women begin the active process of pushing with renewed energy and excitement. The entire energy level in the labor and birth room may increase as the activity and excitement of impending birth grow. Family members present may become engaged as well and can add to the level of encouragement provided to the woman to aid her in overcoming fatigue. Since maternal fatigue can result in a prolonged second stage, it is important to monitor maternal fatigue and to encourage periods of rest between bearing-down efforts.

Evaluation of Fetal Well-Being

The assessment of the FHR or fetal heart tones during the second stage of labor is reviewed in more detail in the *Fetal Assessment During Labor* chapter. Variant FHR patterns are more common in the second stage than in the first stage, especially variable decelerations, prolonged decelerations, and bradycardias. Thus, the FHR is evaluated more frequently in second-stage labor. Current standards recommend assessment every 15 minutes for women without a risk for fetal acidemia and every 5 minutes for women who have an increased risk for acidemia.[35] In practice, the FHR is evaluated more frequently as the second stage progresses and is often checked every two to three contractions in the final phases of the second stage.

Midwifery Management of the Second Stage of Labor

During the second stage, the midwife can offer the woman encouragement and facilitate the efforts of everyone in ways that best help the woman in labor with supportive direction.[36,37] Using this approach, suggestions are offered without an intention to coach her or provide directive instructions. Instead, supportive direction incorporates recommendations to promote effective pushing in context with what has been happening up to that point during second-stage labor. This allows for individualized support of the woman without providing authoritative or directive coaching, neither of which is tailored to the unique needs of the individual woman in labor.

The Family-Centered Birth Environment

The decision of who to include in the birth room is an important one. Home settings and freestanding birth centers generally have few or no restrictions on the number of persons present. Most hospitals allow any number of support persons in the labor room, though restrictions are likely to be placed on the number of persons able to be in the operating room if a cesarean birth is necessary. Hospitals today also often allow siblings to be present during labor and birth; if children will be present, however, the institution usually requires the presence of an adult whose primary responsibility will be care of the child. Children may want or need to leave the birth environment, so an adult who is assigned the role of caring for the child should be prepared to leave the birth room as necessary.

Maternal Pushing Efforts

Several management options may be initiated for helping women push during the second stage of labor, including passive descent, open versus closed glottis technique, and spontaneous versus directed pushing.[6,38] An initial consideration is whether a period of passive descent would be beneficial for the woman who has an epidural or who does not have an urge to push. Once active pushing begins, pushing efforts can be open glottis versus closed glottis (Valsalva).

Delayed Pushing: Passive Descent Versus Immediate Maternal Pushing Efforts

Passive descent as a management strategy was initially introduced for the purpose of reducing the incidence of instrumental birth in women using epidural analgesia. The theory behind its use is as follows: During the process of passive descent (also referred to as laboring down), the fetus descends in response to the force generated from contractions alone and begins to internally rotate once the presenting part reaches the pelvic floor. Encouraging a period of maternal rest prior to engaging in active pushing efforts allows for conservation of the woman's energy until there is a physical stimulus to actively push. Once the woman does engage in active pushing, her efforts will be more effective and efficient in the presence of physical cues from pressure of the presenting part on the pelvic floor.[39]

Several RCTs and two meta-analyses have compared maternal and fetal outcomes in women

who rested for a period of approximately 1 hour prior to pushing with those in women who started pushing as soon as the cervix was found to be fully dilated.[40-46] Most of these studies defined passive descent as no active pushing for 1 to 2 hours unless an uncontrollable urge to push developed or the fetal head was visible at the introitus. In a meta-analysis of seven RCTs, Brancato et al. found delayed pushing was associated with a modest increase in the incidence of spontaneous birth (RR, 1.08; 95% CI, 1.01–1.15; $P = 0.025$), and fewer operative births (RR, 0.77; 95% CI, 0.77–0.85; $P \leq 0.0001$), less maternal exhaustion, and no increase in adverse maternal or neonatal outcomes.[41] In contrast, the systematic review by Tuuli et al. found an increased rate of spontaneous vaginal birth associated with delayed pushing in a meta-analysis of 12 RCTs; however, this increase was smaller and not statistically significant in the RCTs that the researchers assessed to be of high quality.[40]

The findings of a recently conducted secondary analysis of data collected during an observational, cohort study conflict with the findings of previously conducted high-quality RCTs. Yee et al. compared the outcomes of nulliparous women who experienced delayed onset of pushing with the outcomes of nulliparous women who initiated pushing immediately upon entering the second stage.[47] Their findings revealed higher rates of cesarean birth (11.2% versus 5.1%, respectively; aOR, 1.86; 95% CI, 1.63–2.12) and instrumental birth (16.2% versus 11.2%, respectively; OR, 1.26; 95% CI, 1.14–1.40) in the group that used delayed pushing. Furthermore, the women in this analysis had statistically significant higher rates of postpartum hemorrhage and blood transfusion, but no increased neonatal morbidity or mortality.[47]

Most recently, a 2017 systematic review of pushing methods used during second-stage labor identified a longer second stage of labor but shorter duration of pushing and increased rates of spontaneous vaginal birth in women who delayed pushing than in women who pushed immediately.[48] There was no significant increase in third- or fourth-degree lacerations or episiotomies between women who pushed immediately and women who delayed pushing. The investigators found a positive association between delayed pushing and low umbilical cord pH, but no significant difference in NICU admission rates or 5-minute Apgar scores between groups.[45] These authors concluded that there is no conclusive evidence to support or refute any specific method of pushing during second-stage labor for women with or without an epidural, and that decisions about pushing approaches should be made based on the clinical context and the woman's preference and comfort.[44]

Given the conflicting outcomes of the three meta-analyses,[40,41,48] which included some of the same trials, and ongoing questions about safe parameters for length of the second stage, the value and strength of evidence that supports delayed pushing are considered inconclusive. The studies that found passive descent or delayed pushing to be effective noted a modest positive effect of increasing the incidence of vaginal birth in women who have an epidural with a decrease in use of vacuum or forceps of approximately 20%. The findings of the Yee et al. study suggest a relationship may exist between delayed pushing and adverse maternal outcomes in nulliparous women.[47] Thus, given positive effects are small and possible negative effects may occur, until further studies are completed, delayed pushing should be considered on an individual basis for nulliparous women who have an epidural in place. Intra-amniotic

infection, FHR patterns that indicate a risk for fetal acidemia, vaginal bleeding, or other clinical indications for expediting birth are likely contraindications for delayed pushing.

Identification of how long to wait and when to transition to active pushing efforts requires careful consideration. Although no specific guidelines exist at present, it is common practice to offer a period of 1 to 2 hours for passive descent, as these are the time periods used in most of the investigations. Rather than using arbitrary time periods, it may be prudent to encourage active pushing whenever the vertex reaches +1 station, because it is not known if there are long-term adverse effects of delayed pushing on maternal pelvic floor dysfunction. The midwife should assess the effectiveness of pushing efforts soon after they start. If the woman is able to push effectively, the midwife can support her pushing efforts until she gives birth. If her initial efforts do not result in any fetal movement and the fetal station is above 0 station, the midwife may consider allowing a time of rest to encourage passive descent.

Some authors have suggested reducing the concentration of anesthetic in the epidural infusion so that the sensory block is less strong and the woman feels a stronger urge to push. This strategy can be effective if the woman wants to have more sensation, the epidural is able to be titrated, and the woman gives her consent. Nevertheless, totally discontinuing the epidural is not recommended because it results in more pain and no increase in the spontaneous vaginal birth rate.[49,50] Completely removing pain relief from a woman who has used an epidural during labor can result in the sudden onset of intense pain, which can be more detrimental to her pushing efforts than having the epidural in place.

Open-Glottis Versus Closed-Glottis (Valsalva) Pushing

Traditionally, women have been counseled to take a deep breath, hold their breath, and push forcefully throughout the duration of a uterine contraction. The use of breath holding combined with prolonged bearing down results in a Valsalva maneuver that can decrease cardiac output and subsequent blood flow to the uterus. Conversely, open-glottis pushing is similar to the semi-voluntary grunting and pushing associated with defecation. Because the glottis is not closed, this form of maternal pushing effort does not greatly increase intrathoracic pressure and, therefore, does not affect cardiac output.

Studies that have compared Valsalva-type closed-glottis pushing to open-glottis pushing have found that Valsalva-type pushing is associated with more FHR decelerations[3]; a higher incidence of perineal trauma (lacerations, episiotomy)[51]; maternal exhaustion; and an increased risk for cystocele and urinary stress incontinence.[3,52,53] This evidence is compelling, and closed-glottis pushing is not recommended in practice today.[54,55]

Spontaneous Versus Directed Pushing

Spontaneous pushing occurs when a woman in labor responds to the strong sensations of rectal pressure and an urge to push with bearing-down efforts and open-glottis pushing. In contrast, directed or coached pushing occurs when the healthcare provider instructs the woman to push in a specific manner, including direction for the woman to take a deep breath and hold it for a sustained period, typically “to the count of 10.” Directed pushing also includes providing

direction for a woman to push before she feels an urge to do so and asking her to hold the push beyond what she would do spontaneously. **Table 28-6** summarizes the differences between spontaneous pushing and directed pushing. While there are gaps in the literature regarding the benefits of spontaneous pushing, its use has not been shown to cause harm to either the woman or her newborn.[6,39,44,56]

Table 28-6 Comparison of Spontaneous to Directed Approaches to Pushing During Second-Stage Labor

Spontaneous	Directed
Also referred to as physiologic and supportive pushing.	Also referred to as Valsalva and authoritative pushing.
Maternal bearing-down efforts begin when the woman feels an overwhelming urge to push.	Maternal bearing-down efforts begin when a healthcare provider discovers that the woman is fully dilated (10 cm) and announces that she is ready to push.
Pushing is spontaneous—in response to a woman's natural urges and sensations. Usually results in 5–6 bearing-down efforts per contraction of 3–10 seconds each.	Pushing is provider directed—with instructions from a healthcare provider about when and how long to bear down. Usually results in 3 pushes per contraction of 8–10 seconds each.
Pushing often occurs while the woman exhales, with open mouth and open glottis. Usually results in grunting and low groaning.	Pushing occurs while the woman holds her breath. Silence is encouraged. Often results in a Valsalva maneuver.

Maternal Position During the Second Stage of Labor

Principles to consider when recommending positions to promote labor progress in the second stage are reviewed in **Table 28-7**. A woman can push in any position—on her side, on her hands and knees, kneeling, standing, or squatting. The position a woman assumes during second-stage labor depends on her preference, her health status, and the health status of the fetus. Many RCTs have examined upright versus supine positions during the second stage of labor. A meta-analysis of RCTs that compared the outcomes of women without an epidural who pushed in upright positions with the outcomes of women without an epidural who pushed in supine or lithotomy positions identified several potential benefits of pushing in upright positions.[57] Pushing in upright positions was associated with a small reduction in duration of second-stage labor, fewer episiotomies and assisted deliveries, and fewer abnormal FHR patterns.[57] However, pushing in upright positions was also associated with a possible increase in second-degree perineal tears and an increase in maternal blood loss greater than 500 mL.[57] The researchers concluded that without a specific indication to adopt a particular position, women in labor should be encouraged to use the position that is most comfortable and that supports ongoing progress in second stage; this is true for women both with and without an epidural.[57,58] The choice of birthing position can be facilitated by sharing information, asking the woman about her preferences, and using supportive direction.[37]

Table 28-7 Principles to Consider When Recommending Positions in Second-Stage Labor

1. Supine and lithotomy positions are associated with uterine pressure on the vena cava, maternal hypotension, decreased uterine perfusion, and variant fetal heart rate patterns.
2. Upright positions are associated with less pain and stronger contractions.
3. When a woman rounds her back rather than arching it, the uterus and fetal presenting part are better aligned with the pelvis.
4. Leaning forward in an upright position increases the angle between the uterus and the spine, thereby directing the fetal presenting part toward the larger posterior segment of the pelvis.
5. Changing positions frequently promotes changes in pelvic diameters, which could aid the fetus finding the "best fit" during the cardinal movements.
6. Squatting increases the area within the pelvic outlet by approximately 20% and can be most beneficial in the final phase of second-stage labor when the fetal presenting part is in the plane of the outlet.
7. Regardless of the position a woman is in, her legs should not be abducted laterally in an exaggerated manner (lithotomy position) because these positions put increased stress and tension on the perineum.

Despite modest findings in RCTs, older studies that evaluated the effects of position on maternal pelvic diameters suggest that upright positions in the latter stages of the second stage may have advantages.[59,60] Radiographic studies of women in labor in upright and supine positions found that upright positions increase both the anterior–posterior and transverse diameters of the pelvic outlet, which results in approximately 20% more area in the outlet.[59,60] Although these studies are old and will not be repeated due to the adverse effects of X rays, the pelvic joints are more mobile during pregnancy and squatting does cause the sacrum to rotate backward, which creates more room in the plane of the outlet.

Preparing for the Birth

If the birth is taking place in a hospital, the midwife should be aware of institutional criteria for use of a specific location. For example, in some settings the presence of meconium-stained fluid may require added personnel to be in attendance and the location of the birth to change from a single-room maternity care room to a delivery room. General preparations for a hospital birth are outlined in **Table 28-8**.

Table 28-8 **Preparation for Birth in the Hospital**

1. Determine the most appropriate place for the birth to occur. If the woman needs to move to a different room for birth for some reason, inform the woman and her support persons and move to the appropriate setting. In most instances, there is no need to move prior to the birth to a room other than where the labor has occurred.
2. Inform the woman's partner and others present that birth is imminent and review their roles and what to expect.
3. Notify the nursing staff that birth is nearing.
4. Confirm that newborn resuscitation equipment and supplies are present and in proper working condition.
5. Confirm that necessary instruments and materials are in a place of ready access. It is helpful to have additional sterile gloves accessible, should they be needed.
6. Put on protective clothing (gown or other waterproof garment); don gloves using sterile technique.
7. Arrange sterile equipment so that it is readily accessible. Maintain the instruments in a sterile field.
8. Drape the woman in accord with the drapes provided and institutional procedure if indicated.

Care during and immediately following birth is unique, in that both the woman and the newborn may need care simultaneously. Thus, two healthcare providers should always be present. The presence of additional personnel also depends on any risk factors that may be present. It is the responsibility of the midwife to consider the unique risk factors of the woman and newborn, to request the necessary resources in anticipation of the birth, and to know how to activate the call for emergency support should an unexpected complication occur.

In general, if labor is progressing normally, it is best to begin preparations for birth before complete dilation if the woman is multiparous and at the beginning of second-stage labor if the woman is nulliparous. The midwife will need to decide when to don protective wear, including a waterproof gown or clothing and eye protection. If a water birth is planned, the midwife will need to ensure the use of longer gloves or a gown that is fully waterproof to maintain universal precautions.

Management of the Birth

Management of the birth includes using standard hand maneuvers to support the birth, immediate assessment of the newborn, and immediate assessment of maternal status after the birth. Hand maneuvers are reviewed in **Appendix 28A**. In managing the birth, the midwife may need to make quick sequential decisions about the following management techniques: (1) how to provide supportive direction to the woman in labor through the final perineal phase of the second stage of labor; (2) whether to use warm compresses, perineal massage, or a "hands-off" versus "hands-on" approach; (3) the best approach to maintaining perineal integrity while supporting birth of the head; (4) whether to cut an episiotomy; (5) where to place the newborn immediately after birth—that is, whether to facilitate skin-to-skin contact on the mother; and (6) when to clamp and cut the umbilical cord.

Perineal Integrity

As the birth begins, the first focus is on promoting perineal integrity and preventing perineal lacerations. Birth positions known to decrease the incidence of genital tract trauma include lateral and semi-upright positions.[61,62] Squatting is associated with more second-degree lacerations, perhaps because it is a position in which the midwife may have difficulty controlling extension of the fetal head. The position associated with the highest incidence of genital tract trauma is lithotomy because marked abduction of the thighs stretches the perineum transversely so that it becomes a tight band without significant ability to flex around the emerging head.

Perineal support techniques that are purported to decrease the incidence of genital tract trauma include warm compresses, perineal massage, and "hands-off" versus "hands-on" perineal support.[62] Strategies that reduce the risk of perineal tearing are described in **Table 28-9**.[61-63] Most women who give birth vaginally sustain some degree of perineal trauma.[61,62] The types of perineal lacerations are described in **Table 28-10**.[64] Severe perineal lacerations that extend through the anal sphincter are termed "obstetric anal sphincter injuries" (OASIS). Perineal lacerations can result in both short-term and long-term morbidity and pain.

Table 28-9	Strategies to Promote an Intact Perineum
Make certain the woman's thighs and legs are not abducted laterally.	
Use of warm compresses during the perineal phase may decrease the incidence of third- and fourth-degree lacerations.	
Avoid vigorous or sustained perineal massage during the second stage, as these may cause perineal edema and tearing.	
Deliver the fetus slowly between contractions controlling extension of the head so pressure on the perineum is not suddenly forceful.	
If blanching of the perineum is observed, encourage the woman to breathe instead of push, to support slower birth of the fetal head.

Table 28-10 Types of Perineal Lacerations

Perineal Laceration	Description
First degree	Involves the perineal skin only
Second degree	Involves the skin, vaginal mucosa, and posterior fourchette, extending into the perineal body fascia and musculature but not the anal sphincter; includes the superficial and deep transverse perineal muscle and fibers of the pubococcygeus and bulbocavernosus muscles
Third degree	Involves the skin, vaginal mucosa, posterior fourchette, perineal muscles, and external anal sphincter 3a: < 50% of the external anal sphincter 3b: > 50% of the external anal sphincter 3c: Complete rupture of the external anal sphincter and the internal anal sphincter is torn
Fourth degree	Involves the skin, vaginal mucosa, posterior fourchette, and perineal muscles, extending through the external and internal anal sphincter and anterior rectal mucosa
Sulcus tears	Lacerations of the vaginal mucosa and underlying tissue along one or both sides of the posterior column of the vagina instead of the middle inferior part of the vagina
Labial	Laceration that extends from the fourchette anteriorly in one or both of the labia majora bodies
Periurethral	Longitudinal or transverse tear in the labia minora very near the urethra
Clitoral	Periurethral tear that extends into or near the clitoral body
Cervical	Laceration on any part of the cervix, usually on one or both of the lateral sides at approximately 3 o'clock and 9 o'clock, where the anterior and posterior aspects join

Based on American College of Obstetricians and Gynecologists. *Obstetric Data Definitions (Version 1.0).* Washington, DC: American College of Obstetricians and Gynecologists; 2014. Available at: https://www.acog.org/-/media/Departments/Patient-Safety-and-Quality-Improvement/2014reVITALizeObstetricDataDefinitionsV10.pdf?dmc=1&ts=20171212T2301409385. Accessed December 11, 2017.[64]

A meta-analysis of studies examining the effect of various perineal support techniques on perineal trauma revealed that placing warm wet compresses on the perineum continuously during the perineal phase of second-stage labor does not improve the rate of intact perineum but does appear to decrease the incidence of third- and fourth-degree lacerations.[62] Perineal massage with lubricant was associated with an increased incidence of intact perineum and fewer episiotomies, but did not appear to influence the degree of perineal trauma in women who required suturing.[62]

"Hands off" means not touching the fetal head or perineum until the fetal head is crowning (i.e., the biparietal diameter of the fetal head is through the vulva). "Hands on" entails using one hand to maintain flexion of the fetal occiput and the other hand to guard the perineal body by placing fingers on both sides of the perineum. Studies of these two techniques have not found one method to be superior to the other.[62,65] However, a multivariate analysis of the

elements of techniques associated with reduced genital tract trauma in one of the RCTs performed found that controlled birth of the fetal head between uterine contractions is associated with the lowest rate of genital tract trauma (RR, 0.82; 95% CI, 0.67–0.99).[61]

Episiotomy

Routine episiotomy was part of standard obstetric management until the 1990s, as it was historically believed that an episiotomy would decrease the incidence of perineal lacerations and brain damage in the fetus/newborn. The change from routine episiotomy to the rare use of episiotomy occurred over the course of a decade in the 1990s.

In 1989 a seminal study that found episiotomies are more likely to result in third- or fourth-degree lacerations than are spontaneous perineal tears was published.[66] In this study, the incidence of a rectal laceration in women with and without an episiotomy was 28.4% versus 2.2%, respectively (aOR, 8.9; 95% CI, 6.1–13.0).[66] Multiple subsequent studies and a Cochrane meta-analysis validated these findings.[66-70] The 2017 Cochrane systematic review of 12 randomized trials found that 30% fewer women sustained severe perineal trauma if giving birth in sites with restrictive episiotomy policies compared to giving birth in sites with routine episiotomy policies (RR, 0.70; 95% CI, 0.52–0.94); there was no difference in long-term outcomes such as pain, urinary incontinence, or dyspareunia.[67] A large national review of discharge data from hospitals, addressing translation of evidence-based guidelines into the practice of reducing episiotomy use, found that the incidence of episiotomy decreased from 20.3% in 2002 to 9.4% in 2011.[71]

Today routine episiotomy is not recommended.[55,72] The primary indication for an episiotomy is an FHR pattern that indicates a rapidly increasing risk that the fetus is developing acidemia. An additional argument can be made that an episiotomy is beneficial in anticipation of use of forceps or vacuum extractor, or in the presence of risk factors for shoulder dystocia. However, there is no evidence that an episiotomy is beneficial prophylactically in these situations, and this procedure clearly increases the risk for an extension to or through the anal sphincter.

If an episiotomy is determined to be indicated, local anesthesia or a pudendal block can be instituted and then either of two types can be performed: midline or mediolateral (**Table 28-11**). A mediolateral episiotomy is less likely to result in a third- or fourth-degree laceration than is a midline episiotomy. In the United States, there is a greater tendency to perform midline episiotomies, whereas in other Western and European countries the mediolateral episiotomy is preferred. If the distance between the posterior fourchette and the rectal sphincter is unusually short, a mediolateral episiotomy may be preferable to prevent laceration through the rectal sphincter, especially if the woman has any condition that impairs healing ability, which would increase the chance that the episiotomy repair would break down. In short, a midline episiotomy is less painful than a mediolateral episiotomy during the healing process because there are fewer nerve branches in the locale of a midline episiotomy and its repair, but the risk of a fourth-degree laceration is higher when a midline episiotomy is used.

Table 28-11 **Types of Episiotomy**

Episiotomy	Description
Midline	A midline incision that starts at the posterior fourchette and extends inferiorly through the central tendon of the perineal body, including the transverse perineal muscle. Involves the skin, vaginal mucosa, and posterior fourchette and perineal muscles, but not the anal sphincter. Equivalent to a second-degree laceration.
Mediolateral	Incision that begins at the midline in the posterior fourchette and extends laterally and inferiorly away from the rectum. May be right or left mediolateral incision.

Birth of the Fetal Head

The ideal time for birth of the fetal head is between contractions. The combination of the uterine contraction and the maternal pushing effort exerts a double force on the perineum at the moment of birth, which makes birth of the head more rapid and the release of restraining pressure more abrupt. Close communication between the midwife and the woman facilitates a team approach to help the woman gently give birth while making every effort to protect perineal integrity.

Ritgen Maneuver

The Ritgen maneuver, or modified Ritgen maneuver, is an old technique in which the clinician applies pressure on the fetal chin with one hand and pressure on the occiput with the other hand to control the birth of the head. The fetal chin is palpated behind the woman's rectum and pulled forward while the other hand maintains flexion of the occiput. The result is that the fetal head is pulled forward while maintaining flexion. The maneuver is performed between uterine contractions. The original rationale for using this procedure was to control extension of the fetal head and prevent perineal lacerations. Over time, it became a practice used when the birth needed to be expedited.[73,74] This maneuver is rarely used today, as vacuum or forceps are chosen for indicated operative vaginal birth.

The original Ritgen maneuver, which was first introduced in 1855 in Germany, recommended placing fingers in the woman's rectum. The modified Ritgen maneuver places the fingers between the rectum and the coccyx (**Figure 28-2**). The Ritgen maneuver is not associated with a decrease in perineal lacerations.[73,74] Although rarely needed, the Ritgen maneuver may expedite birth by a short period if needed and other resources are not available. The steps involved in performance of this maneuver are detailed in **Table 28-12**.

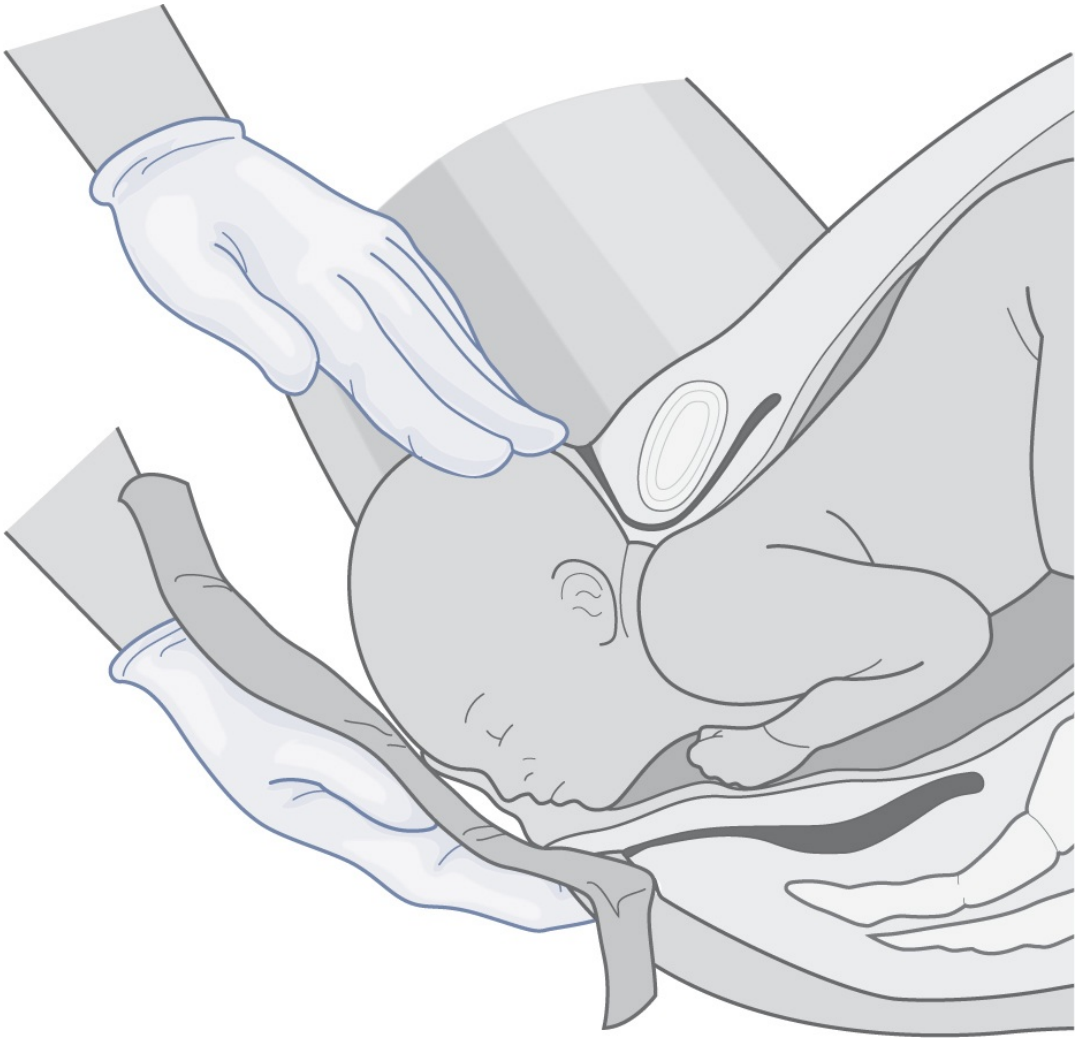

Figure 28-2 Ritgen maneuver.

Table 28-12	Steps for Ritgen Maneuver

The Ritgen maneuver is used to control the birth of the head by controlling both flexion and extension of the fetal head. The maneuver is also used to speed the birth by facilitating the process of extension through application of forward pressure on the fetal chin.

1. One hand remains on the occiput as the fetus is crowning to maintain flexion until after the biparietal diameters are visible at the introitus.
2. The other hand uses a gauze or sterile towel to protect against rectal contamination and palpates the fetal chin in the area between the maternal coccyx and rectum.
3. Forward and outward pressure is then exerted on the underneath side of the chin, and extension of the head is controlled between this hand and the hand exerting pressure on the occiput to control the pace of the birth of the infant's head.

Head-to-Body Interval and Two-Step Birth

Once the head is born, the midwife can move immediately to assist restitution and birth of the body, or wait for the next contraction to effect spontaneous restitution and birth of the shoulders before guiding the infant's body out of the vagina. The assumption is that the *one-step approach* decreases the expulsive phase duration, thereby preventing or mitigating neonatal acidemia. The *two-step approach* is a physiologic phenomenon. Although it is common practice in the United States to effect birth of the newborn quickly once the head is born, no evidence supports the contention that rapid birth is safer than a two-step birth that requires more time. Only a few studies have measured the head-to-body time interval and evaluated measures such as umbilical cord pH values and newborn hematocrit in relation to short or long head-to-body interval.[75-77]

The mean head-to-body interval using the two-step process is approximately 88 seconds, whereas that for the one-step process is approximately 24 seconds.[75] Although umbilical artery pH values have been shown to decline with longer head-to-body intervals, this decline was not statistically or clinically significant after controlling for the duration of the second stage.[75] One study of women whose births were complicated by shoulder dystocia found that a head-to-body interval of less than 5 minutes was not associated with neonatal acidemia.[76] Given these results, it appears the two-step physiologic method is safe when the fetus is not developing acidemia and is not at increased risk for acidemia.

The choice of performing a one-step or two-step method for facilitating birth is based on the individual circumstance. Because umbilical cord occlusion during the expulsive stage can be more constricting than cord occlusion during labor, fetal acidemia can also develop more quickly during this phase. Therefore, the one-step procedure may be better if the FHR pattern indicates possible developing acidemia or if other clinical factors place the fetus at increased risk for adverse effects of acidemia. The other factor to consider when making the decision about a longer expulsive stage is the risk for shoulder dystocia. Although clinical risk factors for shoulder dystocia are not strongly predictive, some authors have proposed that a rapid birth will prevent the anterior shoulder from becoming impacted behind the symphysis. However, there is little evidence to support this claim and other authors argue that utilizing the two-step approach might actually reduce rates of shoulder dystocia by allowing the shoulders to rotate into an ideal position for birth.[78,79]

Hydrotherapy and Waterbirth

Many women express interest in laboring and giving birth while submerged in water. The research regarding maternal and newborn outcomes following water immersion during labor (hydrotherapy) and/or water immersion during birth (waterbirth) is difficult to analyze. Much of the research on waterbirth has been conducted in Europe and consists of observational studies or case reports that did not have sufficient power to discern differences in non-common outcomes.[80,81] Furthermore, when women develop complications, they are generally transferred out of the hydrotherapy group, which results in differential misclassification bias that confounds the study results.[82]

Hydrotherapy During Labor

Although the research on waterbirth is not conclusive, the studies published to date have found water immersion during labor is associated with decreased use of analgesia, higher maternal satisfaction, and reduced duration of the first stage of labor.[80-83] The evidence regarding the effect of hydrotherapy on perineal lacerations is conflicting, with some studies reporting a decrease and others reporting an increase in lacerations.[80,82] Water immersion during labor has not been associated with an increase in infection, decrease in cesarean or operative birth rate, or increase in adverse neonatal outcomes.[80-83]

Waterbirth

Waterbirth refers to birth of the newborn completely underwater. The face of the newborn is gently brought to the surface within 5 to 10 seconds, while attention is paid to the length of the umbilical cord so cord avulsion does not occur.[84] Research assessing outcomes following waterbirth is sparse in contrast to the research findings regarding effects of hydrotherapy during labor. Nonetheless, to date, this body of research has identified improved maternal satisfaction and a slightly shorter duration of labor with waterbirth, although methodologic problems make it difficult to interpret the clinical significance of these results. For example, some studies evaluated addressed waterbirth, water immersion during labor, or a combination of both without clarification of which practice was being evaluated.[80] Thus, the actual effect of fetal immersion in water throughout the birth process is not well established.

Although no adverse maternal or neonatal outcomes in women who give birth in water have been identified when these studies are reviewed as a whole, the observational studies and two RCTs conducted to date are too small to detect any differences in adverse neonatal outcomes, which are rare in healthy women who are candidates for waterbirth.[80,82,85] Several case reports reporting cord avulsion, NICU admission, blood transfusion, neonatal hyponatremia, and neonatal drowning in conjunction with waterbirth have been published.[86] Nevertheless, the real incidence of adverse newborn outcomes is unknown. Schafer reviewed all reports of cord avulsion and calculated a projected rate of 3.1 per 1000 births, with 23% of these events resulting in NICU admission and 13% resulting in neonatal hemorrhage.[86] These figures are a rough estimate because no prospective studies have either tracked the incidence of adverse

neonatal outcomes or reported the incidence of cord avulsion in women who give birth outside of water. The American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) have published a joint position statement that supports water immersion during labor, but urge caution and recommend against waterbirth until more research has been conducted.[87]

Despite a lack of strong evidence either supporting or refuting the value of waterbirth, use of water immersion during labor and birth is of interest to many women, and an option that is available in some settings. The American College of Nurse-Midwives has published guidelines for waterbirth that include indications, contraindications, protocols, and requirements for quality control.[84] These guidelines can be found in the Resources section at the end of this chapter.

Immediately Following the Birth

Placing the Newborn in Skin-to-Skin Contact

The ideal placement for the newborn immediately following the birth is on the mother's abdomen, in skin-to-skin contact, promoting a positive transition from intrauterine to extrauterine life (**Figure 28-3**). Skin-to-skin contact promotes thermoregulation of the newborn, reduces physiologic stress, enhances successful breastfeeding both initially and at 3 months postpartum, and results in improved maternal–infant bonding.[88] Evaluation of the infant, the assignment of Apgar scores, and initial vital signs can be completed while the newborn remains skin-to-skin with the mother.[88]

Figure 28-3 Skin-to-skin care.

Reproduced with permission from Melissa Scott.

Healthy newborns who have uninterrupted contact with their mother may begin to make crawling movements toward her breast after approximately 20 minutes, and by an average of 50 minutes most are correctly sucking and breastfeeding.[88] Newborn procedures should be delayed until at least an hour after the birth so skin-to-skin placement can occur while the

newborn adapts to post-gestational life.

Clamping and Cutting the Umbilical Cord: Delayed Cord-Clamping

Delayed cord-clamping is an evidence-based practice that promotes the transition from intrauterine to extrauterine life and offers other health benefits.[89-92] Delayed cord-clamping involves waiting at least 30 seconds, and as long as 5 minutes, after the birth of the newborn before the umbilical cord is clamped and cut.[90-92]

Delayed cord-clamping allows the blood that was circulating in the umbilical vessels and the placenta to return into the newborn's circulation after birth. This process, which is known as placental transfusion, increases blood volume in the newborn by approximately 30% and red cell volume by 50%.[93] The increased volume, red blood cells, stem cells, and other components of this blood have significant health benefits for all newborns; thus, delayed cord-clamping is recommended as the standard of care.[91,92,94,95]

It is unclear why clamping the umbilical cord immediately after the birth became standard practice in hospital settings in the 1950s and 1960s.[96,97] One review of historical records found references to immediate cord-clamping for purposes of avoiding staining bed linens and avoiding blood loss from the newborn.[98] Another reference suggested immediate clamping could help to reduce maternal postpartum hemorrhage and placental retention.[97] Interestingly, reviews of historical writing about the timing for cutting the umbilical cord found that the timing associated with best outcomes has long been controversial.[98] Nonetheless, until research published in the last two decades called immediate clamping and cutting of the cord into question, it was standard practice to cut the umbilical cord immediately.[90] Modern research has established that waiting for a period of time before cutting the cord is associated with significant benefits for all newborns.[99-103]

The timing and procedure for cutting the umbilical cord are presented in **Appendix 28B**, which includes discussion of how to integrate umbilical cord-clamping in complex clinical situations such as when the birth is complicated by a shoulder dystocia, tight nuchal cord, or newborn need for resuscitation.

Although the definition of delayed cord-clamping varies somewhat in different professional organization recommendations,[91,92,104] delayed cord-clamping has important health benefits for both preterm and term infants. For the term infant, this practice results in higher ferritin levels, reduces the risk of iron-deficiency anemia, and can increase stores of brain myelin, which is important for more rapid and efficient brain communication.[89,105] For the preterm infant, delayed cord-clamping results in less need for blood transfusions, decreased incidence of intraventricular hemorrhage and necrotizing enterocolitis, improved mean systemic blood pressure, and reduced hospital mortality.[99,103,104] Newborns at all gestational ages have better neurodevelopmental outcomes when cutting of the umbilical cord is delayed.[102,106,107] Waiting just a few short minutes after birth has significant health benefits and can be done in all clinical situations, with any type of birth, and across all gestational ages.[90,108]

Umbilical Cord Blood Banking

Cord blood banking involves collecting and storing umbilical cord blood after birth, whereas tissue banking involves storing the umbilical cord or placenta. A public bank stores blood or tissue at no cost to parents, but they give up ownership of the cells and the stem cells can go to any person who qualifies for them. A private bank requires fees for storage, but the stem cells are "saved" for the future for that newborn or family members. ACOG suggests that if stem cells are harvested, they should be stored in public banks because generally these banks distribute more stem cells for transplant to the public.[109]

Mousavi described the quality and quantity of 35,000 cord blood units from around the world and reported that the average cord blood collection volume is 80 mL (24 mL/kg), which contains an average of 13 billion total nucleated cells per unit.[110] Total nucleated cells contain hematopoietic (blood cell manufacturing) stem cells, along with many non-hematopoietic stem cells; these cells can help repair many different tissues in the body.[110] Stem cells are part of the body's innate healing system. Damaged tissue releases cytokines, which signal stem cells to travel to the damaged area and begin the healing process. Animal studies show that human umbilical cord blood stem cells help to heal damage in the body, no matter how they are administered.[111]

Collection of cord blood for banking requires immediate cord-clamping and rules out the benefit of a placental transfusion for the newborn. As more studies find benefits for infants when delayed cord-clamping occurs, ethical issues surrounding umbilical cord blood banking become more prescient. An informed discussion with the woman and her family is needed about the potential risks and benefits of cord blood/tissue collection.

Inspection of the Perineum and Laceration Repair

The third stage of labor begins as soon as the infant is born. This is the time during which the risk for postpartum hemorrhage is the greatest. As soon as the infant is safely being observed/cared for by an assistant, the midwife checks for vaginal bleeding while inspecting the vagina and perineum for lacerations and arterial bleeding. The systematic inspection process, technique for initiating local or pudendal anesthesia, and laceration repair are summarized in **Appendix 28C** through **Appendix 28F**.

Apgar Score

The Apgar newborn scoring system was devised during the mid-twentieth century by Virginia Apgar, an anesthesiologist who worked at a time when use of heavy maternal sedation and anesthesia was common during labor. During this era, it was not unusual for newborns to have respiratory depression and low tone at birth secondary to the large doses of morphine administered late in labor. Dr. Apgar developed the Apgar score as a way of assessing the effects of maternal anesthesia on the newborn.[112, 113] Although the actual reason Apgar developed the score is not known for certain, the simplicity of assessing the newborn to assign this score resulted in rapid adoption into clinical practice. The Apgar score is now universally used in the United States as a measure at 1 and 5 minutes of how well the newborn is adapting to extrauterine life.

Apgar scoring uses five components to assess the newborn.[113] The five components of the Apgar score include key elements of cardiovascular and circulatory status, lung function, and neuromuscular integrity. A score of 7–10 denotes a vigorous neonate, a newborn with a score of 4–6 requires some focused resuscitation efforts, and a newborn with a score of 3 or less requires intensive resuscitation procedures. Several years after the scoring system was published, an acronym was devised using Virginia Apgar's surname. Therefore, some professionals know the scoring system as Appearance, Pulse, Grimace, Activity, and Respirations (APGAR), as noted in **Table 28-13**. The Apgar score may be misinterpreted as an assessment used to detect the presence of perinatal asphyxia. Although some components of the Apgar score are related to pre-birth acid–base balance, this score is not a reliable measure of perinatal asphyxia. Apgar scores are an indicator of resuscitation success, however, and are continued every 5 minutes if resuscitation efforts are ongoing. Moreover, resuscitation efforts should not depend on the first Apgar score for initiation since the first minute of life can be a critical one.

Table 28-13 The Apgar Score

Classic Component	Acronym	Score of 0	Score of 1	Score of 2
Color	**A**ppearance	Blue/pale over entire body	Acrocyanosis Body pink	Body and extremities pink
Heart rate	**P**ulse	Absent	< 100 beats/min	≥ 100 beats/min
Reflex irritability	**G**rimace	No response to stimulation	Grimace/weak cry when stimulated	Cry or attempt to pull away when stimulated
Muscle tone	**A**ctivity	None	Some flexion	Flexed extremities that resist extension
Respiratory efforts	**R**espirations	Absent	Week, irregular, gasping	Strong cry

Based on Apgar V. A proposal for a new method of evaluation of the newborn infant. *Curr Res Anesth Analg.* 1953;32(4):260-267.[113]

To avoid subjectivity in the assignment of the Apgar score, the newborn is examined and Apgar score is assigned by a birth attendant or nurse who is not the individual responsible for conducting the birth. The 1-minute Apgar score is not associated with long-term outcomes. Neonatal mortality is associated with the 5-minute Apgar score, however, and studies in this century continue to demonstrate that relationship, even after the advent of umbilical cord blood sampling and other assessment methods.[114,115]

Conclusion

Throughout all stages of the birthing process, the midwife maintains a safe, secure, respectful environment that supports an optimal labor and birth for the woman, fetus, and newborn. To do so, the midwife must have full awareness of the desires and expectations of the individuals involved in the labor and birth. This will allow the midwife to orchestrate an optimal birth experience within the boundaries of the individual circumstances, birth environment, and clinical factors that serve to influence the care provided to the laboring family.

Introduction

The first hand placement used during birth is directed toward preserving perineal integrity as the fetus emerges. Once the head emerges, the next hand placement is critical as it will allow the midwife to maintain two secure grips on the newborn throughout the birth and immediately after the birth. Newborns are slippery, and sometimes the combination of maternal pushing and uterine contractions results in a rapid forceful birth. It is imperative that the midwife is able to hold the newborn securely throughout the process. The hand maneuvers presented in this appendix can be used in any setting.

Controlling extension of the fetal head with one hand is the technique that has the most evidence with regard to decreasing the incidence of perineal lacerations.[1,2] Other techniques include (1) perineal massage; (2) application of warm compresses; (3) "hands off," wherein the midwife does not touch the fetal head or perineal area until the biparietal diameter is born; and (4) "hands on," which is variously described as flexion of the fetal head to control extension and manual support of the perineum. In practice, the hands-on technique refers to placement of one hand on the fetal head to control extension. The thumb and forefinger of the other hand are placed on either side of the perineum near the ischial tuberosities so that a slight amount of pressure is directed inward to counter the transverse stretching of the perineum caused by pressure from the fetal head.

Research evidence regarding use of prenatal perineal massage and application of warm compresses is of low to moderate quality, but these practices are associated with a small reduction in third- and fourth-degree lacerations in nulliparous women.[1,2] Vigorous massage can create edema and is not recommended. Although randomized controlled trials (RCTs) comparing "hands-off" and "hands-on" techniques for supporting the perineum prior to birth

have not demonstrated superior effectiveness of one technique versus the other, many midwives use some method of perineal support.[1-5] Therefore, although not conclusively evidence based, these techniques are presented here as options for use during birth.

Hand Maneuvers for Birth When the Fetus Is in an Occiput Anterior Position and the Woman Is in a Semi-Sitting, Lateral, or Dorsal Position

1. Ensure both access to the perineum and visibility of the vulvar–perineal area.
   a. The midwife stands or sits in a position that allows for a clear visual field and comfortable access to the woman's perineum.
   b. A sterile drape is placed on a surface within easy reach, on which instruments and a bowl for the placenta are placed.
2. Control extension of fetal vertex. During extension of the head, the anterior–posterior diameter of the fetal vertex gradually changes from the suboccipitobregmatic diameter (9.5 cm) to the occipitofrontal diameter (11.5 cm), and then to the occipitomental diameter (12.5 cm). Gradual extension prevents perineal trauma as these increasing anterior–posterior diameters stretch the perineum during the birth. The primary goal is to prevent sudden extension of the fetal head, which increases the likelihood of perineal laceration.
   a. To control extension of the fetal head during crowning, the midwife places the palmar side of one hand, with fingers held straight, on the portion of the occiput of the fetal vertex visible at the vaginal introitus. This should be done as the vulva begins to stretch around the presenting part, with crowning imminent (**Figure 28A-1**). Control of extension is maintained best when the *fingers are kept in a straight plane with the hand*. This finger positioning allows the midwife to control extension of the head. When just the fingertips are placed on the head, the midwife does not have as much control. If sudden extension occurs with a contraction or maternal pushing, the fingertips are likely to slide along the curve of the fetal head, touch or hurt the sensitive clitoral area, and the head will pop into the midwife's palm, placing rapid pressure on the perineum. The use of one hand to control extension leaves the other hand free to check for a nuchal cord, and handle any equipment or supplies that may be needed. Given that midwives' hands vary in size and that women give birth in many different positions, the actual placement may be less important than identifying a manner in which the individual midwife can comfortably provide the needed control and simultaneously visualize the perineum. Good body mechanics are important to prevent injury to the midwife.

Figure 28A-1 The midwife's fingers are in a flat plane with the palm of the hand to allow maximum control of extension of the fetal head.

i. If a woman is lateral (side-lying), the woman's legs should be bent at the knee, and when open, remain parallel to each other. Pillows or a peanut ball between the knees can increase comfort in this position. If the upper leg is pushed toward the woman's head and flexed more dramatically than the lower leg, the pelvis is forced out of alignment and the perineum becomes tightly stretched. When given the opportunity to raise and position the upper leg spontaneously, many women will not do so until birth is imminent.

ii. Visualization of the perineum and maintaining flexion of the fetal vertex is easiest if the midwife stands behind the woman's back. If facing the woman's abdomen, visualization of the perineum is impaired, but guiding the rest of the birth can be easier. In either position, the midwife's fingers can be placed on the occiput, exerting pressure with the palmar surfaces, toward the perineum as needed to control extension of the head during the birth.

b. If the midwife choses to use a second hand to support the perineum ("hands on" approach): Using the hand that is not controlling the pace of extension of the fetal head, a thumb and one finger is placed on the perineum near the ischial tuberosities below the fourchette, so that the midline area of the perineum, which is likely to tear, is between the thumb and the finger. Applying pressure with the thumb and fingers inward toward each other and the middle of the perineum (perineal body) reduces the transverse pressure created as the fetal head extends.

3. Check for a nuchal cord. As soon as the head has emerged, the fingertips of one hand palpate the infant's neck, sweeping the fingers along the neck in both directions, to

determine if the umbilical cord is looped around the neck. If a nuchal cord is present, slip fingertips between the cord and neck to ascertain how tight the cord is. There are four options for proceeding with the birth if a nuchal cord is present:

- **a.** *Cord reduction:* If the cord is loose, slip it forward over the head before delivery of the shoulders (referred to as reducing the cord over the head).
- **b.** *Birth through the cord:* If the cord is too tight to reduce but still has some mobility, slip it back over the shoulders as the infant is born, allowing the infant to be born through the cord.
- **c.** *Somersault maneuver:* If the cord is too tight to slip over the shoulders but loose enough to permit some movement, use one hand to keep the head close to the maternal thigh throughout the birth of the body and the other hand to "somersault" the body over the perineum, which will limit the traction placed on the cord.[6,7] The somersault maneuver is depicted in **Figure 28A-2**.
- **d.** *Clamp and cut*: If the cord is too tight to accomplish the other preferred steps, double-clamp and cut the cord between the clamps at the neck before the infant's body is born.

4. If planning a two-step process (assuming the cord has not been clamped and cut): While waiting for restitution, external rotation, and the next contraction, the midwife or assistant may wipe fluid from the neonate's face, nose, and mouth with a soft, absorbent cloth but it is not necessary to stimulate the infant at this moment. Suctioning with a bulb syringe of the fetal nasal and oral passages is not necessary.[8,9]

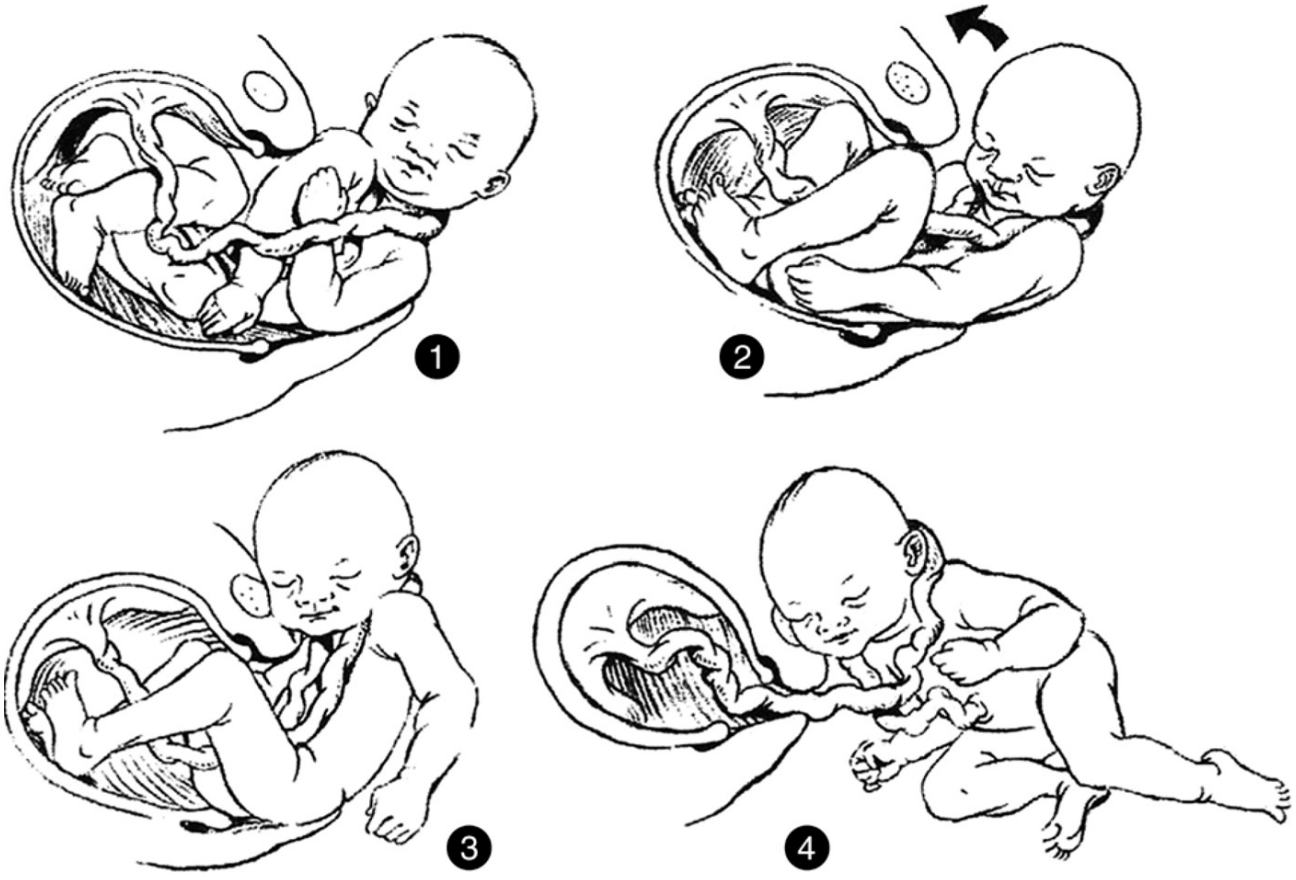

Figure 28A-2 The somersault maneuver involves holding the infant's head flexed and guiding it upward or sideways toward the pubic bone or thigh, so the baby does a "somersault," ending with the infant's feet toward the mother's knees and the head still at the perineum.

1. Once the nuchal cord is discovered, the anterior and posterior shoulders are slowly delivered under control without manipulating the cord.
2. As the shoulders are delivered, the head is flexed so that the face of the baby is pushed toward the maternal thigh.
3. The newborn's head is kept next to the perineum while the body is delivered and "somersaults" out.
4. The umbilical cord is then unwrapped, and the usual management ensues.

   a. Wait for the next contraction and for restitution and external rotation to occur, which will be evident when the occiput rotates 90°.
   b. If there is a need to expedite the birth (e.g., the cord has been clamped and cut), rotation of the shoulders into the anterior–posterior position to facilitate restitution and external rotation can be facilitated by using a modified Rubin's maneuver if needed. Insert and place two fingers over the scapula of the anterior shoulder, and two fingers against the clavicle of the posterior shoulder. Firmly move the infant's head into the oblique diameter of the outlet.

5. Facilitate birth of the shoulders.
   a. Place one hand on each side of the head over the parietal and cheek bones so that the midwife's *fingers point toward the fetal face* and nose, as depicted in **Figure 28A-3**. The midwife's little fingers are closest to the woman's perineum and the thumb is farthest away from the perineum. This is the step that will assure all subsequent maneuvers will result in maintaining a secure hold on the newborn. Remember, *"Pinkies to the perineum."*
      i. For a fetus in the left occiput transverse (LOT) position, the fetus will be facing the woman's right leg, the midwife's left hand will be the bottom hand underneath the fetal head, and the midwife's right hand will be the hand on top of the fetal head.
      ii. For a fetus in the right occiput transverse (ROT) position, the fetus will be facing the woman's left leg, the midwife's right hand will be the bottom hand underneath the head, and the midwife's left hand will be the hand on top of the head.
      iii. Remember, "*Fetus faces right, the midwife's right hand is on top*" (**Figure 28A-3**).
   b. Assist the woman to give birth to the anterior shoulder. Avoid gripping the fetus's neck by keeping the fingers straight so the hands are flat on the sides of the head. During the next contraction, while the woman pushes, exert gentle, downward pressure on the head until the top of the anterior shoulder and axilla can be seen beneath the symphysis pubis. Maintain parallel alignment between the head and the

fetal spine during this process. Pulling down on the head alone laterally flexes the fetal head toward the posterior shoulder. This widens the angle between the neck and anterior shoulder, which can cause undue stretch and injure the infant's brachial plexus.

c. Once the anterior shoulder and axilla is visible, apply gentle upward pressure on the fetal head with both hands, lifting the infant's head following the natural arc of the curve of Carus toward the woman's abdomen. Avoid laterally flexing the infant's neck during this maneuver as well. Some midwives suggest that the perineum can be protected during the birth of the posterior shoulder by sliding the bottom hand over the shoulder and keeping the infant's arms and hands close to the body during the birth.

d. As the posterior shoulder is emerging, pivot the bottom hand under the fetal head, forming a C-shape cup with that hand facing the fetus so that the palmar side of the hand is facing the woman's perineum. Loosely grasp the infant's chest and back between the thumb and fingers. The head will be supported by the midwife's forearm in this position. If the midwife's hands have been placed properly during birth of the head, the midwife's thumb will come to rest near the scapula and the fingers will lay across the infant's thorax with the infant's neck and head resting gently between the thumb and fingers in the webbing between the thumb and fingers of the bottom hand. This is the first secure grip that will be maintained. With the bottom hand in this position, a forceful push will not result in the midwife losing a secure grip on the body. This bottom hand positioning also stabilizes the neck and head. The thumb and fingers are directed down toward the center of the infant's body which prevents circling the neck.

e. Slide the hand that was on the top of the fetal head down the infant's back; grasp one or both thighs, using this hand. This is the second secure grip that will be maintained.

6. Complete the final phase of birth. As the body of the infant emerges, the newborn can be placed immediately onto the woman's abdomen, pivoted to rest on the midwife's forearm facing the midwife, or handed to another clinician for assessment.

a. To place the infant immediately on the woman's abdomen: Using the bottom hand that is supporting the head by cupping the chest and scapula, move the infant in a smooth arc from over the perineum onto the mother's abdomen. Position the infant laterally on the woman's abdomen with the head and face slightly lower than the body to facilitate drainage of oral and nasal fluids.

i. While moving the infant onto the woman's abdomen, confirm that there is no tension on the umbilical cord.

ii. Maintain both secure grips on the newborn until the woman is safely holding her infant.

b. To hand the newborn to another clinician: Pivot the hand cupping the infant's chest and scapula in one of two ways:

i. Keeping the thumb and fingers around the newborn's shoulders, extend a finger to support the occiput and stabilize the neck. The newborn's shoulders are in the palm of the hand, and the thumb and remaining fingers are *resting*—not pressing

—against the sides of the neck. The top hand continues its grasp around legs during this maneuver.

ii. Alternatively, the bottom hand can slide up toward the head and grasp the two parietal bones between the thumb and fingers, with the occiput resting in the palm of the hand. With this maneuver, the neck is stabilized because the scapula rests on the bottom of the midwife's palm (**Figure 28A-4**).

iii. The newborn's hips and legs are then tucked securely between the midwife's bottom arm and body at waist level. The newborn's back is supported on the midwife's lower arm. The newborn's head is held firmly, in a slightly dependent and lateral position to encourage postural drainage. This is the third secure grip that can be maintained regardless of the woman's position. An initial assessment should be conducted at this time. The midwife now has one hand (the original top hand) free to clamp and cut the umbilical cord when necessary.

Figure 28A-3 Placement of hands for birth of the body.

Figure 28A-4 Stabilize the neck while preparing to hand the newborn to another provider.

Hand Skills for Birth of a Fetus in the Occiput Posterior Position

The same hand maneuvers used to facilitate birth for the woman whose fetus is in the occiput anterior (OA) position are applicable for the fetus in the occiput posterior (OP) position, with one exception: The direction of pressure exerted to maintain flexion of the head is maintained by upward pressure instead of downward pressure because the occiput is closer to the rectum than it is to the symphysis. Once the biparietal diameters are visible, releasing the upward pressure on the occiput, in a controlled manner, controls extension.

This technique is also used for the fetus in a face presentation. In a face presentation, the mentum (chin) will be under the symphysis and the rest of the head will be born by flexion of the neck. A face presentation that rotates so the mentum is posterior will not deliver vaginally because the neck is too short. Once the head is out, the remaining hand maneuvers are the same as described previously.

Hand Skills for Birth When the Woman Is in a Hands-and-Knees Position

While the mechanisms of labor are not changed by a maternal hands-and-knees position, the manner in which the infant emerges appears reversed and requires variations in the direction of support and positioning of hands as a result. Visibility and access to effect maneuvers are enhanced in this position. However, while the woman can hear the midwife, she is not able to see the midwife when in this position. As a result, anticipatory guidance to the woman about what to expect, and where she will need to position herself to receive the newborn, should be communicated prior to birth if possible. In addition, there may be increased stress on the anterior labia and on the periurethral area when the woman assumes a hands-and-knees

position for birth. **Figure 28A-5** shows a birth when the woman is in a hands-and-knees position and the fetus is in an occiput anterior position.

Figure 28A-5 Birth of a fetus with a compound anterior arm while the woman is in a hands-and-knees position.

1. As the head emerges, maintain flexion by directing pressure on the occiput in the direction of the anus.
2. Allow the head to extend gradually, maintaining a steady but gentle counterpressure on the vertex. Maintaining flexion until the occiput passes under the symphysis pubis, and extension begins, will reduce the possibility of perineal trauma.
3. It is possible to support the perineum with the other hand alone or with a warm moist towel. Many women appreciate moist heat on the rectal area as the head crowns and extends. If stool is present, cover the anus with a towel to prevent stool from coming into contact with the fetus.
4. The hand maneuvers involved in checking for a nuchal cord, and watching for restitution and external rotation are the same as the maneuvers for birth when the woman is in any other position. In the hands-and-knees maternal position, the hand checking for the presence of a nuchal cord will be palm up and sliding back under the infant's head.
5. To effect birth of the shoulders: Some practitioners guide the anterior shoulder under the symphysis first just as though the woman were in a dorsal position; others reverse the

order and deliver the shoulder nearest the woman's sacrum first.

6. As the upper half of the infant is born, follow the curve of Carus and hold the arms close against the baby's body to protect the perineum and anterior structures.
7. The newborn can then be passed to the woman through her legs, keeping a secure hold on the infant until the woman has a firm grasp on her newborn. The midwife then moves to face the woman and helps her to sit down. It is important to observe for tension on the umbilical cord if this maneuver is selected.
8. Alternatively, the woman can carefully lift one leg, with the newborn and cord being passed under her leg as she completes a turn to sit down facing the midwife. The newborn can then be placed on her abdomen.
